A Pilot Case in Sustainable Renovation of Modern Cultural Heritage

Elias V. Messinas[1](✉) and Tanya Saroglou[2]

Abstract. Achieving sustainable renovation in historic buildings requires reconciling two often competing goals: reducing operational and embodied carbon while safeguarding architectural identity and cultural value. As the European Union advances its 2050 net-zero objectives, the need for renovation strategies that integrate regulatory, technical, and heritage-conservation perspectives has become central to policy and practice. The Horizon Europe project SINCERE responds to this challenge by developing adaptive, resource-efficient renovation pathways for modern-period heritage, combining low-carbon materials, renewable energy technologies, and digital decision-support tools. This paper presents the SINCERE pilot at Building 3 of the Holon Institute of Technology, a 1972 Brutalist reinforced-concrete structure later modified through roof extensions and accessibility upgrades. The project explores how sustainable design strategies—thermal insulating mortars, radiative cooling coatings, and building-integrated photovoltaics—can be incorporated into an existing cultural-heritage fabric without compromising authenticity. The methodological framework employs HBIM and digital-twin environments to simulate energy performance, assess climatic responsiveness, support maintenance planning, and evaluate results towards long-term carbon reduction. Beyond technical validation, the pilot functions as an educational and participatory platform: students and faculty engage in material testing, installation monitoring, and performance interpretation alongside SINCERE partners. Concluding, the study demonstrates how digital workflows, climate-adaptive materials, and nature-based cooling strategies can be integrated into the renovation of modern heritage buildings, offering transferable insights for stakeholders seeking resilient, low-carbon, and culturally responsible reuse of existing building stock

Keywords: Cultural Heritage · Net-Zero · Brutalist · Architecture · Energy Performance

1 Introduction

The renovation of cultural heritage buildings lies at the intersection of conservation, environmental performance, and contemporary use. Buildings account for approximately **40% of energy consumption in the European Union**, making the built environment

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 745–753, 2026.
https://doi.org/10.1007/978-3-032-34930-9_87

a key sector in achieving climate neutrality targets [3]. While much attention has been directed toward new construction, the renovation of heritage buildings—especially those from the modernist period—remains under-addressed.

Modern heritage buildings constructed between the mid-20th century and the 1970s frequently lack insulation and rely on outdated mechanical systems. Retrofitting them is technically challenging because interventions must respect architectural integrity and historic significance. International organizations such as ICOMOS emphasize the need for integrated approaches that combine climate action with cultural heritage preservation [8].

The **Horizon Europe SINCERE project** responds to this challenge by developing adaptive renovation methodologies for post-war modern architecture. The project tests innovative materials, energy-generation technologies, and digital monitoring systems across several pilot sites. This paper focuses on the HIT Building 3 pilot in Holon, Israel, examining how sustainable renovation strategies can be applied to a Brutalist structure while preserving its architectural identity.

2 Cultural Heritage Buildings

2.1 Sustainable Renovation of CH Buildings

Sustainable renovation has become a central theme in architectural and conservation discourse. Traditional conservation approaches emphasized preserving original materials and forms, whereas contemporary strategies increasingly support adaptive reuse and energy-efficient retrofits [5].

Adaptive reuse extends the lifecycle of buildings and reduces embodied carbon while maintaining cultural continuity [2]. However, renovation interventions must reconcile energy performance with conservation constraints. Guidelines from ICOMOS and Historic England advocate minimal and reversible interventions that preserve architectural authenticity [9].

Recent European directives, including the **Energy Performance of Buildings Directive (EPBD)**, promote performance-based renovation strategies that consider lifecycle emissions and compatibility with historic fabric. Sustainable renovation therefore requires a holistic approach incorporating passive design strategies, compatible materials, and digital tools.

Material selection plays an important role in heritage renovation. Breathable insulation materials, lime-based mortars, and natural materials help maintain hygrothermal balance and protect historic structures [1]. Passive strategies such as natural ventilation, shading, and thermal inertia can further improve indoor comfort without compromising architectural integrity.

Digital technologies increasingly support renovation decision-making. Tools such as **Historic Building Information Modelling (H-BIM)** and IoT-based monitoring systems enable simulation, predictive maintenance, and performance tracking. These technologies allow architects, engineers, and building managers to develop interventions that are both environmentally efficient and culturally sensitive.

2.2 Modern and Brutalist Heritage

Modernist and Brutalist buildings occupy a contested position within heritage discourse. Characterized by exposed concrete surfaces and monumental forms, Brutalist architecture is often controversial [7] but represents an important architectural legacy of the post-war period [10].

Many modern heritage buildings face demolition or neglect because they are not widely recognized as heritage assets. Although iconic works by architects such as **Le Corbusier, Louis Kahn, and Marcel Breuer** receive protection, numerous institutional and civic buildings from the same period remain vulnerable.

In Israel, modernist and Brutalist architecture forms an integral part of the country's architectural identity. Many institutional buildings constructed after 1948 independence reflect ideals of progress and civic identity. However, these buildings often suffer from energy inefficiency and limited recognition within heritage protection frameworks (Fig. 1).

Fig. 1. Examples of Brutalist architecture in Israel (left to right): Ben Gurion University; Tel Aviv Museum of Art; Carlton Hotel Tel Aviv (Google search accessed March 5, 2026)

3 The SINCERE Project

3.1 General

The **SINCERE project** addresses the sustainable renovation of modern heritage buildings through interdisciplinary collaboration. The project combines conservation principles with energy transition goals by testing innovative technologies across several pilot sites.

Key components of the SINCERE methodology include: interdisciplinary collaboration among architects, engineers, and conservation specialists; performance-based evaluation of energy and environmental performance; digital tools such as H-BIM and Digital Twin platforms; testing of innovative materials compatible with historic buildings (Fig. 2).

3.2 Innovative Materials

Historic buildings often cannot accommodate conventional insulation solutions. The application of new materials therefore plays a crucial role in improving energy performance while maintaining architectural authenticity. Among the technologies tested in

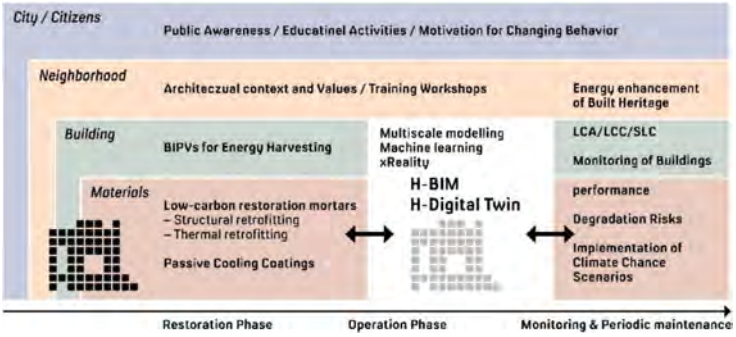

Fig. 2. SINCERE: Different scales and actions towards net-zero energy buildings (SINCERE)

SINCERE are sustainable, and cost-effective restoration materials and practices, energy harvesting technologies, ICT tools and socially innovative approaches, applied on the building structure and external envelope - opaque and transparent.

These technologies enable energy efficiency through enhancement of the building envelope combined with renewable energy technologies, while minimizing visual impact on historic buildings.

3.3 The HIT Pilot Case Study

The SINCERE project includes four pilot sites that allow evaluation of climate-specific renovation strategies and architectural contexts: 1. **Algete, Spain** – testing facility; 2. **Rhodes, Greece** – neoclassical school building; 3. **Holon, Israel** – Brutalist academic building; 4. **Ostrava, Czechia** – industrial heritage complex (Fig. 3).

Fig. 3. SINCERE four pilot sites representing buildings of the 20th century cultural heritage, of diverse uses, different scales and climatic zones (from left to right): Algete, Rhodes, Holon, and Ostrava (SINCERE)

Pilot 3 is the Holon Institute of Technology building 3, an academic building situated in a semi-arid coastal zone. The case study is managed by SINCERE partner ECOAMA. Constructed in 1972 in the Brutalist style, it is characterized by exposed reinforced concrete and deep shading elements. The building has undergone several modifications including a new light metal roof addition and accessibility upgrades. Energy performance is characterized by high cooling demand during hot summers (Fig. 4).

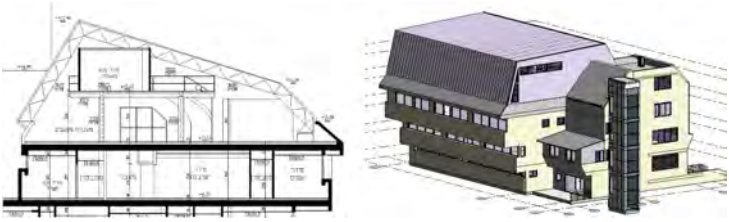

Fig. 4. Section (left) and BIM model by ECOAMA (right) of the gallery space under the roof of the SINCERE Pilot Building 3, at Holon Institute of Technology, Holon, Israel (SINCERE)

3.4 Energy Performance Challenges

The building exhibits significant energy inefficiencies. Uninsulated concrete walls and lightweight metal roof have thermal transmittance values ranging from 3.14 to 3.51 W/m^{2}K, while the roof reaches 5.25 W/m^{2}K, far exceeding those permitted by contemporary Israeli green building standard 5282: 0.60 W/m^{2}K for walls and 1.50 W/m^{2}K for roofs. Resulting in high mechanical cooling demand during hot summers.

Holon's climate zone enables the SINCERE project to monitor the behavior of the proposed intervention in a Mediterranean climate with hot, dry summers and mild, wet winters, with average temperatures at 25 °C and average humidity at 72.5%, with transitional influences from the surrounding desert areas. Due to the high temperatures, the unassisted comfort zone in the psychrometric chart is only 6%, with 94% passive and active (mechanical) solutions needed for thermal comfort (Fig. 5).

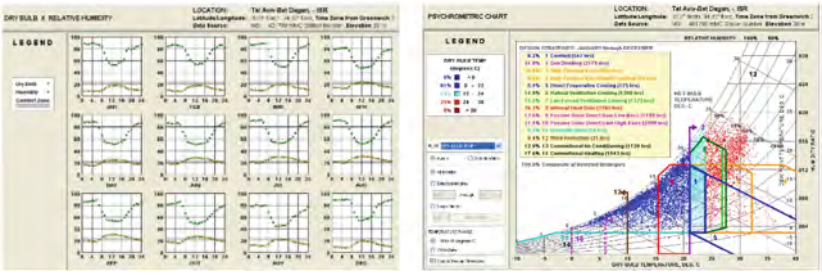

Fig. 5. (left) Annual dry bulb temperatures and humidity (left) in the Holon area and (right) psychrometric chart by Climate Consultant (SINCERE)

HIT's uninsulated wall and roof envelope contributed to thermal bridging and excessive heat gain, while its aging mechanical systems further exacerbated operational inefficiencies. As a result of the increased temperatures within the premises, and the discomfort and increasing rate of illness reported by the users, in 2022 the administration considered insulating the roof or installing additional air-conditioning units. Due to cost and construction constraints, it decided to purchase 4 AC units type 65 WIND by Tadiran, with consumed power in cooling 5.230 KW, estimated at 36.61 KWh daily each, a total estimated additional electric load for the building of 146.5 KWh daily. The provided

immediate thermal comfort, but increased energy consumption. In addition, the external units were exposed on the edge of the roof, while the channels where built-in with sheetrock in suspended ceilings.

This solution introduced new energy burdens: the building, which already consumed approximately 33% more than benchmarks for governmental office buildings, saw an additional 6% increase in energy use from the new AC units alone - based on technical calculations in the absence of historical metered data. Notably, a comparative analysis showed that had the administration opted for roof insulation instead, the return on investment (ROI) would have been approximately 11.1 years, not accounting for the additional cost for mechanical cooling in peak summer months. The challenges faced by the Holon building, reflect similar dilemas by modern cultural heritage, and thus assigned it as an applicable pilot for the SINCERE project.

3.5 Holon Pilot Interventions

Within SINCERE, three main interventions are being tested at the Holon pilot: **Thermal insulating mortars** using hempcrete, a bio-based low-density composite, and PCMs (Phase Change Materials), capable of storing and releasing thermal energy through phase transitions - materials that improve thermal performance while preserving and enhancing concrete surfaces; **Radiative cooling coatings** - surface treatments reduce solar heat gain without altering the building's appearance; **Building-integrated perovskite solar cells (BIPVs)** - photovoltaic cells integrated into glazing elements generate renewable energy while maintaining architectural transparency (Fig. 6).

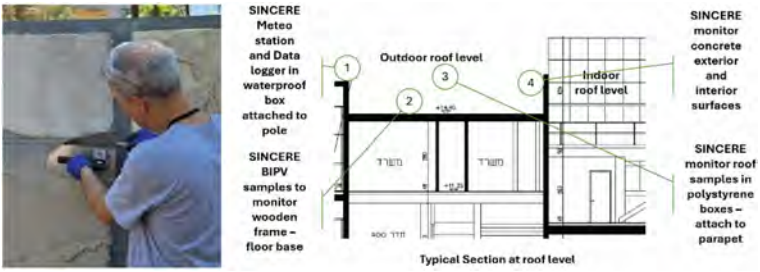

Fig. 6. (left): Applying thermal insulating mortars during the advanced workshop on innovative mortars for structural and thermal retrofitting organized by NCSR Demokritos in Athens, Greece, and (right) diagram of the SINCERE interventions at the Holon pilot (SINCERE).

Monitoring the interventions using embedded sensors collects data on thermal conductivity, surface temperature, material degradation over time. and energy performance. They are further evaluated using H-BIM and Digital Twin systems as part of the SINCERE program (Fig. 7).

3.6 Integration with Academic Use

The HIT academic campus enables integration of the pilot into research and education. Students participate in workshops, data collection, and monitoring activities,

Fig. 7. (left): Snapshots of the mobile screen of the SINCERE digital app of the BIM-based mobile application by Up2Metric that exploits Mixed Reality (MR); (right) snapshot of the SINCERE Virtual Reality (VR) application by Nurogames, for the Holon pilot (SINCERE)

transforming the building into a living laboratory for sustainable heritage renovation (Fig. 8).

Fig. 8. (left) Design workshop of HIT with Democritus University of Thrace (DUTH) in Greece, to explore the reuse of materials of industrial heritage; (right) exploring in short videos the 'Talking Buildings' tool developed by Nethood in SINCERE (E. Messinas & SINCERE)

Educational workshops organized by HIT within the SINCERE framework have involved universities from Greece and Cyprus, fostering interdisciplinary collaboration and knowledge exchange. Similarly within the HIT campus, the SINCERE pilot enables seamless integration of the project's goals into its curriculum, allowing active participation of students in the process, turning the pilot into a living laboratory for sustainable design in innovation for cultural heritage. The building becomes not only a site for architectural preservation and energy performance optimization, but also an inspirational platform for student-led experimentation and innovation.

4 Conclusion

The HIT pilot highlights both the potential and complexity of sustainable renovation in modern heritage buildings. The renovation of HIT Building 3 demonstrates how modern heritage buildings can be adapted to meet contemporary environmental goals while preserving their architectural character. Through the integration of advanced materials, digital monitoring technologies, and academic collaboration, the SINCERE project provides a replicable model for sustainable renovation of cultural heritage buildings in general and Brutalist architecture in particular.

The case also illustrates the importance of policy frameworks supporting the renovation of post-war architecture, which is often excluded from heritage protection policy, thus encourage preservation with compatible energy performance improvements.

As climate targets approach for **2030 and 2050**, the renovation of post-war heritage buildings will become increasingly important. The methodologies tested in SINCERE contribute to developing strategies that reconcile energy efficiency, cultural heritage preservation, and sustainable urban development.

LCA-Based Method for Sustainable Concrete Mix Design in Uruguay

P. Codina(✉), J. Cabrera, P. Vila, and M. N. Pereyra

Universidad de la República, Montevideo, Uruguay
pcodina@fing.edu.uy

Abstract. This study presents the application of a life cycle assessment (LCA)-based calculation method to support sustainable concrete mix design in Uruguay. The aim was to evaluate the environmental performance of traditional and alternative concrete mixtures with comparable technical performance, representative of ready-mix concrete production in Uruguay. The functional unit was 1 m^3 of concrete. Three types of concrete were analyzed: conventional concrete (CC) with two strength levels (25 MPa and 40 MPa) and a self-compacting concrete (SCC). For each case, reference mixtures produced with Portland cement were compared with alternative mixtures incorporating supplementary materials. In CC mixtures, calcined clay (metakaolin) was used as a partial replacement of Portland cement, while in SCC mixtures the cement was partially replaced by quarry crushing fillers obtained from granodiorite and limestone stone powder. The LCA system boundaries were defined as cradle-to-construction site (A1-A4) according to UNIT-ISO 21930, including raw material production, transport to the batching plant, concrete production, and delivery to the construction site. Life cycle inventory data were mainly obtained from the Ecoinvent v3.x database and complemented with local information. Environmental impacts were evaluated using the ReCiPe 2016 Midpoint method, considering the impact categories defined within this method. The results indicate that reducing Portland cement content through the use of calcined clay and quarry fillers significantly decreases environmental impacts, particularly in climate change and fossil resource scarcity, while maintaining the required technical performance

Keywords: Life Cycle Assessment · Concrete Mixtures · Calcined Clay · Crushed Rock Powder · Environmental Impact

1 Introduction

The construction sector produces significant environmental impacts due to the intensive consumption of raw materials and energy required to produce construction materials and infrastructure, as well as the associated greenhouse gas (GHG) emissions generated during industrial processes such as cement production. Globally, the building and construction sector accounts for a substantial share of environmental burdens, including around 30–40% of global energy consumption and up to 39% of energy-related CO_2 emissions [1, 2]. In addition, cement production alone is responsible for approximately 5–8% of

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 754–761, 2026.
https://doi.org/10.1007/978-3-032-34930-9_88

global anthropogenic CO_2 emissions, making it one of the most carbon-intensive industrial activities [3–6]. The construction sector is also associated with other environmental impacts such as air pollution, resource depletion and emissions affecting ecosystems [7, 8].

In Uruguay, these impacts are reflected in the National Greenhouse Gas Inventory (INGEI). According to the latest reported data for 2022, the Industrial Processes and Product Use (IPPU) sector emitted 907 kt CO_{2eq} [9]. When emissions derived from energy consumption in industrial activities reported under the Energy sector of the national inventory are also considered, the overall contribution of industrial activities represents approximately 6.8% of the total national GHG emissions. Carbon dioxide is the predominant gas in the IPPU sector, representing around 55% of its emissions. Within this sector, Portland cement production constitutes the main emission source, accounting for about 83% of CO_2 emissions and approximately 46% of the total emissions of the IPPU sector. Considering the central role of cement as the primary binder in concrete, these results highlight the environmental relevance of evaluating concrete production through life cycle assessment approaches and exploring alternative materials capable of reducing clinker consumption in concrete mixtures.

The aim of this study was to assess selected environmental impact categories associated with the production of concrete mixtures developed within ANII project "*Concrete design using non-traditional materials available in Uruguay with a performance-based and sustainable approach*", through a life cycle assessment approach. The study considered both conventional concrete (CC) and self-compacting concrete (SCC) incorporating alternative materials such as calcined clay and crushed rock powders. The reference mixtures correspond to concretes commonly used in the Uruguayan construction sector, while the alternative mixtures incorporate supplementary materials aimed at reducing clinker content. The assessment aimed to compare the environmental performance of these mixtures while maintaining comparable mechanical performance. The life cycle assessment was conducted in accordance with the methodology defined in UNIT-ISO 14040 [10] and UNIT-ISO 14044 [11]. The system boundaries were defined according to UNIT-ISO 21930 [12], modules A1-A4, which include raw material extraction and production, transportation of materials to the concrete batching plant, concrete production, and the delivery of ready-mix concrete to the construction site.

2 Materials and Methods

2.1 Materials

Portland limestone cement (CPF40) and ordinary Portland cement (CPN40), both in accordance with UNIT 20 [13], were used in concrete mixtures. CC mixtures incorporated CPF40 together with a naphthalene-based water-reducing admixture, whereas SCC mixtures were produced using CPN40 and a polycarboxylate-based high-range water-reducing admixture.

Three supplementary materials (SCMs) were used. Calcined clay (metakaolin), used as a supplementary cementitious material in CC mixtures, was obtained from central Uruguay, specifically from the locality of El Cordobés (Cerro Largo). In SCC mixtures, two crushed rock powders were incorporated as mineral fillers: granodiorite powder

(FG), sourced from Cruz de Carrasco (Montevideo) and limestone powder (FC), obtained from a quarry near Nueva Carrara (Maldonado).

Two natural sands of fluvial origin from the Santa Lucía River were used: a coarse sand (AGPP) and a fine sand (AFT). Coarse aggregates included crushed stone (CM) from a quarry in Cruz de Carrasco (Montevideo) and natural gravel (PR) from Las Piedras (Montevideo).

For CC mixtures, two strength levels were evaluated, corresponding to PR25 and CM40. For each level, a reference mixture and an alternative mixture with partial replacement of cement by calcined clay (PRC1 and CMC1, respectively) were considered. For SCC, one reference mixture (SCCN) and two alternative mixtures with quarry powders as fillers (SCCFG and SCCFC) were analyzed, as summarized in Table 1.

Table 1. Composition (kg/m^3) and properties of CC and SCC mixtures.

2.2 Goal and Scope Definition and System Boundaries

The goal of the LCA was to compare the environmental performance of selected concrete mixtures with equivalent functional performance. The assessment was conducted following a cradle-to-construction site approach (modules A1-A4), in accordance with UNIT-ISO 21930 [12]. These stages include raw material extraction and production (A1), transportation of materials to the concrete batching plant (A2), concrete production (A3), and the transport of ready-mix concrete from the batching plant to the construction site (A4). The placement and finishing of concrete in the structural element (module A5) were not included within the system boundaries of this study.

Module A4 only accounts for the environmental impacts associated with the transportation of ready-mix concrete from the concrete batching plant to the construction site. The modelling approach assumes a central mix configuration, in which concrete is fully mixed in a stationary plant mixer prior to loading into delivery trucks; therefore, the mixing process is entirely included in module A3. However, under typical conditions in Uruguay, concrete production is predominantly based on truck-mixing operations, where

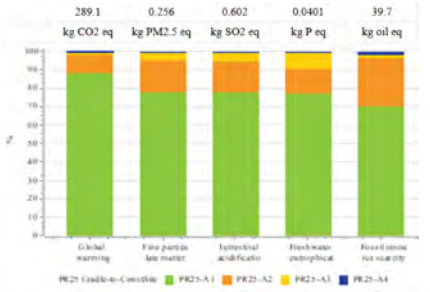
mixing occurs within the truck mixer after loading and is completed at the construction site. This difference was a modelling simplification adopted.

2.3 LCA Modelling Assumptions and Inventory Data

The life cycle assessment model was developed in SimaPro Craft (version 10.3.0.1) using data obtained from the experimental mix designs and complemented with secondary data from the Ecoinvent v3.x database [14]. Assumptions regarding transportation distances, electricity consumption and production processes were defined to represent the concrete production conditions in the Montevideo Metropolitan Area.

The functional unit was defined as 1 m^3 of concrete produced at the batching plant. The transport distances considered in the LCA model were as follows: 385 km for CPN40, 107 km for CPF40, 246 km for the calcined clay, 30 km for the gravel, 14 km for the crushed stone, 45 km for AFT, 67 km for AGPP, 14 km for FG, and 102 km for FC. Additionally, 7.5 km between the concrete batching plant and the construction site was considered. Regarding transport modelling, cement and calcined clay were modelled using heavy-duty trucks (32 metric ton, diesel, EURO 3), while aggregates (sand and coarse aggregates), the crushed rock powders (FG and FC) and transport of ready-mix concrete were modelled using medium-duty trucks (7.5–16 metric ton, diesel, EURO 3), in accordance with the datasets available in the database.

The location of the ready-mix concrete plant was defined hypothetically as the barycenter of the three main ready-mix plants in the metropolitan area of Montevideo, assuming a representative peripheral location. The construction site was similarly defined as a hypothetical point at the geographical center of the city.



2.4 Life Cycle Impact Assessment (LCIA)

The life cycle impact assessment (LCIA) was carried out using the ReCiPe 2016 Midpoint method available in SimaPro. Table 2 summarizes the relationship between these general impact categories and the corresponding ReCiPe 2016 Midpoint indicators considered in the study.

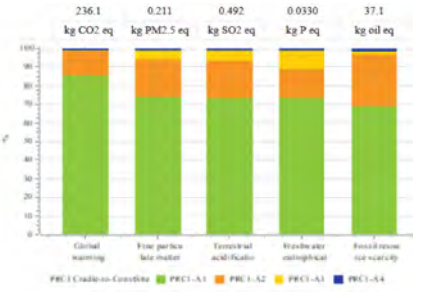


Table 2. General impact categories and ReCiPe 2016 Midpoint indicators.

General Impact category	ReCiPe 2016 Midpoint indicators used in SimaPro
Climate Change	Global warming (GWP)
Human health	Fine particulate matter formation (FP)
Ecosystem quality	Terrestrial acidification (TA) and Fresh water eutrophication (FWE)
Non-renewable resource use	Fossil resource scarcity (FRS)

f) SCC-FG.

Fig. 1. Relative contribution of each life cycle stage to the selected environmental impact categories and comparison among different concrete mixtures.

g) SCC-FC.

h) environmental impact categories for CC and SCC mixtures.

Fig. 1. (*continued*)

Figure 1 a–g present the contribution of the different life cycle modules (A1-A4) to the environmental impacts of the analyzed concrete mixtures. For each mixture, the stacked bars represent the relative contribution of each life cycle module within the cradle-to-construction site system boundary, allowing the identification of the processes that dominate the environmental profile of each concrete. The total impact value for each category is shown above the corresponding bars. Figure 1h shows the comparative environmental impact categories for CC and SCC mixtures. The values are expressed as percentages relative to the mixture with the highest impact in each category.

PR25 presents the lowest environmental impacts due to its lower cement content, whereas CM40 shows higher impacts associated with increased binder demand. SCCN exhibits a distinct profile due to its higher paste content and the use of chemical admixtures for self-compatibility.

Although the transport stages included in modules A2 and A4 contributed to the overall impacts, their relative contribution was significantly lower than that associated with raw material production in module A1, particularly cement manufacture. These results highlight that, within the cradle-to-site boundary, the environmental performance of ready-mix concrete was largely governed by the cement content and paste volume of the mixture. When considering the Global Warming Potential (GWP) indicator, the upstream production of raw materials (A1) represented the largest contribution for all the evaluated mixtures, accounting for approximately 88% of total emissions for PR25, 91% for CM40, and up to 96% for SCCN. Transportation of materials to the concrete plant (A2) represented the second most significant contribution, ranging from about 3% to 11% depending on the mixture, while the concrete manufacturing stage (A3) and the transport of ready-mixed concrete to the construction site (A4) represented only minor shares of the total GWP.

The comparison between mixtures PR25 and CM40 and their corresponding mixtures incorporating calcined clay (PRC1 and CMC1) highlights the influence of partially replacing Portland cement with calcined clay. The results showed that the mixtures containing calcined clay showed lower environmental impacts in most of the evaluated midpoint categories, particularly in GWP and fossil resource scarcity (FRS), due to the

reduction in cement consumption. In terms of GWP, the incorporation of calcined clay resulted in a reduction of approximately 18% compared with the respective reference mixtures (PR25 and CM40). This behavior was consistent with previous life cycle assessment studies of concrete, which identify cement production as the main contributor to environmental impacts [15].

The comparison between the self-compacting concrete mixtures SCCN, SCCFG, and SCCFC highlights the influence of incorporating quarry powders on the environmental performance of the mixtures. The results indicated that both SCCFG and SCCFC exhibited lower environmental impacts than the reference SCCN mixture across all the evaluated categories. In terms of GWP, SCCFG showed a reduction of approximately 33%, while SCCFC achieved a reduction of about 26% relative to SCCN. These improvements were primarily attributed to the lower cement content and, in the case of SCCFG, the shorter transport distance between the quarry and the concrete batching plant.

4 Conclusions

This study applied an LCA-based approach to evaluate the environmental performance of conventional and self-compacting concrete mixtures incorporating locally available supplementary materials in Uruguay. The results showed that environmental impacts were mainly governed by raw material production, particularly Portland cement manufacture, which dominated module A1 in all mixtures.

In conventional concrete, the partial replacement of Portland cement with calcined clay reduced the GWP by approximately 18% compared with the reference mixtures. In self-compacting concrete, the use of crushed rock powders as mineral fillers led to GWP reductions of approximately 33% for SCCFG and 26% for SCCFC relative to the reference SCC mixture, mainly due to lower cement content and, for SCCFG, the shorter transport distance of the filler.

A reduction in fine particulate matter formation was also observed in mixtures with lower clinker content, suggesting additional benefits for human health. Overall, the results indicate that clinker reduction strategies, combined with locally available supplementary materials, can improve the environmental performance of concrete mixtures in Uruguay while maintaining suitable functional performance.

However, the results should be interpreted within the cradle-to-construction site boundary considered in this study, and future work should include sensitivity and uncertainty analyses, as well as a broader assessment of additional life cycle stages.

Building Green Campuses: A Framework for Sustainable Higher Education

Rame Likaj, Gezim Hoxha(✉), Bukurije Hoxha, Blerina Blykbashi, Eronita Jasiqi, Erion Shala, and Liridon Bytyçi

Faculty of Mechanical Engineering, University of Prishtina, 10000 Prishtina, Kosovo
gezim.hoxha@uni-pr.edu

Abstract. Conducted within the Kosovo–Albania bilateral project "Education and Energy Management on University Campuses", this study combines a survey of 232 respondents across 14 academic units with carbon footprint analysis to assess energy use, resource consumption, mobility and sustainability practices. The results show that energy consumption is primarily concentrated in laboratories, IT systems, cooling and lighting, reflecting the structural requirements of engineering education and the infrastructure dependent nature of university energy use. While environmental awareness and individual engagement in sustainable practices are relatively high, institutional systems for energy management, resource efficiency and sustainability integration remain limited. In the carbon-intensive energy in Kosovo context, even modest efficiency improvements can contribute meaningfully to emission reduction, while digitalization introduces both efficiency gains and increased ICT-related energy demand. The findings indicate that sustainability outcomes are primarily determined by institutional and infrastructural conditions rather than individual behaviour, underscoring the need for governance-driven rather than behaviour-focused interventions. The study is relevant for universities in transitional contexts seeking to improve environmental performance under constrained governance and infrastructure systems.

Keywords: Carbon footprint · Energy saving · Eco-friendly transport · Recyclable materials · Sustainable campus

1 Introduction

Universities play an important role in shaping knowledge, skills and attitudes for sustainable development. This study, part of a bilateral collaboration between FME - University of Prishtina and FE - University of Tirana, examined sustainability practices and perceptions within the university community to inform a draft Green Campus framework aimed at integrating environmental sustainability into academic life, research and institutional culture while improving educational and energy management capacities [1].

2 Literature Review

National studies and policies in Kosovo and Albania address climate change and co_2 emissions. However, there is a lack of studies identifying specific sources, reasons, and approaches for lowering emissions in schools and higher education institutions [2, 3]. Some energy audits and efficiency improvements have been completed, but surveys show that professors and students are still dissatisfied with the incorporation of environmental sustainability into courses and university operations remain insufficiently sustainable [4]. Recycling, reuse, and reduction efforts on campuses are scarce, and environmental awareness programs are often infrequent [5]. This emphasizes the need to increase understanding among all educational stakeholders about sustainability, emission sources, environmental damage, and energy-saving methods.

In contrast, the EU and the United States have produced extensive guidelines, tools, and best practices for educational institutions to reduce emissions and promote renewable energy [6–8]. These frameworks emphasize active engagement of staff and students while providing pathways to carbon neutrality and greenhouse gas reduction goals [9, 10]. Educational institutions should also be categorized by type, structure, practices, energy sources, and climate zone to allow for realistic comparisons, as evidenced by 29 existing categorisation standards [11]. According to studies, universities are among the greatest energy consumers in the public sector, second only to hospitals in terms of carbon intensity [12].

Energy conservation reduces overall consumption through behavioral or operational adjustments, whereas energy efficiency achieves similar outcomes through technological improvements [13, 14]. Linking energy education to institutional policies can increase the effectiveness of sustainability-oriented action [15]. Educational institution initiatives, such as lectures, training, fairs, and contests, encourage students and staff to use energy responsibly while also supporting larger sustainability goals [16]. Context-specific interventions, including low-emission vehicles, emission testing, and remote health monitoring, have been shown to reduce co_2 emissions and improve public health [17].

3 Methodology

This study adopts a mixed-methods framework within the Kosovo–Albania project "Education and Energy Management in University Campuses," integrating survey research with a campus carbon footprint assessment at the University of Prishtina.

To ensure institutional representativeness, a structured survey was administered across all 14 academic units, yielding a final sample of $n = 232$ (43.1% teaching staff, 44.8% students, and 12.1% administrative personnel). The questionnaire was structured into dedicated sections evaluating demographics, mobility patterns, energy-saving behaviors, recycling practices and stakeholder perceptions of university sustainability initiatives. Concurrently, environmental impacts were quantified through carbon footprint calculations covering energy, water, waste and transport sectors, utilizing standardized emission factors from Kosovo's national greenhouse gas inventory (2023–2024) [6].

This design integrates surveys, statistical analysis, and emissions accounting to correlate individual behaviors with institutional energy dynamics, informing a Green Campus framework.

4 Analysis and Discussions

This study interprets sustainability performance at the University of Prishtina through socio-technical systems and multi-level governance perspectives, emphasizing that environmental outcomes are primarily determined by institutional structures rather than individual behavior. The results consistently show that sustainability practices exist at the behavioral level but are not effectively translated into system-wide institutional performance due to structural and governance constraints.

4.1 Analysis of Energy Consumption and Carbon Footprint Assessment

The energy profile (Table 1) demonstrates a strong concentration of electricity use in laboratories, IT infrastructure, cooling systems and lighting. This reflects the functional requirements of engineering education and confirms that energy demand is embedded within the socio-technical configuration of the university system rather than shaped by individual user behavior.

From a socio-technical transition perspective, such patterns reflect regime stability and infrastructural dependency, where established technical systems constrain transformation pathways. In Kosovo's carbon-intensive electricity system 1.34 kg of co_2, this structural dependence significantly amplifies emissions. The percentage contribution was calculated as the ratio of measured annual emissions from the Faculty of Mechanical Engineering (FME) and the estimated total University of Prishtina emissions relative to the national greenhouse gas inventory reported for Kosovo (2023–2024), ensuring consistent unit conversion and system boundary alignment.

Table 1. co_2 emissions from the FME building and from all UP units

co2 emission factor (kg • co2/kw • *h*)	1.34
energy consumption (kw • *h*/year)	34918
total co2emission (kg • co2)	46790.12
total (mton/year)	$4.67901 \bullet 10^{-5}$
total in kosovo (mton/year)	5.68
% fme s*h*ares wit*h*in kosovo	0.00082%
% up s*h*ares wit*h*in kosovo	~0.01148%

4.2 Resource Consumption and Digital Transition

Thermal energy data (Fig. 1) indicate seasonal demand fluctuations and inefficiencies linked to outdated heating systems and limited automation, reinforcing the role of infrastructure rather than user behavior in energy losses.

Digital transformation introduces a dual effect, while reducing paper consumption, it increases electricity demand for related ICT devices. This produces a compensatory consumption consistent with efficiency rebound theory, where gains in material efficiency are offset by higher energy use in digital systems. These findings demonstrate that digitalization does not fundamentally improve sustainability outcomes unless accompanied by governance mechanisms that regulate energy consumption across ICT infrastructures.

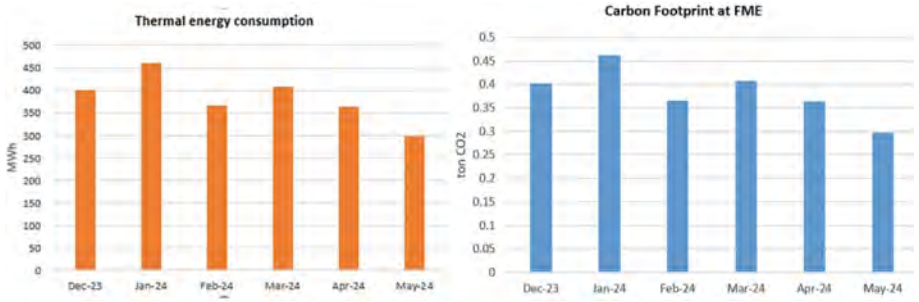

Fig. 1. a) Monthly thermal energy consumption (kWh) by building zone, for 2024, b) Monthly carbon footprint (kg CO_2) over the reporting period.

4.3 Mobility, Operations and Education

Figure 2 presents mobility patterns among students, teaching and administration staff, including average travel distance and transport mode distribution. The results show that despite relatively short travel distances, private car use remains dominant, while the share of public transport and shared mobility is comparatively low.

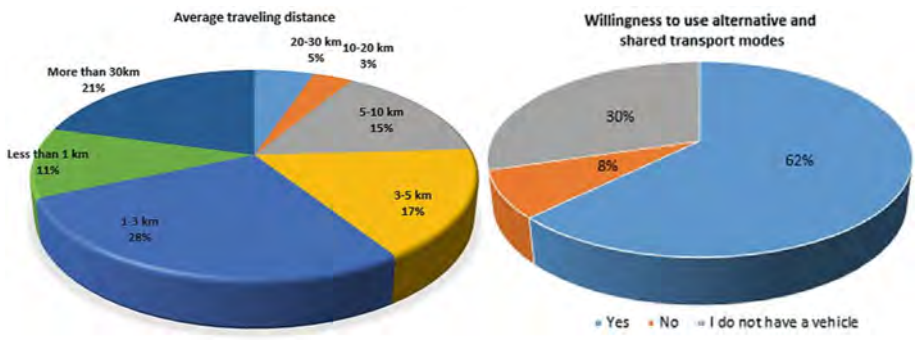

Fig. 2. a) Average travelling distance b) Distribution of alternative and shared transport modes (n = 232, 43.1% teaching, 44.8% students, 12.1% administrative staff).

Figure 3 illustrates sustainability practices within university operations, including energy-saving behavior, waste reduction and resource reuse. The findings show a high level of individual engagement in energy-saving actions, however, structured institutional practices such as systematic recycling and resource management remain limited. This suggests a gap between individual behavior and institutional operational systems. Operational sustainability is uneven, with strong individual practices but weak system-level implementation.

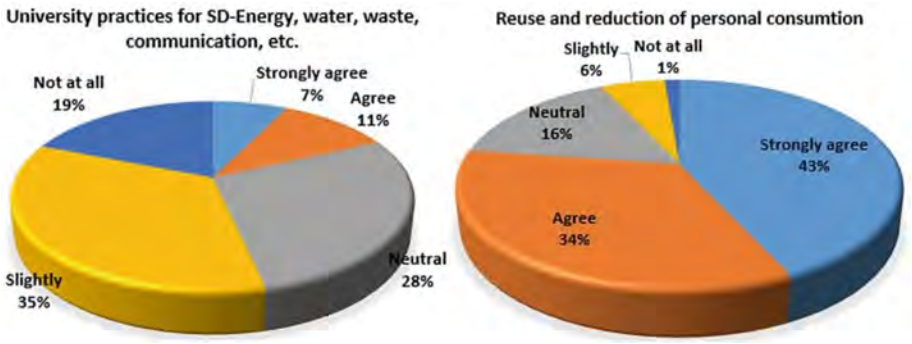

Fig. 3. a) Individual energy-saving and waste-reduction practices, b) Reuse and resource reduction practices (n = 232).

Figure 4 presents perceptions and actions related to sustainability integration in education. The results indicate that while awareness of sustainability topics is relatively high, their integration into formal curricula remains inconsistent and dependent on individual academic initiatives rather than standardized program structures.

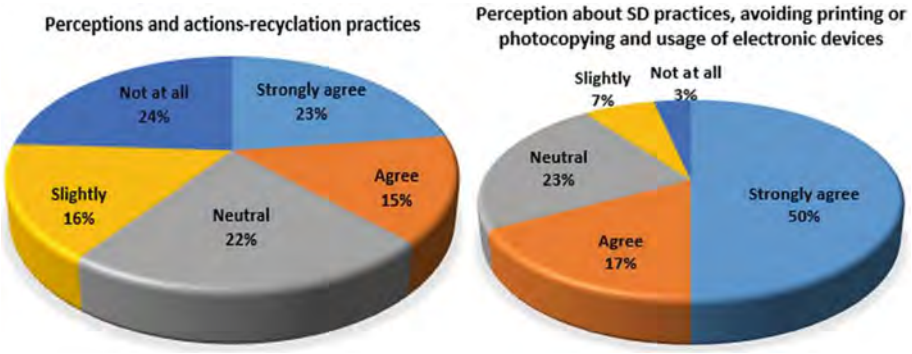

Fig. 4. a) Perceptions and actions related to sustainability integration, b) Perceptions about sustainable practices (n = 232).

4.4 Cross Domain Synthesis and Systemic Interpretation

Across all domains, results show strong individual sustainability awareness but weak institutional capacity to scale or integrate practices, indicating a clear micro and meso misalignment consistent with socio-technical transition theory. Carbon footprint findings confirm that impacts are driven mainly by structural energy dependencies rather than behavior, making sustainability a system-level outcome shaped by infrastructure, operations and governance.

In general, sustainability in higher education emerges as a socio-technical system property rather than individual action, shifting the focus from behavior change to institutional transformation. These findings align with Valls-Val and Bovea [4], whose review of carbon footprint studies in higher education identified that energy consumption is dominated by operational infrastructure rather than occupant behavior and that governance capacity is the primary differentiator between high and low performing institutions. The concentration of electricity demand in laboratories and IT systems is further consistent with Hong et al. [15], who found such spaces account for 40–60% of total university electricity use regardless of climate zone or institutional size. In contrast to Stough et al. [12], who reported relatively high levels of formal sustainability curriculum integration at Western European universities, this study confirms that sustainability education at the University of Prishtina remains decentralised and initiative-dependent, reflecting a meso-level governance deficit common to universities in transitional institutional contexts.

4.5 Implications for Green Campus Transformation

Effective sustainability transition in higher education requires a shift from behavior-focused actions to governance-driven system redesign. Transformation depends on aligning infrastructure, operations and academic governance into a coherent institutional system. In transitional contexts such as Kosovo, the main barrier is not awareness but limited institutional capacity for coordination, reflecting systemic barriers to scaling sustainable practice. The Green Campus transition therefore, requires institutional reconfiguration through alignment of technical, administrative and educational systems. Regarding transferability, elements of the Green Campus model vary in their context-specificity. Kosovo's high emission factor (1.34 kg co_2/kw*h* vs. EU average 0.25–0.3 kg co_2/kw*h*) means that the energy and decarbonisation objectives in Table 2 yield disproportionately larger emission reductions here than at comparable European institutions, these should be recalibrated to the local emission factor when applied elsewhere. Conversely, the governance, curriculum integration and mobility domains address structural challenges and coordination deficits, decentralised decision-making, infrastructure-dependent behaviour as documented across higher education systems at different income levels and energy contexts [10, 11]. These elements are therefore broadly transferable to other universities in transitional economies, while institutions in high-income EU countries may apply the governance architecture of Table 2 as a benchmarking tool with recalibrated KPI thresholds.

4.6 Development of the Green Campus Framework

The Green Campus framework translates empirical findings into an integrated implementation model linking objectives, indicators, responsibilities, timelines and monitoring (Table 2). It functions as a governance system aligning energy, resources, mobility, education and institutional management within a unified sustainability structure, supported by carbon accounting, energy audits and digital dashboards in line with EU.

Green Deal and SDG targets. The model comprises interdependent domains: energy and emissions, resource efficiency and circularity, sustainable mobility, curriculum integration and governance and monitoring, reflecting the interconnection of technical, operational and institutional dimensions of university sustainability.

Implementation is defined through KPIs and assigned responsibilities to ensure accountability and comparability. Table 2 operationalizes the framework into measurable actions for monitoring and policy tracking across university units.

Table 2. Green campus governance model for the technical faculty

Strategic objective	KPI (EU/SDG-aligned)	Responsible actors	Timeline	Monitoring method	Expected impact	EU Green Deal/SDG link
Reduce energy consumption	kWh/m^2/year reduction	Energy manager, administration	1–3 yrs	Smart meters, energy audits	Lower energy demand	EU Energy Efficiency Directive: SDG 7, 13
Expand renewable energy	% renewable electricity	Faculty + partners	2–5 yrs	PV (photo voltaic) production data	Grid dependence reduction	EU Green Deal Clean Energy: SDG 7, 13
Improve water efficiency	Liters/person/day	Facility management	1–3 yrs	Water meters	Reduced water use	EU Circular Economy Action Plan: SDG 6
Strengthen waste circularity	% waste recycled	Sustainability office	1–2 yrs	Waste audits	Reduced landfill impact	EU Circular Economy Strategy: SDG 12
Sustainable mobility transition	% low-carbon commuting	Campus mobility unit	2–5 yrs	Mobility surveys	Lower transport emissions	EU Sustainable Mobility Strategy: SDG 11,13
Integrate sustainability incurricula	% courses updated	Academic departments	2–4 yrs	Curriculum review	Green skills development	EU Green Skills Agenda: SDG 4, 13
Strengthen sustainability governance	Sustainability office operational	Rectorate/Dean's Office	1 yr	Governance KPIs	Institutional coordination	EU Governance for Sustainability: SDG 16

5 Conclusions

The results indicate that sustainability performance at the University of Prishtina is shaped more by structural and institutional conditions than by individual behavior. This study provides empirical evidence on energy use and sustainability practices in a higher education setting within a transitional context, highlighting the importance of institutional coordination and operational capacity for efficient resource management and environmental performance. Improving sustainability outcomes requires infrastructure modernisation, administrative coordination and the integration of energy considerations into routine institutional processes. These findings are particularly relevant for higher education systems under resource and governance constraints. The study contributes to the literature on socio-technical transitions in higher education by showing how institutional capacity conditions the effectiveness of sustainability actions. It suggests that embedding sustainability within university governance, supported by digital monitoring and performance-based accountability, can accelerate this transition. Future research should extend this framework to multi-university comparisons to validate its transferability across different institutional and infrastructural contexts.

Existing Methods for Stress–Strain Analysis of Masonry Vaults and Numerical Investigation of Crack Formation Mechanisms in Historical Masonry Vaults for Sustainable Reconstruction and Heritage

Dina Khaliullina(✉)

Moscow State University of Civil Engineering (MGSU), Moscow, Russia
khaldin.global@gmail.com

Abstract. This paper presents a study of existing stress–strain analysis methods for masonry vaults and a numerical investigation of crack formation mechanisms in historical masonry structures. The research focuses on cylindrical and groin vaults of a cultural heritage building in Kazan, constructed from clay brick masonry. Traditional analytical approaches developed for vaults in the 18th–20th centuries are reviewed in order to establish a methodological basis for modern numerical modelling. A finite element model was developed in LIRA to simulate the behaviour of masonry vaults under self-weight and under several degradation scenarios, including differential settlement, support displacement, and partial volume shifting. Material parameters were defined based on in-situ testing. The results indicate that diagonal cracking patterns primarily arise from differential settlement of the supporting structures, which corresponds to the observed cracking on site. Additional crack initiation was registered under rotational and lateral support movements, demonstrating the sensitivity of masonry vaults to loss of spatial stiffness. The numerical results closely reproduced real crack patterns and allowed identification of the most probable structural causes

The study enables identification of the actual causes of cracking in masonry vaults and supports the design of strengthening measures in critical zones only, thereby optimising reconstruction costs while preserving historical heritage. In addition, preliminary numerical analysis makes it possible to predict crack locations before visible damage occurs and to strengthen vulnerable structural elements, such as foundations. The results demonstrate that sustainable reconstruction and conservation of historical masonry vaults should be addressed through a comprehensive structural assessment

Keywords: Historical masonry vaults · Vault analysis methods · Crack formation mechanisms · Finite element modelling · Sustainable reconstruction

Brick masonry vaults of historical buildings represent complex spatial thrust systems whose structural behaviour largely depends on the condition of the supporting contour and the foundation. In the reconstruction of cultural heritage buildings, a key task is not

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 771–779, 2026.
https://doi.org/10.1007/978-3-032-34930-9_90

only the restoration of the load-bearing capacity of the structures but also the preservation of their original material fabric with minimal intervention. This requires a justified identification of the causes of crack formation in order to avoid excessive strengthening measures and unnecessary dismantling.

This study examines the vaults of a cultural heritage building located in Kazan, including a cylindrical vault in the basement in axes B–C/1–2 and a groin vault on the first floor in axes A–B/5–6. According to the results of the structural survey, diagonal cracks with an opening width of up to 2 mm were identified in the masonry of the vaults [1]. The aim of this work is to determine the causes of crack formation in the vaults and to develop strengthening measures in the necessary zones, thereby optimising reconstruction costs while preserving the historical heritage.

Masonry vaults are generally subjected to loads from their self-weight as well as from the structural elements located above them, including environmental effects [2]. Under loading, a vault mainly works in compression. The resulting vertical compressive forces are transferred to the supports. In many types of vaults an additional horizontal force arises, meaning that the structure also develops thrust. This horizontal thrust may be relatively small or may be resisted by a ring tie or other reinforcement embedded within the body of the vault.

The objective of the research is to identify the mechanism of crack formation in the considered vaults through numerical modelling of different deformation scenarios of the supporting contour. The obtained results make it possible to determine the most probable causes of the observed damage and to justify local strengthening measures aimed at extending the service life of historical structures.

In the context of sustainable and circular reconstruction, the application of numerical modelling makes it possible to minimise unnecessary structural intervention and to preserve the original masonry fabric of historical buildings. Identification of the actual causes of crack formation supports targeted strengthening of structurally vulnerable zones only, reducing excessive demolition, material consumption, and construction waste.

1 Existing Methods for the Stress–Strain Analysis of Masonry Vaults

Masonry vaults represent complex spatial thrust systems whose structural behaviour is governed primarily by compressive stress transfer and horizontal thrust acting on the supporting contour. Due to the heterogeneous structure of masonry and the variability of material properties, accurate analytical evaluation of the stress–strain state of vaults remains a challenging engineering task. The structural behaviour of vaults depends not only on their geometric parameters but also on the stiffness of the supporting structures and the interaction between individual masonry elements. For this reason, the analysis of masonry vaults has historically been based on simplified analytical approaches derived from empirical observations and structural mechanics.

The earliest approaches to the design and assessment of masonry vaults were based on empirical formulas developed from observations of historical structures [3]. Researchers such as Lesquillier, Rankine and Kerner proposed relationships for estimating vault

thickness and geometric proportions depending on the span and rise of the vault. These empirical formulas were derived from the analysis of long-term performance of masonry structures and were intended primarily for preliminary design. Later studies by Rondelet and Schwarz refined these approaches by introducing parameters related to the ratio between loading and allowable compressive stresses in masonry [3, 4]. However, such empirical methods often lead to conservative design solutions and do not fully account for the complex interaction between loads, geometry and material properties.

Further development of analytical methods was associated with the application of the limit equilibrium theory [5]. According to this concept, the safety of a masonry vault is assessed by analysing the position of the thrust line within the masonry section. If the thrust line remains within the middle third of the section, tensile stresses are avoided and the vault remains stable.

Another analytical approach was proposed by Onishchik, who developed a method based on equilibrium equations in so-called "dangerous sections" [5]. In this method, the internal forces in characteristic sections of the vault are determined and subsequently verified for eccentric compression and shear resistance.

Although these analytical approaches provide valuable insight into the behaviour of masonry vaults, they involve significant simplifications and cannot fully represent the complex stress–strain state of spatial masonry structures. Therefore, modern research increasingly relies on numerical modelling methods, particularly the finite element method, which makes it possible to analyse complex structural behaviour and to simulate crack formation mechanisms in masonry vaults [6].

2 Case Study. Investigated Structure

The object of the study is a cylindrical vault of the basement located in axes B–C/1–2 and a groin vault of the first floor located in axes A–B/5–6. According to measurements obtained during the structural survey, the vault thickness ranges from 270 mm to 300 mm depending on the thickness of the plaster layer. The vaults and walls of the basement and the first floor are constructed of solid clay brick masonry with brick grades ranging from M25–M50 to M75 and lime–sand mortar with grades from M15 to M25–M50, as presented in Tables 1 and 2 [1], according to masonry design standards [7].

The brick vaults of the basement and first-floor intermediate floors perform a dual structural function:

– ensuring the overall spatial stiffness of the building;
– carrying a part of the vertical service loads acting on the floors.

Therefore, the removal of the brick vaults even in local areas, not to mention their complete dismantling throughout the building, would lead to a loss of the spatial stiffness of the structure and potentially to the collapse of the building.

In the basement vaults located in axes B–C/1–3, a system of cracks with an opening width of up to 2.0 mm was identified, as well as a crack with an opening width of 4.0 mm in axes B–C/4–5. In the first-floor vaults located in axes A–B/2–3, B–C/3–4 and A–B/4–5, a system of cracks with an opening width of up to 5.0 mm was observed. According to Clause 3 [8, 9], the condition of the vaults is assessed as limited serviceability. The

defect maps are shown in Figs. 1 and 2, and the symbols used for crack identification are presented in Table 3.

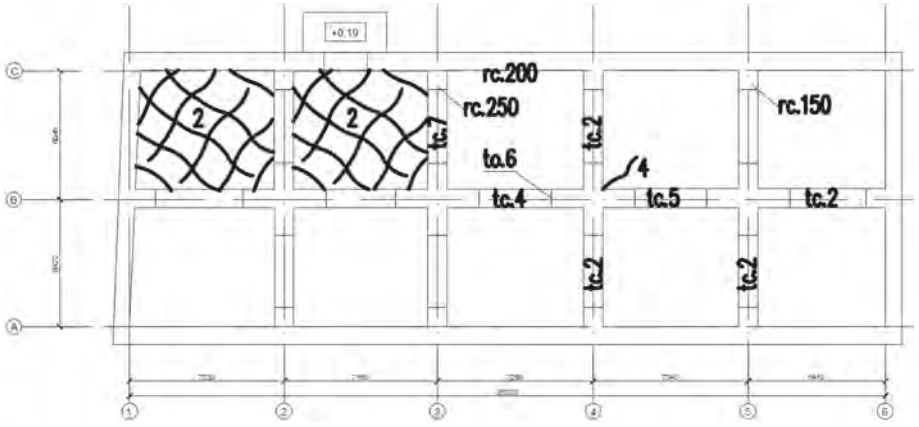

Fig. 1. Defect map of the basement vaults.

One of the most common types of damage in masonry structures is cracking. According to statistical data, the most frequent causes of crack formation in masonry structures are:

- differential settlement of foundations (65–75%);
- structural overloading (10–15%);
- temperature deformations (10–15%);
- moisture-related deformations (5–8%);
- special loads and impacts (2–5%).

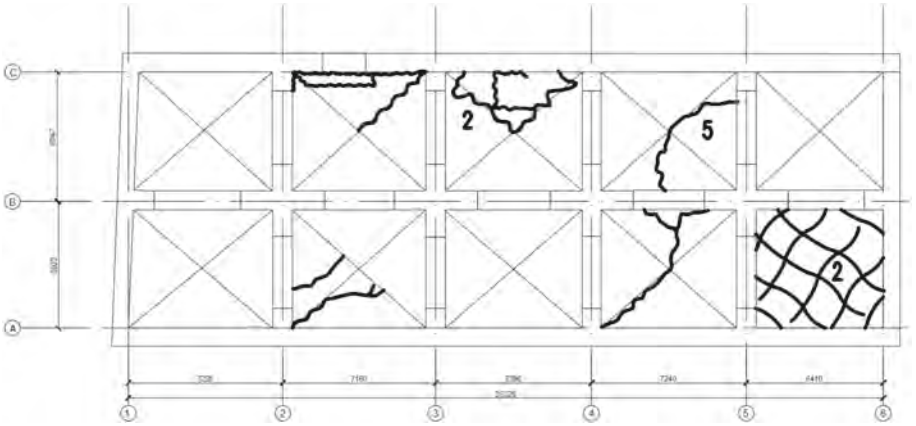

Fig. 2. Defect map of the first-floor vaults.

Table 3. Defect symbols used in the crack map

Symbol	Description
tc.1	Crack at the crown of the vault (crack width 1 mm)
to.1	Crack at the support of the vault (crack width 1 mm)
rk.100	Masonry damage with a depth up to 100 mm
1	Crack (or crack system) with a crack width of 1 mm

According to the conducted structural survey, it is necessary to restore the spatial stiffness of the building and the load-bearing capacity of the brick vaulted floor structures of the basement and the first floor. For this purpose, it is necessary to identify the causes of crack formation and to strengthen the required structural elements.

3 Research Methodology in the LIRA Software Package. Research Program

For the structural analysis, the LIRA software package was used. The software implements the finite element method (FEM), which is an efficient numerical method for solving a wide range of boundary value problems of a continuous medium. The method is based on replacing the investigated structure with a finite number of discrete elements connected at nodes.

During the development of the computational model, quadrilateral, rectangular, and triangular spatial finite elements were used (Fig. 3). The cylindrical vault model consists of 290 elements, while the groin vault model consists of 316 elements.

The numerical experiment included two sequential analyses:

– behavior of the cylindrical and groin vaults under self-weight loading;

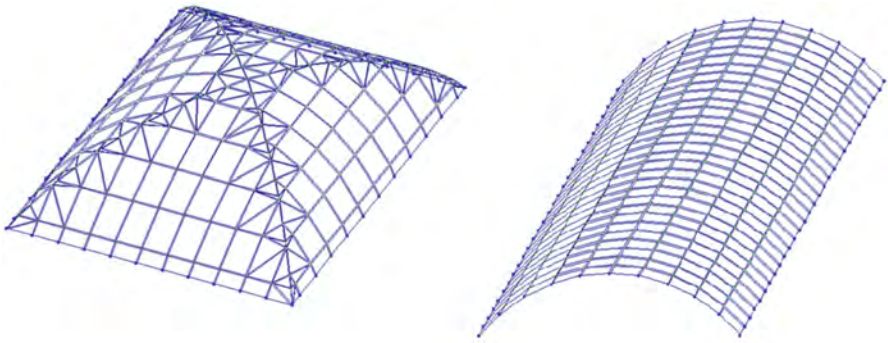

Fig. 3. Masonry groin vault and cylindrical vault models.

– behavior of the vaults with the introduction of a failure factor.

The aim of the study was to reproduce diagonal cracks corresponding to the defect map. To achieve this, the following scenarios were simulated:

– sequential displacement of the corner of the support contour;
– shear displacement of part of the structure volume;
– settlement of the support.

The simulated deformation scenarios were selected based on characteristic crack formation mechanisms in masonry vault systems reported in previous studies and structural survey observations.

4 Results

According to the obtained results, failure under self-weight does not occur. Both the groin vault and the cylindrical vault work in compression. The vault thickness adopted during the design stage may therefore be considered optimal.

A fragment of the internal forces in shell elements of the cylindrical vault under support settlement is presented in Table 4. For each element, the following parameters are given: N_X – normal stress along axis X_1; N_Y – normal stress along axis Y_1; M_X – bending moment acting on the section orthogonal to axis X_1; M_Y – bending moment acting on the section orthogonal to axis Y_1. Based on these data, it is possible to determine in which elements cracks are formed.

Visualization of the formed cracks was carried out for groin and cylindrical vaults under all conditions of crack formation, namely sequential displacement of the corner of the support contour, shear displacement of part of the structure volume, and settlement of the support.

As a result, under settlement of the support, cracks were obtained that coincide in location with those observed in the structure. It was established that crack formation in the cylindrical vault located in axes B–C/1–2 of the basement occurs due to differential foundation settlement, while crack formation in the groin vault located in axes A–B/5–6

Table 4. Internal forces in shell elements of the cylindrical vault under support settlement (fragment)

Element No.	N_x (t/m^2)	N_y (t/m^2)	M_x (t)	M_y (t)	Crack formation at $\sigma_x > 0.05$ MPa	Crack formation at $\sigma_y > 0.05$ MPa
1	16.085	−2.682	0.333	−0.023	yes	no
2	−1.335	3.399	0.338	−0.143	no	no
3	−22.267	−10.395	−1.366	−0.026	no	no
4	−5.721	−11.553	−1.193	0.000	no	no
5	−1.353	−2.253	0.173	−0.029	no	no
6	−0.528	−0.064	−0.024	0.004	no	no
7	−0.308	0.443	0.013	0.008	no	no
8	−0.419	0.048	0.005	0.010	no	no
9	−0.584	−0.629	0.003	0.008	no	no
10	−0.704	−0.602	0.003	0.004	no	no
11	9.331	−9.693	0.233	−0.224	yes	no
12	−2.264	4.811	0.127	−0.402	no	no

of the first floor occurs due to cracks in the supporting walls, which in turn were caused by a weak foundation.

The obtained result corresponds to the results of the structural survey; the building has a rubble foundation, which will subsequently be strengthened. The numerical results demonstrated qualitative agreement with the crack patterns identified in the structural survey and defect maps.

During the study, the causes of crack formation in the remaining vaults were also identified. In the vaults located in axes B–C/4–5 of the basement and A–B/2–3 of the first floor, crack formation occurs due to sequential displacement of the corner of the support contour. In the vaults located in axes B–C/2–3 and B–C/3–4 of the first floor, crack formation occurs due to shear displacement of part of the structure volume.

5 Conclusions

Numerical modelling using the finite element method made it possible to reproduce different scenarios of vault behaviour under settlement of the support, sequential displacement of the corner of the support contour, and shear displacement of part of the structure volume. It was established that under the action of self-weight failure does not occur, and the formation of diagonal cracks is mainly associated with differential foundation settlement and the loss of stiffness of the supporting walls. The numerical analysis demonstrated the sensitivity of masonry vaulted systems to support settlement, sequential displacement of the corner of the support contour, and shear displacement of part of the structure volume.

Comparison of the numerical modelling results with the defect map showed a correspondence between the calculated zones of tensile stresses and the cracks actually identified in the structure. This made it possible to determine the most probable causes of the damage and to establish the priority of strengthening the structural elements.

The application of numerical analysis at the stage of reconstruction design makes it possible to identify cause-and-effect mechanisms of damage, prevent excessive intervention in historic masonry, and limit strengthening works to local zones only. Such an approach supports sustainable and circular reconstruction by preserving the original material fabric of heritage buildings, reducing construction waste and unnecessary material consumption, and extending the operational life cycle of existing structures.

The use of the finite element method in the analysis of complex spatial thrust systems made of brick masonry provides a deeper understanding of structural behaviour under the combined interaction of building elements. This is particularly important when working with cultural heritage structures, where the causes of crack formation are not always obvious and require comprehensive engineering analysis. The study focuses on identifying the most probable crack formation mechanisms rather than simulating the full long-term damage evolution of the masonry vaults.

Abstract. The existing building stock needs to undergo an extensive retrofit process to meet the decarbonisation targets set by European directives, and university/educational buildings have characteristics that make them a complex category. Namely, it is essential to ensure an effective balance among indoor air quality, energy performance, operational sustainability, and, moreover, the ability to remain resilient to the impacts of climate change. In this study, an experimental investigation is conducted in a university office located in a Mediterranean climate. Indoor environmental parameters were monitored under different operating conditions, including unoccupied periods, typical occupancy patterns, and natural ventilation strategies based on thermal comfort and CO_2 levels. The analysis enabled estimation of the building's natural infiltration rate and evaluation of the effectiveness of manual and demand-controlled natural ventilation approaches. The collected data provided an experimental basis for developing a calibrated indoor environmental model of the investigated office, which reproduced the main measured CO_2 trends under the monitored operating conditions. The calibrated model can support future investigations of ventilation strategies aimed at improving indoor air quality while reducing thermal discomfort under different seasonal and climate conditions. Overall, the study provides a basis for the future assessment of ventilation strategies in university office buildings

1 Introduction

The building sector is internationally recognised, at European and national levels, as highly energy-intensive and, for this reason, has been at the centre of policies aimed at improving its energy and, consequently, environmental performance for more than

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 780–788, 2026.
https://doi.org/10.1007/978-3-032-34930-9_91

25 years. With the latest revision of the European Energy Performance of Buildings Directive (EPBD 2024/1275), to achieve a zero-emission building stock by 2050 [1], Member States are required to prepare a national building renovation plan and to establish minimum energy performance requirements.

Indoor air quality (IAQ) was already addressed in the previous version of the Directive (2018/844) [2], but in the latest revision, it assumes an increasingly central and recognised role. Both the national plan and the minimum performance requirements must account for indoor air quality to ensure an appropriate balance between energy efficiency and healthy indoor conditions.

Several studies have related IAQ to human health and performance [3, 4], and for this reason, a wide range of research activities focusing on the monitoring of indoor air contaminants have been conducted in the last decade. Since it is recognised that there is an impact on work and learning performance, monitoring campaigns are conducted in schools, offices, and even residential environments to correlate the evolution of indoor pollutants with occupants' perceptions and productivity.

Most studies of IAQ are based primarily on experimental campaigns. In this study, the objective is to develop a model calibrated with measured data to subsequently test various strategies aimed at improving indoor conditions. The monitoring campaign was conducted in an office zone within a university building under different operating conditions. Indoor air temperature and CO_2 concentrations are discussed. The measured data were used to calibrate the office model, which can serve as a starting point for testing a wider range of possibilities to achieve the best trade-off between indoor air quality and energy efficiency. Moreover, building energy simulation tools, such as EnergyPlus, enable modelling and evaluation of indoor CO_2 concentrations and generic contaminants. The measured data could be used to identify correlations between CO_2 and other pollutants, and the simulated CO_2 from the calibrated model may then be used as an indicator for a preliminary evaluation of ventilation adequacy and occupancy-related indoor air quality conditions.

2 Case Study

The study was conducted in an office zone within a university building in Naples, Italy, with a Mediterranean climate (Italian climate zone C).

The building under investigation is one of the University of Naples Federico II's engineering facilities. Built between 1956 and 1965, it houses classrooms for teaching, student services offices, study rooms, laboratories, and offices for teaching and research staff (Fig. 1A). It has a reinforced concrete structure. The thermal transmittance (U-value) for external walls is 0.89 W/m^2K, while the U-values for the roof and ground floor are 1.00 W/m^2K and 0.92 W/m^2K, respectively. With reference to the transparent building envelope, double-glazed windows with a thermal transmittance value of 3.2 W/m^2K and an aluminium window frame without a thermal break are installed. The monitoring campaign was carried out in an office located on the 11th floor of the building (highlighted in yellow in Fig. 1A, and detailed in Fig. 1B) facing west.

Environmental parameters affecting indoor air quality were monitored over two weeks in March 2026 using an air-Q Pro sensor, which allows the measurement of

Fig. 1. Engineering facilities of the University of Naples Federico II, Italy with highlighted office investigated (A), office (B).

parameters related to thermal comfort, such as air temperature and relative humidity, as well as other variables affecting indoor environmental quality, including indoor carbon dioxide concentration, carbon monoxide, oxygen, particulate matter, nitrogen dioxide, ozone, volatile organic compounds, formaldehyde, and noise.

Regarding the outdoor climatic conditions during these two weeks of monitoring, air temperature ranged between 8 °C and 20 °C. The lowest temperatures were recorded during nighttime, between 3:00 and 6:00, while peak values occurred between 13:00 and 15:00. Temperature trend was relatively gradual during both the increase and decrease phases, whereas the relative humidity varied between 60% and 70%.

The monitoring campaign was conducted under different conditions; the following ones were analysed in this study:

- during a weekend, with no occupancy and with both windows and the door closed. Several other days under this configuration have been monitored;
- on a weekday, with a variable number of occupants, mainly with the windows and door closed. In the afternoon, due to indoor thermal discomfort reported by the occupants, one window was opened for one hour;
- on a weekday, with a variable number of occupants, with the door closed and several window-opening strategies adopted, initially based on the indoor CO_2 levels recorded and subsequently in response to thermal discomfort reported by the occupants.

Occupancy during weekdays varied due to occasional entries and exits by other occupants, as described in detail in the analysis of the monitored data.

These tests, characterised by different operating conditions, make it possible to evaluate the natural infiltration of the building during unoccupied periods with fixed window and door positions, the accumulation of CO_2 due to occupancy, and the efficacy of ventilation strategies driven by thermal comfort and CO_2 levels.

Although a wide range of indoor air quality parameters was monitored, the present study focuses on CO_2 as a tracer of occupancy and ventilation. The analysis of additional pollutants will be addressed in future work. CO_2 concentration was used to calibrate the dynamic model of the office space developed in DesignBuilder® and simulated in EnergyPlus. The model will serve as a basis for exploring ventilation strategies that

improve indoor air quality while limiting thermal discomfort, and for investigating their effects on energy demand.

3 Results

3.1 Weekend Test

The trends for indoor air temperature and carbon dioxide concentration from Friday afternoon to Monday morning are shown in Fig. 2.

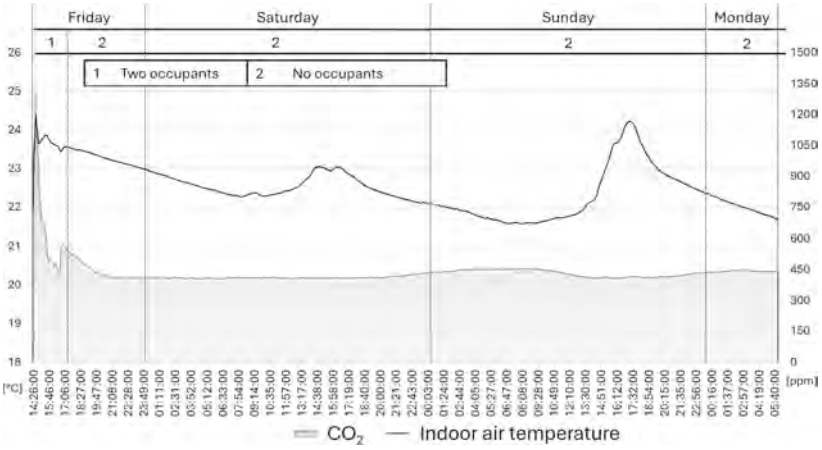

Fig. 2. Trend of indoor air temperature and CO_2 concentration within the office during the weekend.

On Friday afternoon, until around 17:00, occupants remained in the office. Due to the high indoor temperature, around 24 °C, one of the windows was opened, involving a reduction in CO_2 concentration and a slight temperature decrease. From 17:00 onwards, the office remained unoccupied with door and windows closed. CO_2 concentration gradually decreased until it reached a stable value, with slight fluctuations, mainly due to infiltration. Indoor air temperature showed a daily fluctuation, with peak values in the afternoon, consistent with the office's west-facing exposure, characterised by increased solar gain in the early afternoon.

This type of monitoring allows the evaluation of the natural infiltration rate using the CO_2 decay method [5, 6], assuming a well-mixed indoor air and a constant outdoor CO_2 concentration of around 400 ppm (Eq. 1).

$$\frac{dC_{in}}{dt} = ACH(C_{out} - C_{in}) \tag{1}$$

where C_{in} and C_{out} C_{out} are the indoor and outdoor CO_2 concentrations, respectively, and ACH is air changes per hour (h^{-1}).

Monitoring under these conditions was repeated multiple times to account for the dependence of natural infiltration on outdoor conditions, such as wind intensity and the

temperature difference between indoor and outdoor environments [7]. The evaluation of ACH was conducted in accordance with ASTM E741 [8], considering a significant portion of the decay curve in which $\ln(C_{in} - C_{out})$ exhibits a linear trend. Only cases with a sufficiently high initial concentration difference (≥ 350 ppm) were selected. The results indicate an air change rate of 1.18 ± 0.14, with variability fully consistent with previous studies [7].

3.2 Weekday Test – Typical Office Use and Strategy for Natural Ventilation Based on Occupant Comfort

During the first monitored weekday, the office was occupied for approximately 8 h by a variable number of people, ranging from 2 to 4, as shown in Fig. 3.

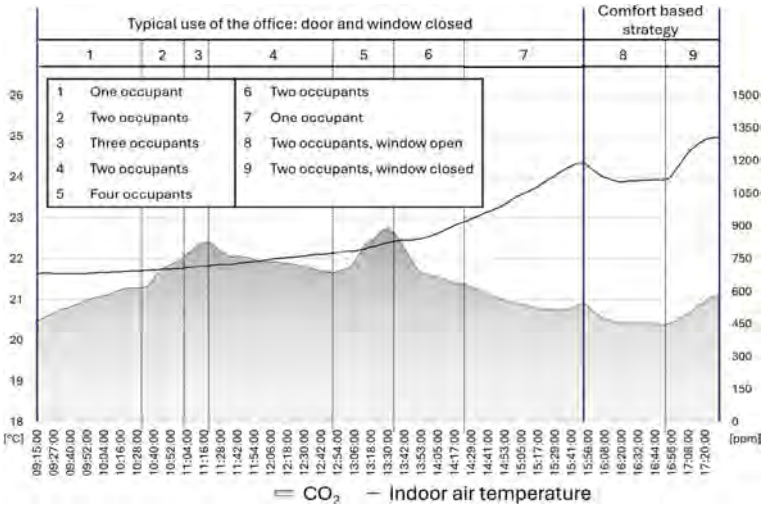

Fig. 3. Trends of indoor air temperature and CO_2 concentration in the office during a weekday under typical occupancy conditions.

For most of the day, doors and windows remained closed, and the only variations concerned the number of occupants. An increase in CO_2 concentration was observed with increasing occupancy, reflecting metabolic emissions. In the afternoon, around 16:00, due to thermal discomfort caused by the high indoor temperature, one window was opened for about an hour, resulting in a reduction in CO2 concentration and a decrease in air temperature of about 1 °C.

3.3 Weekday Test – Typical Office Use and Strategies for Natural Ventilation Based on CO_2

During the second monitored weekday, no strategy was adopted in the first four hours, similarly to the previous day (Sect. 3.2), and a very similar trend was observed (Fig. 4).

From 12:00 onwards, a CO_2-based natural ventilation strategy was adopted, with a threshold of 800 ppm for window opening. Once this value was reached, one window was opened for 30 min, resulting in a reduction of around 300 ppm.

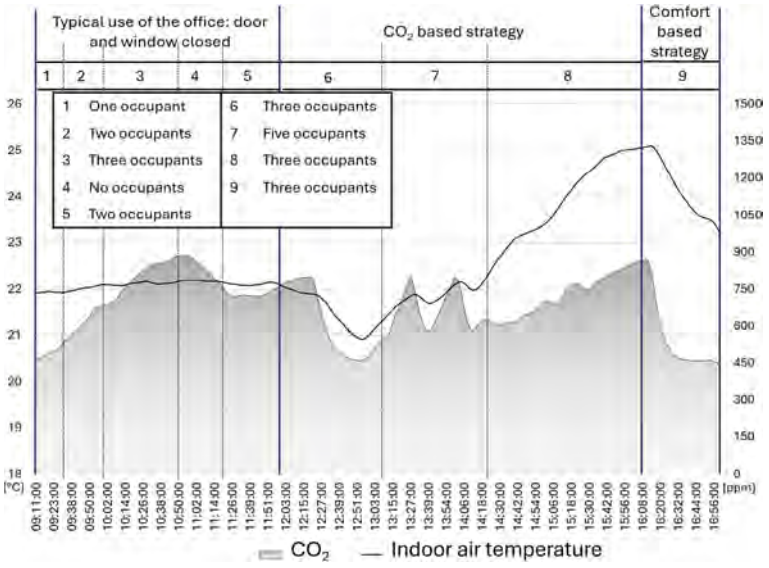

Fig. 4. Trends of indoor air temperature and CO_2 concentration in the office during a weekday under typical occupancy conditions, with CO_2-based and comfort-based natural ventilation strategies.

Then, from 13:00 onwards, a threshold for window closing of 600 ppm was established. Under high occupancy, from three to five occupants (phase 7 of Fig. 4), the 800 ppm threshold was frequently and rapidly reached, requiring repeated window-opening cycles. Approximately 10 min were required to reduce the CO_2 concentration by about 200 ppm (achieving the threshold for window closing of 600 ppm). However, with five occupants in the office, the concentration returned to 800 ppm in approximately 20 min. The CO_2 control strategy is effective, but under high occupancy conditions, frequent natural ventilation cycles are needed.

Moving to phase 8, with three occupants, the CO_2 concentration returned to 800 ppm after approximately 70 min. In the final phase (phase 9), the window was opened even after the concentration dropped below the 600 ppm threshold because elevated indoor temperatures caused thermal discomfort for the occupants.

The opening of window, and thus natural ventilation, also affected other pollutants. For example, trends in PM2.5 and PM10 during phases 7 and 8 are shown in Fig. 5. The increase in particulate matter during window opening highlights the need to balance CO_2 dilution benefits against possible increases in exposure to outdoor particles when optimising IAQ.

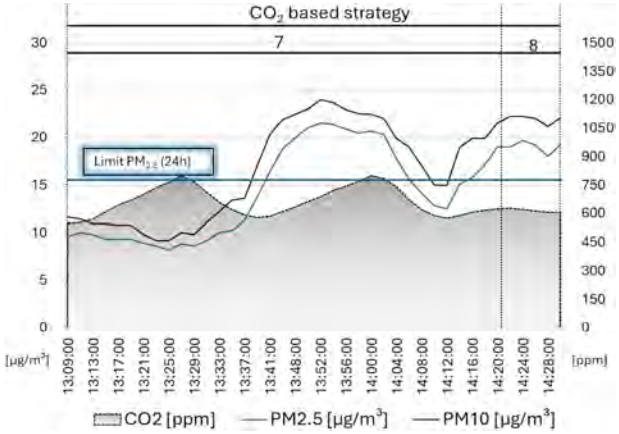

Fig. 5. Trends of indoor CO_2 concentration and PM2.5 and PM 10 in the office during a weekday under typical occupancy conditions, with CO_2-based natural ventilation strategy.

4 Calibrated Model on CO_2 Concentrations

The results of the monitoring campaign provide a robust experimental basis for calibrating a dynamic building energy model developed in EnergyPlus. The data concerning the natural infiltration (ACH) achieved in Sect. 3.1 were used, specific schedule for occupancy and natural ventilation were set, and CO_2 generation based on the occupants' gender and age according to [9] was assigned. About outdoor conditions, weather file was modified using data obtained from meteorological stations. The outdoor air temperature and relative humidity, corresponding to the data shown in Fig. 6, ranged between 14–18 °C and 60–70%, respectively.

The comparison between measured and simulated indoor CO_2 for the weekday discussed in Sect. 3.3 is shown in Fig. 6.

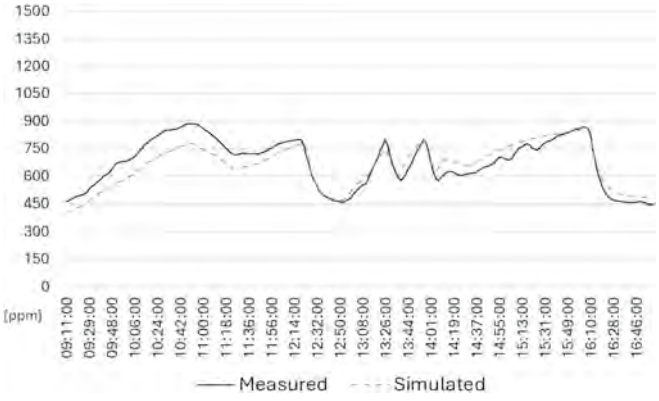

Fig. 6. Measured and simulated indoor CO_2 concentration profiles.

Overall, the model reproduces the main trend of the measured CO_2 profile and the main changes associated with occupancy variation and window-opening events discussed in Sect. 3.3.

5 Conclusions

The study presented an experimental and modelling analysis of indoor air quality in an office environment under different operating conditions. The monitoring campaign enabled the evaluation of natural infiltration rates and the assessment of natural ventilation strategies based on CO_2 concentration and thermal comfort. The calibrated dynamic model reproduced the main measured trends and can support future assessments of natural ventilation strategies under different seasonal and climate conditions. The results should be interpreted considering the short monitoring period and the fact that the analysis refers to a single office under specific operational conditions. Within these limits, the study provides a useful basis for future investigations of ventilation strategies in university office buildings.

[3] School of Sciences, University of Minho, Guimarães, Portugal

Abstract. Material Flow Analysis (MFA) and Material Stock Analysis (MSA) have become key approaches for understanding resource dynamics and metabolism in cities, while supporting the transition toward circular economy models. Recognized as important drivers of this transition, information technologies offer new possibilities for supporting materials analysis and achieving circularity and sustainability objectives. Technologies such as City Information Modeling (CIM) can support and promote circular economy and sustainable practices in cities. Despite the potential applications, the use of CIM for material analysis remains unexplored. Building on a prior critical analysis of the literature, this study presents a methodological framework for the use of CIM in urban material analysis. Guided by the synergies between Building Information Modeling (BIM) and Geographic Information Systems (GIS) identified in the literature, this paper explores how CIM can be applied for MFA and MSA. Furthermore, this research aims to contribute to the theoretical understanding of how digitalization can strengthen the analytical capacity of MFA and MSA and promote data-driven decision-making in circular urban planning. By bridging current methodological gaps, this study provides a conceptual foundation for integrating digital tools into future urban material analysis frameworks, paving the way toward more transparent, adaptive, sustainable, and circular cities

Keywords: Circular Economy · Urban Metabolism · Material Flow Analysis · Material Stock Analysis · City Information Modeling

1 Introduction

Cities are dynamic and complex entities that hold considerable potential to lead the transition toward climate neutrality, circular economy (CE), and sustainable development [1–3]. The CE approach offers substantial promise for addressing urban sustainability challenges by reducing waste, improving resource efficiency, and fostering economic,

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 789–796, 2026.
https://doi.org/10.1007/978-3-032-34930-9_92

environmental, and social benefits. Cities are central players in the CE transition, offering a platform for testing innovative solutions by minimizing waste, optimizing resource flows, and enabling transformative patterns of production and consumption [4, 5]. A circular economy treats nothing as waste, but rather as a potential resource, requiring a comprehensive understanding of urban systems and their resource flows [6]. This perspective is central to urban metabolism, understood as the process by which cities extract, retain, transform, and discharge resources, which provides an overview of resource use, waste generation, and environmental impacts [7]. By treating the city as a collection of systematic and interrelated processes, metabolic analysis enables the identification of resource utilization problems and supports effective sustainability measures [8]. As interest in circular cities grows, urban systems must be understood as an integrated whole, a perspective intrinsically linked to the concept of urban metabolism, which analyses the flows, stocks, and transformations of resources through cities. Understanding material flows and stocks is particularly important for "closing, slowing, and narrowing" material loops and improving urban resource management.

The built environment accounts for roughly 35–45% of global material use and around 25% of global waste generation [12, 13], making construction-related flows and stocks particularly critical to examine. Material Flow Analysis (MFA) is defined as "a systematic assessment of the state and changes of flows and stocks of materials within a system defined in space and time" [14]. Grounded in mass-balance principles, MFA quantifies inputs, outputs, and internal flows across multiple scales and time frames and is widely applied as a flexible decision-support tool [6]. Material Stock Analysis (MSA) complements MFA by identifying and quantifying materials that remain within the socio-economic system for extended periods, such as construction materials, with stocks conventionally defined as materials with a service life of at least one year [6]. Together, MFA and MSA support efforts to close, slow, and narrow material loops, advancing resource management and sustainable urban development.

Here, digital tools play a central role in accelerating the transition towards a circular and sustainable built environment. Technologies such as City Information Modeling (CIM) can promote CE and sustainable practices within cities [9, 10]. CIM integrates diverse data sources, technologies, and analytical tools, including Building Information Modeling (BIM) and Geographic Information Systems (GIS), into a unified, intelligent city model. This integrative approach leverages multi-source urban data for comprehensive collection, integration, processing, and analysis, including material urban analysis. In this regard, BIM models contribute to the building-level material data for detailed stock calculations, while GIS can be used for spatial analysis and mapping, providing georeferenced urban data. Together, these technologies promote a holistic view of material flows in urban environments. Despite growing interest in CIM's capabilities, the literature lacks studies linking CIM to the implementation of CE strategies in urban contexts, and very few explicitly connect CIM to MFA and MSA methods [11].

To address this gap, this paper presents a conceptual framework for applying CIM to urban material analysis. Guided by BIM–GIS synergies identified in the literature, the study provides a conceptual foundation for integrating digital tools into future MFA and MSA frameworks, paving the way toward more transparent, adaptive, sustainable, and circular cities.

2 Literature Review on Digital Tools for Urban Material Analysis: Current CIM Applications

GIS and BIM, two fundamental components of a CIM environment, are extensively documented in the literature. GIS has been widely applied in MFA and MSA studies [7, 15, 16], valued for its capacity to map spatial and temporal patterns, classify building typologies, and provide spatially referenced data for estimating material stocks and flows. BIM contributes through detailed material databases and its ability to manage complex information across the building life cycle [16, 17]. Despite their individual potential, combined synergies between GIS and BIM for material analysis have been less explored in the literature.

Notably, some studies have been integrating BIM and GIS for material analysis without referencing CIM. Parezanović et al. [16] assessed building material stocks by combining BIM models with GIS cadastral data, while Triantafyllidis et al. [17] used geo-referenced BIM models for MSA, observing that GIS linkage enhances spatial analysis capacity. In both cases, the technological foundations align closely with CIM principles. From the reviewed studies, only one explicitly applies the CIM concept, proposing a materiality-based city information model (mCIM) that integrates GIS and BIM datasets to develop a material cadastre map [13].

CIM remains in the early stages of conceptual and practical development. Although its potential is acknowledged in the literature, its application to CE, specifically for material analysis, in cities, remains largely unexplored. In contrast, the core technologies for CIM, namely GIS and BIM, are well established in CE, MFA, and MSA research. Many studies examine these tools separately, analyzing spatial patterns and modeling building characteristics, thus demonstrating their usefulness for estimating material stocks, for instance. When combined, their integration frequently mirrors CIM logic, even when the term is not employed, suggesting a terminological and conceptual gap attributed to the novelty and lack of a standardized definition for CIM. This reveals a clear research opportunity: to systematically apply CIM-based approaches to MFA and MSA, building on the BIM–GIS synergies already demonstrated in the literature. In this way, CIM can serve as an instrument for data-driven decision-making in circular urban governance, promoting a holistic, detailed view of material dynamics across the urban network.

3 Methodology

This study adopts a qualitative, framework-development research design, aimed at producing a conceptual contribution rather than empirical quantification. Grounded in the findings of a prior critical literature review [11], the methodology follows an inductive reasoning approach, moving from the identification of theoretical gaps and technological synergies in the literature toward the proposition of an integrated framework.

The critical literature review in the aforementioned prior work [11] examined the relationships among CIM, MFA, and MSA by addressing the research question: *"Is City Information Modeling currently defined and used in the context of Material Flow and Stock Analysis?"* The review was conducted across the Web of Science and Scopus

databases, which were selected for their breadth and quality of peer-reviewed literature. Retrieved records were screened to remove duplicates and papers unrelated to the research question. Limitations of that review include potential omission of studies from non-indexed repositories, terminological variability not fully captured by the search string, and a degree of subjectivity inherent to the screening process.

4 CIM-Based Framework for Urban Material Analysis

The proposed framework conceptualizes CIM as an integrative data infrastructure that can bridge urban-scale spatial analysis and material accounting methods. It is structured around three interconnected layers: a data input layer, aggregating georeferenced urban datasets from GIS platforms, BIM models, and open data repositories; a processing layer, where material quantities are calculated through MFA and MSA methods; and an output layer, translating analytical results into decision-support information for circular urban planning. The framework is designed around four core principles: interoperability between data formats and platforms; spatial and temporal scalability; transparency in data provenance and calculation logic; and alignment with circular economy objectives, particularly the closing, slowing, and narrowing of material loops. Figure 1 schematically illustrates the proposed framework, comprising three major layers: data input, processing, and decision support.

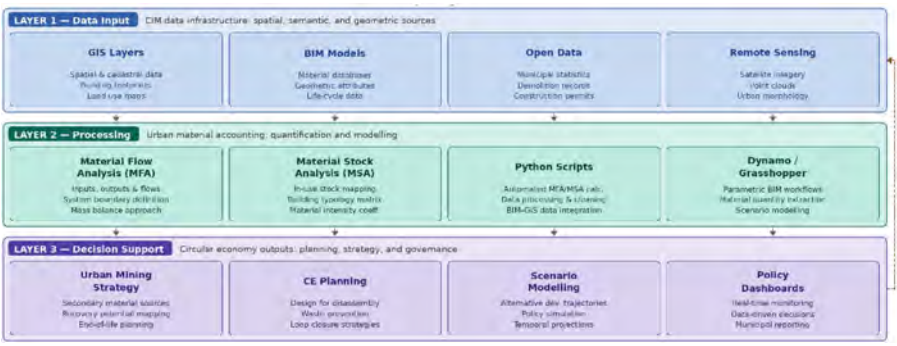

Fig. 1. Schematic diagram of the three-layer CIM-MFA/MSA framework: data input, processing, and decision-support output layers.

MFA requires a systematic quantification of material inputs, outputs, and internal flows within a spatially and temporally defined system boundary. CIM's capacity to integrate multi-scale, georeferenced urban datasets makes it a suitable infrastructure for populating these requirements. At the urban scale, GIS layers provide data on land use, building footprints, infrastructure networks, and administrative boundaries, enabling the outlining of system boundaries and the classification of material flow categories. At the building scale, BIM models contribute semantic and geometric attributes, including material specifications, quantities, and life-cycle data, that can be aggregated to calculate flows entering and leaving the urban system. Together, these CIM components allow for

a spatially explicit MFA that captures not only total material volumes but also their geographic distribution across urban districts or functional zones. Furthermore, CIM's temporal dimension enables tracking flow dynamics over time, supporting longitudinal analyses and monitoring policy interventions.

MSA focuses on identifying and quantifying materials retained within the built environment over extended periods. CIM supports this task by providing a comprehensive, spatially referenced inventory of the urban building stock, combining the geometric resolution of BIM with the territorial coverage of GIS. Building typologies derived from GIS-based cadastral data can be cross-referenced with material-intensity coefficients, typically sourced from BIM models or standardized databases, to estimate the total stock of construction materials embedded in the urban fabric. A key advantage of a CIM-based MSA is its dynamic updateability: as demolition permits, renovation records, and new construction data are incorporated, the stock model can be revised continuously, enabling near-real-time monitoring of material availability and waste generation potential. This dynamic capacity is essential for identifying urban mining opportunities and anticipating future secondary material flows.

The analytical outputs generated by the CIM–MFA/MSA framework can directly inform CE strategies at the urban scale. Material flow data can support waste prevention planning and the design of reverse logistics systems, while stock data can identify concentrations of recoverable materials suited to urban mining initiatives or design-for-disassembly policies. By georeferencing these outputs within the CIM environment, municipalities and urban planners gain access to spatially specific, evidence-based tools to prioritize circular interventions across different districts or building groups. Beyond static reporting, the framework opens the possibility for scenario modeling, simulating the material consequences of alternative urban development trajectories, and for near-real-time policy feedback through integrated dashboards. This positions CIM not merely as a data repository but as an active instrument for data-driven decision-making in circular urban governance, consistent with the broader digitalization agenda of the EU twin transition.

5 Discussion

The proposed framework advances the theoretical understanding of how digitalization can augment the analytical capacity of established urban metabolism methodologies. A persistent limitation of MFA and MSA has been their dependence on fragmented, manually compiled datasets, which constrain both the spatial resolution and the temporal dynamics of the resulting analyses. By conceptualizing CIM as an integrative data infrastructure that combines the territorial coverage of GIS with the semantic and material-level detail of BIM, the framework directly addresses this limitation. Rather than replacing MFA and MSA, CIM improves them from static, resource-intensive assessments to spatially explicit and dynamically updatable analytical tools. This repositioning is theoretically significant: it suggests that the methodological future of urban material analysis lies not in refining the accounting methods themselves, but in strengthening the data infrastructure that feeds them.

The framework can also help address the terminological and conceptual gap identified in the literature. As the review demonstrated, BIM–GIS integration already mirrors

CIM logic in several existing studies; however, the theoretical coherence that a CIM framework provides is absent. By formalizing this integration under the CIM concept and mapping it against MFA and MSA requirements, this paper provides a conceptual foundation that is currently lacking, and that future empirical work can build upon.

From a practical point of view, the framework offers guidance for municipalities, urban planners, and policymakers seeking to operationalize digital tools for circular urban management. The decision-support output layer, encompassing scenario modeling, urban mining strategies, and policy dashboards, translates analytical outputs into the spatially referenced, evidence-based information that urban governance increasingly demands. Crucially, the framework's design principles of interoperability, scalability, and transparency align with the broader European digitalization agenda, making it compatible with existing urban data platforms and municipal planning workflows. By enabling data-driven decision-making on material stocks and flows, the framework supports the shift from reactive waste management toward proactive circular urban planning.

Nevertheless, several limitations must be acknowledged. First, data availability and standardization remain significant barriers: while IFC and CityGML provide established exchange formats, interoperability between BIM and GIS platforms is still partial in practice, and the quality of available data varies considerably across urban contexts. Second, data accessibility, legalization, and lack of knowledge are the main constraints at the institutional level. Institutional capacity poses a challenge as many municipalities lack the technical expertise and infrastructure required to construct and maintain a CIM environment at the scale envisioned by this framework. Furthermore, data privacy and security can pose obstacles to CIM implementation and adoption, as they involve ethical, ownership, and regulatory issues. Third, and most importantly, the framework presented here is conceptual. Its propositions are grounded in the literature and informed by documented BIM–GIS synergies, but they have not yet been subjected to empirical validation. Claims regarding feasibility, accuracy, and scalability remain to be tested through practical implementation. Future research should prioritize case study applications that can cross-check the framework's assumptions against real urban datasets, refine its methodological components, and assess the practical conditions under which CIM-based material analysis can be meaningfully integrated into circular urban planning processes.

6 Conclusions

Building on a prior critical literature review, this study proposed a three-layer conceptual framework that positions CIM as an integrative data infrastructure for urban material analysis, structured into data input, processing, and decision-support output layers. Guided by the BIM–GIS synergies already demonstrated in the literature, the framework proposes an integration logic that existing studies implicitly adopt but have not yet theorized.

The framework aims to make two principal contributions. Theoretically, it provides a conceptual foundation for understanding how digitalization can strengthen the analytical capacity of MFA and MSA, transforming them from static, data-intensive exercises into spatially explicit and dynamically updatable tools for circular urban planning. Practically,

it offers a structured approach for municipalities and urban planners seeking to leverage digital tools for evidence-based resource management and circular economy decision-making, aligned with broader European digitalization and sustainability agendas.

As a conceptual contribution, the framework requires empirical validation before operational conclusions can be drawn. Future research should focus on implementing and testing the framework through case study applications, assessing its feasibility and accuracy against real urban datasets, and developing the data standards and interoperability protocols necessary for broader replication across diverse urban contexts. Ultimately, this study contributes to a growing body of work aimed at building more transparent, adaptive, and circular cities, in which digital tools and material intelligence work to support the transition toward sustainable urban futures.

Converting Cold Attics – A Scalable Strategy for More Sustainable Cities

Elia Archesso(✉)

Lund University, Lund 223 62, Sweden
el3645ar-s@student.lu.se

Abstract. Cold attics are a widespread feature of the Swedish residential building stock and are known for their structural vulnerabilities. In older buildings, these spaces often represent one of the most problematic envelope components, being associated with significant heat losses and moisture-related issues such as mould growth. These problems compromise the durability, energy performance and safety of the whole building. Among possible interventions, converting attics into habitable spaces offers a combined approach, delivering technical and environmental benefits at both building and city scale by reinforcing urban compactness and locating new housing where services already exist. This study examines the conversion of cold attics into residential units in three properties in Malmö, analysing architectural, energy and environmental implications. After the conversion, all buildings improved their energy class by at least one level. Daylight conditions were assessed using different design strategies to maximise the daylight potential provided by roof exposure. The environmental assessment focused on embodied impacts, comparing attic conversions with average values for new residential construction in Sweden. The converted attics show substantially lower embodied emissions per square metre, demonstrating that reusing existing structures is far more sustainable than building new housing. Finally, the study highlights effects beyond the scale of the single building: attic conversion avoids land consumption, makes use of existing infrastructure, increases housing supply in well-connected areas at low cost and supports urban densification strategies. The results show that this approach can be applied at large scale and contribute to more sustainable buildings, neighbourhoods and cities

Keywords: Cold attic · Sustainable cities · Building energy · Conversion · Daylighting

1 Introduction

1.1 Cold Attics

Cold attics are known to be prone to mould and moisture problems due to the low ventilation rate and the uncontrolled humidity levels of these spaces, which can lead to the downgrade and potential rotting of wood structural elements [1]. Cold attics can also have an important impact on the energy use of the whole building. For example, if

https://doi.org/10.1007/978-3-032-34930-9_93

the floor beneath them is not thermally insulated, cold attics can act as "heat sponges" that absorb all the heating energy that rises from the lower spaces, increasing the energy needed for apartments right under it [2].

1.2 Project Aim

Different solutions for tackling the moisture and energy problems mentioned above have already been explored, the most famous being insulating the attic space to lower the heat losses through the attic. This solution is effective for its purpose, as Hamid et al. [2] already assessed. However, a conversion of cold attics into apartments would not only improve the building's energy performance but also contribute to reducing the housing crisis without having the same impact on the environment as constructing a new building. Cold attic conversion would also help to preserve the green areas on the outskirts of cities and at the same time improve the efficiency of existing buildings as programmed by the "Renovation Wave" [3].

The aim of this research, therefore, is to study the conversion of cold attics into apartments for three different properties located in Malmö for a total of five multi-family apartment buildings. Each building is either part of a complex of similar buildings or representative of a common construction style used for other residential structures of that period. This choice helps to demonstrate the large-scale applicability of this solution for the rest of the city and potentially the rest of Sweden. For each renovated attic, the annual energy use and the environmental impact per square meter of gross area are the main results that will be presented. A comparison of the environmental impact will also be presented between the conversion of the five attics and the average impact of a new residential building in Sweden. Finally, the potential social and economic impact of these conversions is discussed.

2 Methods

2.1 Case Studies

The research focused on the central area of Malmö, chosen for two main reasons: the higher availability of suitable attics in older neighbourhoods (such as Rörsjöstaden, where buildings date back to 1870), and the proximity to the city centre, which guarantees better access to public transport, shops and social services for future residents. Three properties were selected, differing in construction period and typology, to demonstrate the applicability of the conversion strategy across a representative portion of the existing building stock. The proposed designs feature a total of 48 new apartments with an average size of 32.64 m^2.

Property A (Kungsgatan 24, 1902) features a double-sloped roof with a peak interior height of 4.0 m. The main intervention consisted of replacing the shallower courtyard-facing slope with a new insulated shed roof, preserving the street elevation character and yielding 10 new apartments. Daylighting is provided through skylights and new vertical windows on the courtyard wall.

Property B (Sofierogatan, 1943) comprises three Functionalist buildings (B1, B2, B3) sharing the same structural design. All three attics offer a peak height of 3.95 m,

allowing conversion without modifying the main roof structure. Terraces are created on the west-facing side, while skylights serve the east-facing zones, yielding a total of 36 new apartments across the three buildings.

Property C (Torekovsgatan 2, 1946) is the most constrained case, with a peak height of 3.15 m. The renovation includes extending existing façade insulation to all uninsulated walls and relies exclusively on skylights for daylighting, yielding 6 new apartments. A summary of the key characteristics of each case study is provided in Table 1.

Table 1. Summary of case study characteristics.

Property	Year	Style	Attic peak height [m]	New apartments	Apt. size range [m^2]	Daylight strategy
A	1902	Jugend	4.0	10	32–35	Skylights + vertical windows
B1	1943	Functionalism	3.95	12	29–35	Skylights + terraces
B2	1943	Functionalism	3.95	12	28–35	Skylights + terraces
B3	1943	Functionalism	3.95	12	27–35	Skylights + terraces
C	1946	Låga lamellhus	3.15	6	33–35	Skylights only

All glazing elements share the same thermal and optical properties across the three properties: skylights use a high-performance unit ($U_w = 0.92$ W/m^2K, $g = 47\%$), vertical windows a triple krypton unit ($U_w = 0.90$ W/m^2K, $g = 22\%$), and all glazing is equipped with automated interior fabric shading activated when direct solar radiation exceeds 250 W/m^2.

2.2 Buildings Analysis

Energy simulations were performed with ClimateStudio following Boverket regulation [3]. Each building was first simulated in its current state to establish a base energy use, validated against energy declarations and steady-state calculations. Where detailed construction information was unavailable, assemblies were assumed according to Björk et al. [4] based on building type and period. Ventilation flow was set per SS-EN 16798-1:2019 [5], with an envelope infiltration rate of 0.03 $m^3/(s{\cdot}m^2)$ for the renovated scenario versus 0.10 $m^3/(s{\cdot}m^2)$ for the base case, and mechanical ventilation at 35 l/s per apartment. Internal gains, heating setpoint and occupancy were set according to Boverket guidelines.

The main envelope improvement in all cases was roof insulation: 235 mm of glass wool with a new vapour barrier and gypsum board finish, resulting in a roof U-value

of 0.12 W/m^{2}K. The Primary Energy Number (EPpet) — the indicator used to assign energy classes in Sweden — was calculated for both the base case and the renovated scenario using the inputs in Table 2. For Property A, where heating is supplied by a mix of district heating and a ground source heat pump, the full demand was conservatively attributed to district heating for simulation purposes, while correct values were used for DHW COP and weighting factor. U-values for all new envelope elements are summarised in Table 3.

Table 2. Input used for the EP_{pet} calculation based on the heating system used.

Heating system	Heating COP [−]	F_{geo} [−]	Airing losses [kWh/m^2]	DHW circulation losses [kWh/m^2]	VF [−]	DHW COP [−]
District heating	1.0	0.8	4.0	5.0	0.7	1.0
GSHP	1.0	0.8	4.0	5.0	1.8	2.5

Table 3. U-values in W/m^{2}K for the renovated scenario for the renovate attic of the three case studies.

Element	Property A	Property B	Property C
Existing exterior wall	1.88	2.10	0.34
Roof	0.12	0.12	0.12
Partition wall – apartment divisor	0.15	0.15	0.15
Partition wall – room divisor	0.44	0.44	0.44
Slab	0.93	0.93	0.93
Ground slab	3.20	3.20	3.20
Ground wall	3.39	3.39	3.39
Skylight	0.50	0.50	0.50
New added window	0.57	0.57	–
New exterior wall	0.15	0.15	–

Thermal comfort was assessed by counting the annual hours with operative temperature above 26 °C, with a limit of 80 h following BELOK guidelines [7] — the most restrictive among the Swedish and Danish references consulted [6]. Comfort was achieved through passive measures only: automated shading and natural ventilation, without mechanical cooling.

Three daylighting metrics were simulated for each dwelling: Daylight Factor (DF, minimum 1% per BBR [8]), Useful Daylight Illuminance (UDI, 100–2000 lux range,

8:00–18:00 schedule [9]), and Spatial Daylight Autonomy (sDA300/50%, threshold 55% of area per LEED [10]). The shading activation schedule from the thermal comfort simulation was applied consistently across all daylighting calculations.

Environmental impacts were calculated using Boverket's climate database [11], covering stages A1–A5.1 (Global Warming Potential). The GWP per m^2 was determined for each new envelope element and summed across all case studies. Results were compared to the mean embodied impact of new Swedish apartment construction (310 $kgCO2e/m^2$ BTA) from Malmqvist et al. [12]. As Boverket's database applies a conservative 25% factor to all material impacts, using product-specific EPDs could further reduce the calculated values.

To simplify the study complexity, the same construction sets were applied across all three cases for the new elements, except for the façade. The façade of Property C was made uniform by extending the existing mineral wool insulation to the remaining uninsulated walls. For Properties A and B, the original exterior walls were retained, and a new insulated wood stud wall was added only where structurally required: as the supporting structure for the new roof slope in Property A, and as the enclosure for the new terraces in Property B. Where terraces were constructed, an additional XPS insulation layer was placed on top of the existing slab to ensure thermal insulation and waterproofing for the apartments below. The U-values of all new envelope elements are summarized in Table 3. As the focus of the study was the effect on the energy performance of the overall building, the structural integrity of the proposed interventions was not analyzed in detail and would require additional verification.

3 Results

The attic renovation brought similar changes on the heating demand of all the three case studies. The overall heating demand of each building increased by a maximum of 3% after the different attic renovations. At the same time, the heating energy use intensity (heating energy use per square metre of floor area) of all the buildings decreased between 16% and 18%. Thanks to the additional insulation, property C had a reduction of 51% for the heating demand of the whole building and of 63% for the heating energy use intensity. The Primary Energy Number (EP_{pet}), of each property also saw important improvements. Each building after the attic renovation saw a promotion to a higher energy class. As for the heating demand, property C had a more substantial improvement from class E to class C (Table 4).

The thermal comfort of each apartment was verified in all the new apartments considering the shading system and natural ventilation, keeping the number of hours with an operative temperature over 26 °C under the set limit of 80 h.

The daylight performances of the renovated apartments show the high effectiveness of skylights in daylighting applications to reduce the energy demand for electric lighting. All the renovated attics of the three properties have a mean DF well above the required 1%. The renovated attics perform great also in terms of daylighting where between the three cases the lowest percentage of time with a useful illuminance is 53.10%. Although this result can be partially assumed from the UDI performance, the $sDA_{300/50\%}$ of each new attic is particularly excellent with more than three quarters of the attic's area meeting the 300-lux requirement for at least 50% of the time.

Table 4. Primary energy number and energy class change after the attic renovation.

Case study	Energy Class		EP_{pet} [kWh/m^2/yr]	
	Before	After	Before	After
Property A	F	E	139	125
Property B1	F	E	138	123
Property B2	F	E	140	126
Property B3	F	E	148	132
Property C	E	C	116	65

The last results presented are the environmental impacts of the newly renovated attics. Figure 1 shows the effectiveness of cold attic renovations, comparing impacts of such renovations with the average impact of a new apartment building.

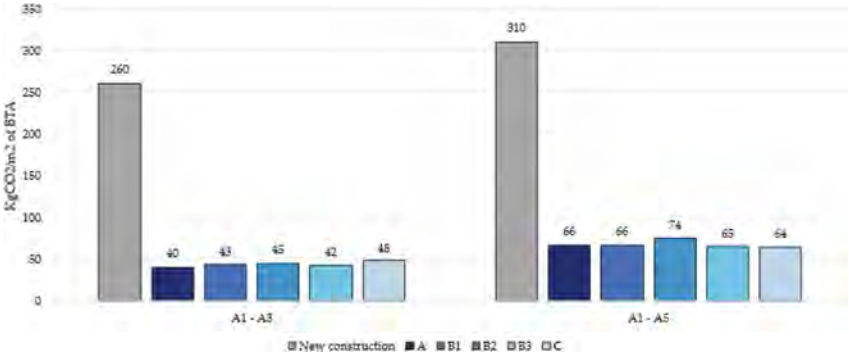

Fig. 1. Environmental impact comparison between a new construction and the different renovated attics per m^2 of BTA.

4 Discussion

Looking at the presented results, a first reflection on the energy performances of the chosen buildings before and after the renovation can be made. The renovation of cold attics solves one of the problems mentioned in the introduction, which is the heat loss through these spaces. If we look at the variation in heat demands across all buildings, it becomes clear that renovating attics can help decrease the heat demands of the original buildings. Even though the reduction is not significant, the savings on the heating energy are almost equal to the heating demand of the new spaces.

Another more intuitive way of understanding the impact of the renovations is looking at energy class improvements, which was the desired result but not taken for granted before the calculations. In this study, all the buildings, which before the renovations were all starting from class F, already fulfilled the energy class requirements [13] for 2033 eight years in advance thanks to the attic renovations. In particular, the conversion of property C is also an example that demonstrate how pairing this renovation with an energy efficiency improvement can help on achieving a zero-emission building stock by 2050.

The reasons on why attics should be converted into apartments are not only backed by the consequent energy improvements, but also by the impressive low environmental impact when compared to the construction of a new building. The results presented clearly show that renovating attics is a valid strategy to reduce the emissions caused of the residential building sector when compared to the environmental impact of new constructions. The choice of the materials used is also a crucial factor in the estimation of the environmental impact of the conversion. As specified previously, the impact calculated in this study used generic data provided by Boverket database which always includes a supplemental conservative factor of 25% on the impact of each material. Using product-specific EPDs could reduce noticeably the impact of the conversions studied by opting for less environmentally impactful products such as bio-based insulation materials or glazing made from recycled materials.

Another important benefit of converting cold attics is also the social life quality of the new apartments. While it is true that the urban expansions bring positive changes in the cities for example creating new infrastructures (such as the new Tram line built in Lund as part of the city's expansion project of Brunnshög), it is also true that new residential constructions would then be placed far from the city center, becoming an issue for the new residents. Previous studies already demonstrated this issue, showing how the uncontrolled and unplanned urban sprawl relates to the raise of social inequalities in terms of access to employment opportunities, public services and urban amenities [14]. As the opposition to this expansionist trend, attic conversion would contribute at achieving the "15-min city" concept that aims creating self-sufficient neighborhoods.

Automated Detection and Quantification of Building Transformations in the UK

Rebanth Kanner(✉), Danielle Densley Tingley, Martin Mayfield-Tulip, and Ahsan Khan

The University of Sheffield, Sheffield S10 2TN, UK
rkanner1@sheffield.ac.uk

Abstract. Urban areas evolve through continual construction, extension, and demolition, but most monitoring approaches still deliver limited or infrequent information. Although deep-learning techniques have advanced building-change detection, they tend to focus on identifying change rather than measuring its magnitude. In contrast to countries with centralised building registers, the United Kingdom lacks a unified, open-access source of development data, leaving only fragmented local datasets. Consequently, high resolution aerial imagery offers the most consistent and scalable basis for capturing temporal changes nationwide. This study addresses these gaps by creating an automated and scalable pipeline that enables the detection and quantification of building transformations. These transformations include estimates of footprint area change to assess (re)development intensity. The process uses high resolution time-series aerial photographs from EDINA Digimap, which offers consistent, orthorectified imagery across the UK at spatial resolutions up to 12.5 cm. The study makes use of the existing HD-Net architecture, which employs feature decoupling and multi-scale deep supervision to produce precise, high-resolution footprint masks. Once the binary footprint masks are generated, they are analyzed for temporal differences, enabling the identification and quantification of new construction and demolition events. Results highlight the change in building stock in Sheffield between 2012 to 2021 identifying and quantifying building transformation events in terms of change in footprint area. This enables forecasting of secondary resource flows for reuse and more efficient lifecycle response. Information regarding extension and new construction could also help estimate material demand, and the difference between them can help decide future circularity strategies

Keywords: Buildings · Change detection · Deep learning · Circularity

1 Introduction

Urban areas are dynamic systems shaped by continuous cycles of construction, expansion, and demolition. Understanding how the built environment evolves over time is essential for urban planning, infrastructure provision, sustainability assessment, and resource management. However, systematic monitoring of building stock change remains challenging. Conventional approaches rely on cadastral updates, surveys, or

https://doi.org/10.1007/978-3-032-34930-9_94

administrative records that are often incomplete, inconsistent, or infrequently updated [1]. In many countries, the absence of a unified, open-access national building register further limits the ability to track development patterns at scale, leaving researchers and policy-makers dependent on fragmented local datasets.

Advances in remote sensing and deep learning have created new opportunities for automated urban monitoring. High-resolution aerial imagery, collected regularly and consistently across large areas, provides a reliable foundation for detecting physical changes in the built environment. Recent deep-learning models [2–4] have demonstrated strong performance in building extraction and change detection tasks, yet most studies focus on identifying whether change has occurred rather than quantifying its magnitude. Knowledge of this information in turn supports the prediction of secondary material flows for reuse and more effective lifecycle planning. Building change detection can directly support urban mining and material flow planning by identifying where demolition and new construction are occurring, enabling estimation of secondary material availability and primary material demand. It can also inform adaptive reuse and circular construction strategies by distinguishing between redevelopment, extension, and expansion patterns, helping policymakers prioritize refurbishment over replacement and reduce waste generation.

2 State of the Art

Remote sensing based urban monitoring has increasingly shifted from traditional rule based image analysis to deep learning methods capable of automatically learning complex patterns from high resolution imagery [2]. Early approaches based on manually crafted features struggled to generalize across varying urban forms and imaging conditions, while convolutional neural networks (CNNs) enabled substantial improvements in building footprint extraction. More recent work explores models that better capture spatial complexity, such as LDFormer [3], a hybrid CNN–Transformer framework that integrates local features with global attention to improve segmentation accuracy in complex urban scenes.

Another major research direction addresses the influence of image resolution and scale on extraction performance. The Super-Resolution Fusion [4] approach combines the Enhanced Deep Residual Networks for Single Image Super-Resolution [5] with the HyperSeg [6] segmentation model to enhance spatial detail before classification, improving the detection of small or densely packed buildings. Similarly, Multiresolution

Analysis Transfer Learning [7] applies wavelet decomposition to train models sequentially from low to high resolution representations, enabling the learning of scale invariant features while reducing training time. In parallel, research has considered computational efficiency for large-area monitoring. The Edge-Aware YOLO-v8 [8] framework adapts a real-time instance segmentation model by incorporating multi-scale feature pyramids, a Triple Feature Encoder, and explicit boundary extraction using a Prewitt operator, achieving faster inference while reducing noise and jagged building outlines. Collectively, these studies illustrate a broader movement toward specialized deep learning pipelines that balance accuracy, scalability, and operational feasibility for urban analysis.

Within this progression, HD-Net [9] (High-Resolution Decoupled Network) represents a targeted advancement focused specifically on precise boundary delineation, a critical requirement for measuring the change in the footprint of the building. Built on the HRNet [10] backbone, HD-Net introduces a Feature Decoupling–Recoupling module that separates building body features from boundary features before recombining them to produce sharp, high-resolution masks. This design directly addresses the blurred edges commonly produced by conventional CNN segmentation models and achieves state-of-the-art performance with relatively low parameter complexity. Because quantifying urban development requires consistent and geometrically precise footprints across time to reliably estimate changes in area, HD-Net is particularly well suited to multi-temporal analysis of construction, extension, and demolition. Its emphasis on boundary accuracy and computational efficiency therefore makes it an appropriate methodological foundation for detecting and quantifying building transformations from high-resolution aerial imagery in the present study.

3 Study Area

The study area is the city of Sheffield, United Kingdom, which serves as a representative urban case study for analysing building transformation processes. The objective is to quantify changes in building footprint area between 2012 and 2021, distinguishing between new construction and demolition.

The analysis uses high-resolution time-series aerial imagery from EDINA Digimap, providing consistent, orthorectified coverage at spatial resolutions of 25 cm. These data enable the extraction of detailed building footprint masks across multiple time points. Ordnance Survey National Geographic Database (OS NGD) building data are used as ground truth to verify detected footprint changes, providing authoritative spatial information on building extents and attributes for independent validation of the magnitude and type of observed transformations.

It should be noted that some of the aerial images, particularly the older set, exhibit imperfect orthorectification, particularly around tall buildings, which can introduce geometric distortions and lead to errors in measured footprints. The long temporal gap between image acquisitions (nine years) may also result in slight misalignment between datasets, affecting change detection accuracy. In addition, imagery captured at different times uses varying sensors and lighting conditions, producing differences in exposure, hue, and saturation that can influence model performance and footprint extraction consistency. However, steps have been taken to reduce the effects of these discrepancies in the imagery

Although OS NGD data provide an authoritative reference, they may include temporal update delays and representation differences compared to image-derived footprints. Where discrepancies were identified, the footprints were manually corrected or redrawn to ensure closer alignment with the observed building extents at each time point. These combined factors introduce uncertainty that must be considered when interpreting measured building transformations.

4 Methodology

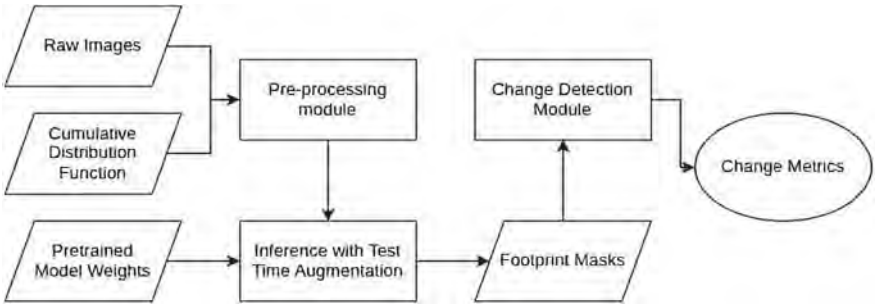

Fig. 1: General Methodology

Figure 1 shows the general workflow of the proposed pipeline. The images are first normalized to an optimized cumulative distribution function(CDF) by matching their intensity distributions. This is to adjust differences in hues and saturations, which can otherwise degrade footprint inference. The normalized images are then input to the HD-Net model [9], where inference is performed using additional test-time augmentation (TTA), and the results are aggregated to further increase robustness. The outputted masks then pass through a rule-based change detection module, which polygonises the footprints and matches paired polygons using overlap, area, and centroid proximity. Identified matches are ignored and the construction and demolition metrics(footprint areas) are calculated from the remaining polygons.

For evaluation purposes, a dataset of 80 tile pairs was compiled across four cities, each pair separated by at least a nine-year interval. Each tile consists of a 1 km^2 raw aerial image and a corresponding 1 km^2 ground-truth building footprint derived from historic OS NGD building data. This dataset was used for hyperparameter analysis to determine the optimal CDF reference and parameter settings for the footprint extraction and change detection modules.

5 Results and Analysis

5.1 Footprint Extraction

The results of footprint extraction on the evaluation dataset are presented in Table 1. Precision measures the correctness of positive predictions (i.e., when a pixel is predicted as a building, whether it is actually a building), while recall measures the proportion of actual building pixels that are successfully detected. The F1 score provides a combined metric that balances precision and recall while accuracy reflects overall classification performance, taking into account both building and non-building pixels.

Overall, the results, visualised in Fig. 2, indicate strong and consistent performance throughout the test set, as reflected by high F1 and precision scores. However, factors such as imperfect orthorectification, spatial misalignment between the images and OS footprints, along with other inaccuracies in the OS footprints, may have introduced

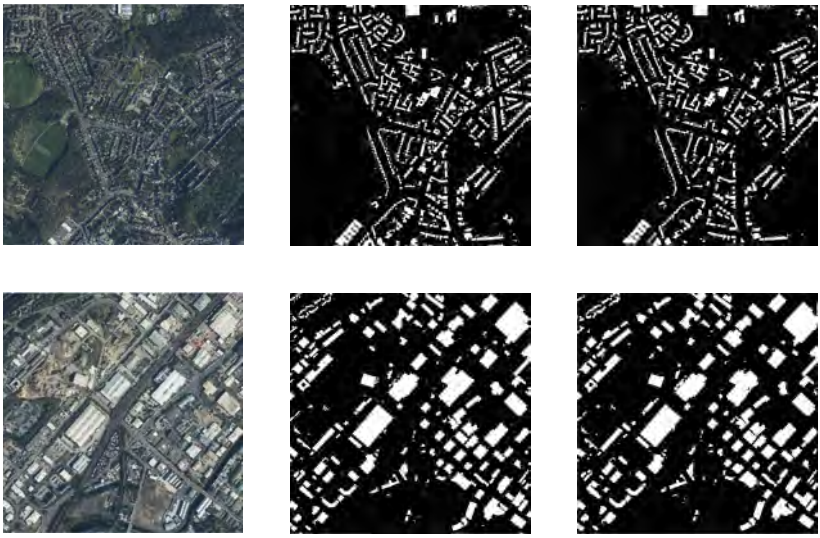

Fig. 2: Comparison of example raw images, ground truth masks, and predicted masks for two sample tiles.

errors affecting performance. Even so, qualitative inspection suggests that applying the identified corrections to the ground truth data of the evaluation dataset would likely lead to further improvements in the reported results.

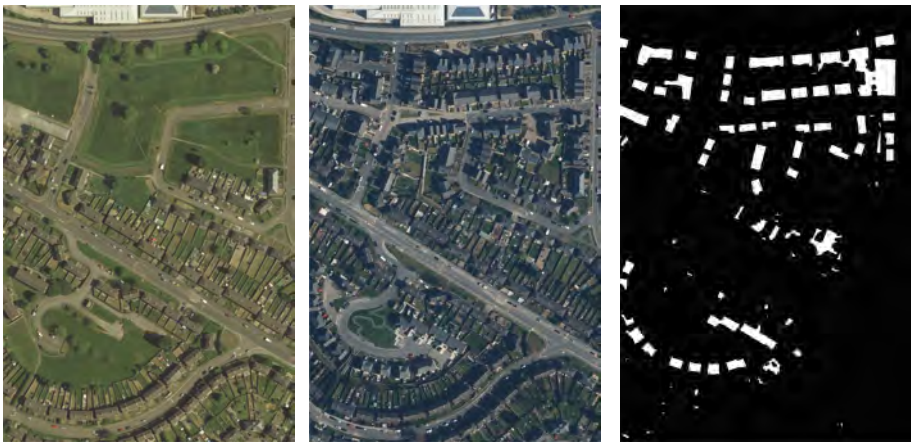

Table 1: Per-city test metrics.

Dataset	F1	Precision	Recall	Accuracy
Birmingham 2013	85.79%	83.41%	88.30%	92.79%
Birmingham 2022	88.75%	88.90%	88.61%	94.54%
Bristol 2014	87.15%	83.82%	90.77%	93.10%
Bristol 2023	88.03%	85.35%	90.89%	93.54%
Manchester 2009	84.54%	85.56%	83.55%	93.37%
Manchester 2023	87.50%	90.68%	84.54%	94.33%
Sheffield 2012	85.36%	83.79%	86.98%	94.35%
Sheffield 2021	88.31%	88.86%	87.76%	95.42%

5.2 Change Detection

Performance varied substantially between cities, with the lowest overall error observed in Sheffield, followed by Manchester, while Birmingham showed notably higher error. Construction estimates were highly accurate in Sheffield and Manchester, indicating

strong detection of new development, while Birmingham exhibited large overestimation in both demolition and construction, leading to poorer net change estimates. From additional manual inspection it appears the change detection module performs particularly well when identifying greenfield construction, as can be seen in Fig. 3, but requires further improvement in other scenarios particularly in demolitions and in dense urban environments. This error is likely partly due to inter-year image misalignment and radiometric differences, which introduce footprint inconsistencies into the rule-based change detection.

(a) Sheffield 2012 **(b)** Sheffield 2021 **(c)** Identified New Construction

Fig. 3: New construction identified by the change module.

Table 2: Change detection errors for selected city pairs (area in m^2).

City Pair	Demo Error (m^2)	Cons Error (m^2)	Net Error (m^2)
Birmingham	+29,900 (+51.6%)	+27,662 (+60.6%)	−2,238 (−18.2%)
Sheffield	+11,319 (+40.2%)	−42 (−0.1%)	−11,360 (−32.9%)
Manchester	+11,749 (+16.2%)	−4,039 (−3.7%)	−15,789 (−41.5%)

5.3 Sheffield Study

Across the Sheffield study area, a total of 402 paired tiles were analysed to quantify building transformation between 2012 and 2021. Using a pixel area conversion of 0.0625 m^2(since each pixel is 0.25 m × 0.25 m), the change detection module identified approximately 1.30 million m^2 of demolition and 2.84 million m^2 of new construction. This corresponds to a net increase of about 1.54 million m^2 in building footprint area over the study period, indicating substantial expansion of the built environment. These

totals however should be interpreted alongside the Sheffield error estimates in Table 2. The near-zero construction error reported for Sheffield suggests that the estimated construction area (2.84 million m^2) is broadly consistent with the reference data at city scale, whereas the positive demolition error indicates that demolition is likely being overestimated. This implies that the true net increase in footprint area between 2012 and 2021 is likely larger than the reported 1.54 million m^2, since an inflated demolition estimate reduces the net change (construction minus demolition). Even with this uncertainty, the results indicate substantial growth in Sheffield's built footprint over the study period, with change dominated by new construction rather than demolition-led redevelopment.

6 Conclusions and Further Work

This study developed an automated pipeline combining a module for radiometric normalization using histogram matching, the HD-Net architecture for high-precision footprint extraction, and test-time augmentation (TTA) to improve inference robustness. The footprint extraction component performed reliably across the test dataset, demonstrating the effectiveness of the integrated pipeline for producing consistent building masks from multi-temporal aerial imagery.

In contrast, the change detection module exhibited lower reliability, particularly in dense urban environments and demolition scenarios. The current approach relies solely on binary footprint masks, which limits its ability to distinguish complex transformations such as partial demolition and building extensions. Future work will therefore focus on integrating RGB imagery alongside footprint masks to improve robustness and accuracy, also enabling the identification of more nuanced changes beyond complete construction and demolition events.

Once change detection performance has been improved, linking detected transformations with OS NGD attributes offers significant potential to enrich the analysis. This integration could support the transition from footprint-based change measurement toward estimation of building material stocks and flows, enabling more detailed assessments of resource demand, reuse potential, and circular economy strategies within the built environment.

Transition Toward Circular Infrastructure Management in Tourism Enterprises: A Latvian Case Study

Sarmite Rozentale(✉), Dace Dance, and Mara Grinberga Silaua

Vidzeme University of Applied Sciences, Valmiera, Latvia
sarmite.rozentale@va.lv

Abstract. Effective infrastructure management plays a crucial role in implementing circular economy (CE) strategies, promoting resource efficiency, reducing waste, and ensuring business viability. This creates a challenge in exploring opportunities for convergence between the environmental and economic dimensions in small tourism businesses. To this end, the Latvian Council of Science funded a study by Vidzeme University of Applied Sciences and the School of Business and Finance of the University of Latvia. Using a Participatory Action Research (PAR) approach, ten small tourism-related enterprises participated in the study, focusing on joint research, action, and understanding to create knowledge together with them and for their benefit. The study involved in-depth interviews, focus group discussions, and financial data analysis. Adopting CE principles in infrastructure management enables tourism enterprises to reduce costs, increase resource efficiency, and minimize waste, which is economically beneficial given the rising cost of resources. It includes designing and constructing infrastructure, adapting outdated infrastructure to new needs, and using water- and energy-saving equipment and technologies for wastewater treatment. Despite the potential benefits, there are also challenges and limitations to transitioning to circular infrastructure management. The initial costs of implementing a CE can be a barrier for many small tourism enterprises. Such an approach includes investments in new infrastructure and technology. Another limiting factor is the low level of awareness and understanding of the principles of the CE. To overcome these obstacles, greater awareness, supportive regulations, and cooperation among all stakeholders are needed

Keywords: Circular Economy · Infrastructure Management · Small Tourism Enterprises

1 Introduction

The circular economy (CE) has become a significant area of research in the tourism industry, given its increasing importance in policymaking, particularly in the European context. Several authors point out that the introduction of CE principles can streamline business processes, reduce costs and resource consumption, and mitigate negative environmental impacts [1, 2]. Furthermore, the integration of such principles promotes the efficiency and sustainability of the sector [3].

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 813–822, 2026.
https://doi.org/10.1007/978-3-032-34930-9_95

Studies indicate that large companies generally possess the necessary resources, skills, and knowledge to implement CE principles [4]. The pursuit of competitive advantage in global markets has long been a key driver of sustainable and responsible business management. However, small and medium-sized enterprises (SMEs) often face difficulties in consistently implementing the transition to a CE, as they often lack the resources, knowledge, and strategic approach to integrate sustainability into their business practices from a circular perspective. Companies must balance profitability with political and environmental considerations. However, the transition to a CE requires significant financial resources and knowledge, both of which are often limited, especially for SMEs [5].

The study used a participatory action research (PAR) approach, involving ten small tourism businesses. This approach is based on joint research, practical action, and awareness-raising, generating knowledge in collaboration with companies and for their direct benefit.

The research area was, firstly, Gauja National Park, which is the largest and oldest specially protected nature area in Latvia and one of the country's most important tourist destinations; secondly, Valmiera, which is an important administrative, economic, and cultural center of the Vidzeme region; and thirdly, Riga, as the capital of Latvia, which is the country's largest tourist destination. This choice provides a broader context for the analysis of the activities of tourism enterprises, which share common operational challenges - inefficient infrastructure and pronounced seasonality of demand.

This article analyzes the transition to a circular business model in small-sized Latvian tourism companies and organizations, with a particular focus on infrastructure management as a key factor in increasing resource efficiency, reducing waste, and ensuring business sustainability.

2 Theoretical Framework

This section presents the theoretical framework of the analytical perspective used to investigate the infrastructure management of Latvian small-sized tourism enterprises in the context of a CE.

Based on the study's methodological approach, we used the concepts of circular infrastructure management and the circular business model framework as complementary research lenses to examine the current situation of small tourism businesses in Latvia and their potential to transition to more circular management. The theories used in the study were selected for their ability to explain circular-economy-based infrastructure management at the company level.

Recent literature shows a shift from "traditional" infrastructure or facility/asset management toward a lifecycle, data, and flow-based approach, in which infrastructure is viewed not as a linearly consumed resource, but as a set of materials, information, and value that can be managed over the long term [6].

Traditional corporate infrastructure management focuses on facility management, procurement, service specifications, and process structuring [7].

Recent literature has increasingly adopted a CE approach, which shifts the focus of infrastructure management from operations to circular life-cycle management [8, 9].

Digital tools such as Building Information Modelling (BIM), Historic Building Information Modelling (HBIM), Digital Twins (DT), and data platforms enable information to be used in the design, construction, operation, renovation, and demolition of buildings [10].

Another key area is information and knowledge management, emphasizing that digitalization improves the management of information and knowledge, standardizes data structures, and promotes data traceability, storage, usability, and reuse. Infrastructure management is the planning, operation, maintenance, and improvement of infrastructure so that it operates efficiently, safely, and sustainably throughout its life cycle [11, 12].

The implementation of the circularity principle is not possible without appropriate policies, a regulatory framework, and a system of standardization [13].

Although the topic of circularity has developed rapidly, there are also some gaps. First, many studies are conceptual or at the framework level, but there are relatively few empirical studies on how companies integrate circularity into infrastructure management in practice [14]. Second, while there are many indicators and methodologies, there is no single dominant approach that is standardized and easily comparable across companies [15]. Third, the perspective on buildings and construction is well developed, but models for managing internal infrastructure within companies across sectors are less developed [16]. Companies face organizational, financial, and institutional barriers to implementing the CE.

The main principles of circularity applicable to infrastructure are resource efficiency – minimizing resource consumption, for example, energy-efficient buildings, smart heating and lighting systems, and effective water management [17].

3 Methods

To increase the commitment of small tourism businesses to implementing CE practices in infrastructure management, we conducted an action research project in collaboration with 10 Latvian companies in the tourism sector located in areas representing various tourism contexts – protected natural areas, regional tourism centers, and the metropolitan environment. This approach is characteristic of case study methodology, which enables analysis of complex economic phenomena, including the implementation of the CE, across various contexts and situations [18].

According to the Eurostat glossary, tourism encompasses a wide range of sectors in accordance with the European Community's statistical classification of economic activities (NACE Rev. 2) [19]. The organizations involved in the study represented various industry segments, including manor and country estate hotels, event organizers, a state museum reserve, the sports base of the Latvian National Sports Center, the National Zoo, beverage producers that combine production with tourism, and a regional public transport service provider. The study also included regional non-governmental organization's involved in nature conservation and environmental education.

The participatory research process consists of three stages (Fig. 3). The first stage is preparatory, involving the selection of companies through the analysis of publicly available information, such as their websites, social media, annual reports, and industry

policy planning documents. An initial interview is conducted to assess the company's suitability for the study and willingness to participate in action research. This process prepares the company to discuss CE issues and their application in infrastructure management with the researchers. If a participation agreement is reached and the outcome is positive, a contract is signed.

The second stage involves collecting data through in-depth, face-to-face interviews with senior management to gain direct insight into the company's infrastructure and assess its knowledge and experience of the CE. It is followed by defining the data in accordance with the literature, considering the specific sector and nature of the business. The company submits qualitative and quantitative data, including a self-assessment of how CE principles are applied in infrastructure management. This self-assessment includes a CE log documenting specific daily examples in accordance with the 9R framework, adapted from Potting [20].

The third stage involves analysis and implementation. This stage includes evaluating, validating, and cleaning data, as well as assessing the company's current experience with the CE and its potential to transition to a circular-economy approach to infrastructure management. The company's annual report's financial data was also taken into account. Following the procedure, researchers and business representatives collaborate in a joint workshop to identify issues and create solutions.

Fig. 3. Research Design

Finally, a plan is developed to transition to a more circular management style. For eight months, researchers and companies worked together on the action research project.

4 Results

The company's core business areas summarize the analysis results. Overall, fixed asset management takes a practical approach to resource conservation, guided by economic logic and experience in daily operations. However, adopting a more systemic approach to the CE requires structured data management, investment planning, and infrastructure optimization. An assessment of the current situation reveals positive practices, such as prioritizing durable equipment, repairing equipment instead of replacing it immediately, leasing or sharing some equipment, and evaluating investments based on return on investment. These practices align with CE principles, such as extending product lifecycles, optimizing resource consumption, and divesting from unnecessary fixed assets.

However, most companies lack a fixed-asset lifecycle management system and do not analyze equipment repair costs, equipment-specific energy consumption, or equipment service life. It means that infrastructure is managed reactively rather than strategically. This situation is particularly characteristic of the management of historic buildings, where technical information is fragmented or not collected. In this context, the implementation of HBIM and DT solutions would provide an opportunity to transition to data-driven and proactive infrastructure management. In the area of energy management, companies are already using several energy-efficiency solutions, such as energy-efficient light bulbs, motion sensors, ventilation timers, thermostats, and automatic heating controls, as well as selecting energy-efficient equipment. Some companies also track energy consumption for individual buildings and equipment, have conducted energy audits, and have installed more modern heating or ventilation systems, such as heat pumps or heat-recovery ventilation systems, which significantly reduce energy consumption. However, in most cases, no energy management system has been established. Table 4 presents the study's results, highlighting the study's areas and their strengths and weaknesses.

Table 4. The participatory research results

Area	Key Strengths	Most Common Weaknesses
Fixed Asset Management	Regular maintenance and repairs, in-house servicing in certain cases, reusing car and equipment parts, renting or sharing equipment, leasing unused space and land, and investing in more energy and water-efficient and environmentally friendly solutions.	A systematic life-cycle analysis of fixed assets is not carried out everywhere. This results in a lack of data on repair costs, service life and optimal replacement times. This limits the ability to assess long-term impacts.
Waste Management	Systematic sorting; sending cardboard, glass, metal, equipment, and parts for recycling; storage of reusable parts; regular waste reports and audits at some companies.	Not all companies have a detailed waste stream analysis; the recycling rate and the total amount of waste generated are not always measured.

(*continued*)

Table 4. (*continued*)

Area	Key Strengths	Most Common Weaknesses
Energy Monitoring and use of Renewable Energy	LED lighting; optimization of heating and ventilation; selection of energy-efficient equipment; consumption monitoring; ISO 50001 or an equivalent energy management approach in some companies; separate metering by building.	The use of renewable energy sources is generally low; not all locations have comprehensive energy data analysis or clear KPIs; not all facilities have modernized infrastructure.
Water Monitoring	Water consumption monitoring at some companies, on-site treatment facilities, wastewater management, and, in certain cases, water metering.	The approach to water circulation is inadequate; there is no technical water reuse, rainwater is rarely used, and comprehensive consumption analysis is not always available.

5 Discussion

Although sustainability has been considered a key factor for long-term growth in infrastructure management for several decades, there is still a significant methodological and empirical problem: it is not sufficiently clear how the principles of sustainable infrastructure management are actually transferred from the research sector to small tourism businesses and what resources and processes are required for this.

Our research, based on the literature on the CE of tourism sources in management processes of the built environment, developed a methodology and took action to support small tourism enterprises transitioning to a CE in infrastructure management. As a result of the study, we developed a roadmap for the transition to better implementation of circular principles in small tourism enterprises (see Table 5).

Table 5. A roadmap for transitioning to more circular infrastructure management.

Main objectives	Planned activities	Expected result/indicators
Create a common understanding and database for CE	• Develop a circular infrastructure management action plan • Conduct a waste audit • Define key resource indicators • Induction training for employees • Implement digital data accounting • Prepare project applications for external funding	Baseline indicators set, action plan approved.
Resource efficiency (energy, water)	• Energy management approach • Pilot projects for water saving (use of rainwater for irrigation, technical needs) • Optimization of energy consumption in historic buildings (automation, sensors, regulation)	Reduced risk of increased operating costs; prepared the basis for larger investments.
Waste prevention and management	• Implement full waste flow accounting (domestic, biological, hazardous) • Expand sorting infrastructure throughout the territory + visitor information	Increased waste diversion rate; less dependence on landfills
Fixed asset management	• Gradually introduce BIM, HBIM, and DT solutions into fixed asset management to ensure data-driven, efficient, and sustainable infrastructure management, but at a minimum, develop a "life cycle plan" for fixed assets (repair, lease, replacement).	Ability to monitor technical condition, energy consumption, and maintenance needs in real time.

(*continued*)

Table 5. (*continued*)

Main objectives	Planned activities	Expected result/indicators
System-level innovations	• Annual evaluation and public reporting of sustainability indicators • Incorporating circular objectives into the strategy	Increasing competitiveness

It is recommended that the resource efficiency and CE indicators defined in the guide are integrated into digital material passports and linked to BIM, HBIM and TD solutions to enable the structured management of lifecycle data for fixed assets.

6 Conclusion

The transition to infrastructure management based on the principles of the CE is hindered by high initial costs, low awareness and the requirement for supportive regulations and collaboration. This presents a particular challenge for businesses in historic buildings, where changes to engineering systems require significant investment, as well as design and coordination. Many traditional sustainability solutions, such as insulation, renewable energy infrastructure, ventilation modernization, and water reuse, are either technically unfeasible or too expensive for the company. This situation clearly demonstrates objective limitations to sustainable, rational decision-making. HBIM and DT solutions can help businesses in the tourism sector to manage historic buildings sustainably and promote the CE. This is particularly important for businesses that manage cultural heritage sites such as castles and manors, where balancing high visitor numbers with building preservation is essential.

In the Baltic States, including Latvia, solutions for the management of cultural heritage in the tourism sector using HBIM and DT are still in the early stages of development. However, Latvia already possesses significant technological and institutional potential in this area. Currently, universities, companies and cultural heritage institutions primarily use laser scanning, photogrammetry, BIM and 3D archiving for documentation and restoration projects. However, integrating these technologies with sensor data and real-time analytics could facilitate the data-driven management of tourism infrastructure.

As small businesses often face financial constraints when transitioning to a CE, sustainability financing should be primarily viewed as a tool for strengthening internal efficiency and competitiveness. Data-driven process improvements, resource monitoring, automation and employee skills development require relatively small investments that can be financed from existing cash flow and deliver quick, measurable returns.

The most effective approach is a phased financing model, starting with small improvements using internal resources, moving on to co-financing and loans, and finally implementing larger investments with EU and national support. This approach reduces financial risk, strengthening business resilience during the transition period while promoting sustainable infrastructure and resource management in the tourism sector.

Acknowledgments. This research is funded by the Latvian Council of Science project "Assessment of Resources and Processes for Implementing Circularity and the Green Deal in the Tourism System (CirToS), project No. lzp-2023/1-0478."

Re-evaluating Comfort: A Data-Based Analysis of Latent Transport Poverty in Latvian Urban Mobility

Dita Zemīte(✉) and Māra Grīnberga-Šilaua

Vidzeme University of Applied Sciences, Valmiera, Latvia
dita.zemite@va.lv

Abstract. The European Commission's Action Plan for the European Pillar of Social Rights recognises transport as a basic service and its critical role in promoting social inclusion and ensuring equal opportunities. Furthermore, sustainable transport and mobility are prioritised at both global and regional levels, through policy frameworks and strategic planning tools

The most recent National Travel Survey (NTS) conducted in Latvia shows that around 80% of annual passenger-kilometres in Functional Urban Areas (FUA) are generated by fossil-fuelled private cars. The most recent 2024 assessment of the Transport Development Guidelines for 2021–2027 also reveals that the projected reductions in greenhouse gas emissions have not been achieved, mainly due to the continued reliance on private cars. The previous NTS showed that 38% of respondents cited personal comfort as the main reason for using private cars. This study investigates whether "comfort", which is often identified as the main motivator for car travel, reflects a genuine desire or compensates for shortcomings in public transport systems. In situations of limited availability and accessibility, comfort can serve as an indicator of transport poverty, encompassing its dimensions of accessibility, availability, affordability and adequacy. By conducting statistical and trip-stage analysis of NTS data in Riga FUA, this study identifies patterns of latent transport poverty, in which car dependency may mask underlying inequality and exclusion

The conclusions emphasise the importance of integrating transport poverty reduction strategies into the development of a Sustainable Circular Transport System in transport planning to further promote inclusive and sustainable mobility

Keywords: Transport poverty · People mobility · Travel survey · Circular transport system · Sustainable mobility

1 Introduction

To align national policies with the European Green Deal and related European policy frameworks [1], as well as with the United Nations Sustainable Development Goals No. 11 (Sustainable Cities and Communities) and No. 13 (Climate Action) [2], Latvia needs to transform its transport system to achieve climate neutrality.

The latest evaluation from 2024 of Latvia's Transport Policy Guidelines indicates that the planned reduction in greenhouse gas (GHG) emissions in the transport sector has not been achieved [3], road transport and private cars undoubtedly impact that, available data from 2023 proves that 97.4% of the total transport GHG are from road transport and 50.5% of those are generated by passenger cars [4]. According to the National Travel Survey (NTS) 2021, the passenger modal split shows that almost 82% passenger-kilometres per year were travelled by private cars [5] in Functional Urban Areas (FUA) [6] of Latvia. In 2025, electric vehicles accounted for around 1% of the total car fleet, while almost 70% of passenger cars were diesel-powered at the beginning of 2025 [7]. Environmental concerns are further exacerbated by the age structure of the vehicle fleet: 76% of cars are over 10 years old, and 26% are over 20 years old [8]. To address the issue of private cars, the Circular Economy (CE), is proposed, a system that aims to reduce waste and recycle resources, and offers a way to move from linear to Circular Transport System (CTS) - which is designed to separate travel from using limited resources - to Sustainable Circular Transport Systems (SCTS) that also consider social fairness and people's well-being [9–12].

This study examines the concept of CTS from the perspective of CE transport service use perspective [13] and analyses that the social dimension of sustainability is not sufficiently reflected in existing concepts. To address this gap, the paper proposes to expand the concept towards SCTS that includes social considerations.

The empirical analysis focuses on travel patterns in the Riga FUA using trip data from the NTS. In particular, the study examines "comfort" if stated by survey respondents as a key factor influencing private car use for the particular trips and assesses the availability of public transport (PT) alternatives in terms of accessibility and travel time. Accessibility is considered as one of the four dimensions of transport poverty and is therefore used to assess the potential of PT as an alternative to private car transport use in Riga FUA.

The findings suggest that the use of private cars in Riga's FUA could be explained less by psychological motivation or status considerations and more by structural factors, such as lack of transport and the limited competitiveness of PT in terms of accessibility and service provision [14–16]. The results contribute to the discussion on structural changes in transport system aimed at improving the competitiveness of PT in the transition to SCTS and achieving mobility justice [17].

2 Literature Review: from Linear to Sustainable Circular Transport Systems

A transportation system consists of infrastructure, vehicles, terminals (networks) that enable the movement of passengers and freight (demand) between locations (nodes) [18]. CTS are socio-technical structures designed to decouple mobility from the consumption of finite resources [19]. Unlike the linear model, CTS employ a closed-loop approach throughout the entire material and energy cycle. This change is mainly explained by Socio-Technical Transition Theory, which suggests that real change occurs only when new technologies align with changes in how people use them, the rules that govern them, and the cultural conversations surrounding them [20]. However, early formulations of CTS often emphasise material efficiency - specifically, the "3R/4R" principles of

industrial ecology (reduce, reuse and recycle/ reduce, reuse, recycle, recover) - while possibly neglecting social considerations and the essential "human" requirements for a resilient network, such as community engagement and equitable access to resources [9, 19, 21, 22].

To address this issue, the concept of SCTS has been developed. The SCTS functions as a comprehensive system that integrates economic efficiency, social responsibility, and behavioural change [23]. This evidence points to a shift from a technical materials science perspective to a comprehensive approach that integrates social justice.

While CTS mainly emphasizes the optimization of resource flows and environmental efficiency, SCTS includes the social dimension of sustainability. Within SCTS, the dimensions of transport poverty – accessibility, availability, affordability and relevance – can be addressed in several ways. First, accessibility can be improved by shifting the focus away from private car use towards widely interconnected multimodal networks and PT systems that meet the diverse needs of users, for instance in densely populated FUAs. Second, accessibility can be improved through urban planning approaches that reduce physical distances to essential services and PT stops, such as compact urban development or concepts such as "superblock" [24]. Third, affordability ensures that mobility services remain financially accessible. Finally, adequacy and accessibility require that transport services are inclusive, equitable and meet the mobility needs of different population groups [12, 25].

Ultimately, SCTS not only optimizes transport operations, but also fundamentally transforms them. By integrating these dimensions into its conceptual framework, SCTS supports the transition to a circular transport system that is not only resource efficient but also socially inclusive.

3 Methodology

The study uses case of Latvia - Northern European country and a member of the European Union since 2004, characterised by a developed but evolving transport network; however, low population density, population decline and budget constraints in reducing regional PT services limit the prospects for sustainable transport and complicate the provision of connectivity without private cars. The total area is 64,589 km^2, the population is 1.9 million according to the latest data in 2025 by Central Statistical Bureau of Latvia, and the population density is 30 inhabitants per km^2 [26], making it one of the least populated countries in the EU. The total length of Latvian transport lines has kept decreasing since 1990 [27].

For this study, a quantitative descriptive comparative approach based on statistical data analysis was used. Descriptive statistics were used to analyse the distribution of travel times for private car and PT trips. Visual inspection of the histograms indicated that the travel time distribution deviated from the normal therefore non-parametric Wilcoxon rank sum test was used. Statistical analyses were performed using the RStudio.

The study uses trip microdata from the NTS 2017 (N = 14011) [28]. The NTS provides nationally representative information on individual daily travel habits, including trip characteristics, mode of transport, trip distance and stated reasons for choosing the mode of transport.

For this study, the dataset was filtered using the following criteria:

– Geographical and temporal scope – Riga FUA and working days.
– Mode of transport – only trips made by private car and driver of the car.
– All purpose trips included, excluding those where the main purpose stated was accompanying persons.
– Main reason for choosing a car for a trip – comfort was selected.

The analysis aimed to assess whether car use motivated by personal comfort that according to the results of the NTS 2017 where 38% of respondents indicated personal comfort as the main reason for choosing a private car [29], could theoretically be replaced by PT and whether such travel behaviour may be indicative of underlying constraints related to the accessibility and availability dimensions of transport poverty. Within this framework, PT mobility options were systematically assessed, travel time and number of transfers were made by selecting two Wednesdays in March 2026, a departure time of 2 PM (when multiple travel options were available, the fastest connection was selected), and publicly available PT schedules on Google Maps. The standardised assumption for this analysis was that available PT and rail routes, as well as schedules, had not changed substantially in 2026 compared to 2017. The analysis focused on the differences in travel time between private cars and PT. The analysis did not include individual-specific constraints that might have influenced the choice of transport mode (e.g. physical limitations, household responsibilities or employer requirements), as such preconditions were not available in the data set. Therefore, the comparison reflects the theoretical substitution potential, not the realised probability of behaviour. The approach enabled assessment of whether the stated reason for "personal comfort" may mask structural mobility constraints and thus reflect latent transport poverty rather than purely preference-based travel behaviour.

The analysis may be subject to survey-year bias, as it relies on data from the NTS 2017; however, it ensures conceptual coherence with the study's aim, assess car trips motivated specifically by personal comfort considerations. In Latvia, the most recent national travel survey was conducted in 2021, however it did not include a specific question on a reason for choosing a private car.

4 Results

When comparing travel times between private cars and PT alternatives, significant differences were observed. The Wilcoxon signed-rank test confirmed that travel times by PT are significantly longer than travel times by car ($V = 0$, $p < 0.001$). The average travel time ratio between PT and car travel was 4.05, indicating that trips by PT would require more than four times the travel time. Only 10.7% of trips could be made by PT in twice the travel time than by car, and only 3.0% of trips in 1.5 times the travel time than by car. Furthermore, 51.7% of trips using PT would exceed the travel time by at least 30 min.

Table 1 presents descriptive statistics on travel times by car and PT for the analysed trips in Riga FUA. The results show significant differences between the two modes of transport. Travel times by PT are significantly longer compared to travel times by car.

The Fig. 1. shows the distribution of private car and PT travel times in the Riga FUA. The results show a clear difference between the two modes of transport. Car travel times are significantly shorter and more uniform, with a lower median and a relatively

Table 1. Descriptive statistics of travel times for cars and PT.

Travel mode	Median (min)	Min (min)	Max (min)	IQR
Car	10	1.3	70	14.15
PT	41	10	218	37

narrow interquartile range. In contrast, PT trips have significantly longer travel times and greater variability. Several extreme values were observed for PT, indicating particularly long travel times, in some cases exceeding 150 min.

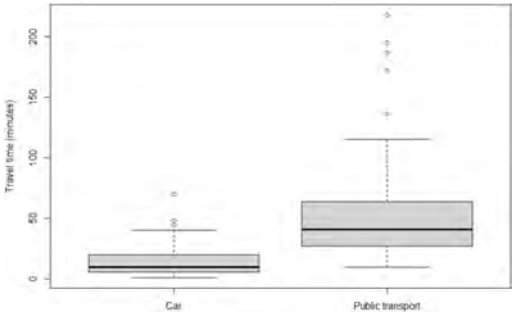

Fig. 1. Distribution of travel times by mode of transport (private car and PT) using box plots in the Riga FUA.

5 Conclusions

The results show a significant travel time disadvantage of PT compared to car travel. Such differences can increase reliance on private cars and limit the competitiveness of PT alternatives. The findings also suggest potential access inequalities in Riga FUA, as people without access to a car may face longer travel times when using PT. Improving the competitiveness and connectivity of PT in terms of travel time could therefore be important to support SCTS development.

Acknowledgments. The NTS data used in this research were obtained within the project "Passenger Mobility and Road Traffic", which was co-funded by Eurostat under a grant agreement and implemented by the CSB. Co-funded by the European Union. Views and opinions expressed are, however, those of the author(s) only and do not necessarily reflect those of the European Union.

The research was supported by the project No. lzp-2023/1-0478 and 1.1.1.8/1/24/I/001 "VeA un ViA doktorantūras grants".

Advancing Circularity in Resource Intensive Public Facilities: A Participatory Action Research of Museums, Zoological Gardens and Sports Facilities

Dace Dance(✉), Mara Grinberga-Silaua, and Sarmite Rozentale

Vidzeme University of Applied Sciences, Valmiera, Latvia
dace.dance@va.lv

Abstract. Public facilities such as museums, zoological gardens, and sports venues, which support community well-being and economic activity, are resource-intensive as they have high demands for materials, energy, water, and generate significant amounts of waste.

Furthermore, because public resources finance them, they are uniquely positioned to serve society through their direct targets and to serve as role models for circularity practices.

This study adopts Participatory Action Research (PAR) to investigate a national museum, a national sports event facility, and a national zoological garden using a multicriteria framework that combines secondary data analysis, stakeholder interviews, and an examination of circularity strategies and practices. The same model has been applied to all participants, with slight adaptations, thereby making the data comparable and the evaluation outcomes more closely aligned with the participants' real operational context.

Data collection is based on a self-evaluation questionnaire, semi-structured interviews, participatory focus groups, field observations, and reflective diaries of circularity practices maintained by participants, with a final evaluation at the end of a one-year study.

Findings reveal each facility's circularity potential, current challenges and barriers. The main challenges for zoological gardens are water management and improving organic waste loops; for sports facilities, it is infrastructure modification and strategies for shared-use resources; for museums, it is maintaining conservation through digitalisation and resource-sharing strategies.

The results demonstrate that circularity practices not only improve nature conservation directly but also strengthen public institutions' resilience and operational efficiency. Being visible through their actions increases public engagement with circularity.

1 Introduction

Zoos, sports organisations, and museums are prime candidates for circular economy (CE) research because they both consume vast resources and generate substantial waste, and they uniquely influence tourists and local communities. These organisations use large daily quantities of water and energy for infrastructure, visitor services, and facility management, leading to significant amounts of food, packaging, and organic waste. The tourism and cultural sector stands out as a major driver of energy and water consumption and as a notable contributor to CO_2 emissions and waste. Addressing these pressures by implementing CE principles is therefore essential for sustainable development. At the same time, these institutions hold considerable untapped potential for advancing the circular economy [10]. They serve as role models of circular practices for society, such as waste sorting, material reuse, and sustainable infrastructure solutions.

In the circular economy, value creation in public infrastructure management relies heavily on effective asset management, resource circulation, and extending the infrastructure life cycle. Furthermore, because public procurement accounts for a massive portion of the economy, these state and municipal facilities have the power to act as first movers, creating vital demand-side pressure in the market to accelerate the broader transition to a circular economy [12].

Still, there is a gap in understanding the functional reality of *why* they are struggling to implement deep circular practices. The gap lies in the fact that current CE literature focuses on macro-level systemic shifts, and the R framework for CE [5] often overlooks the unique constraints of resource-intensive public institutions in geographically sensitive areas. In addition to recent practical CE studies and developed self-assessment tools tailored for the tourism sector, they focus on private Small and Medium-sized Enterprises (SMEs), such as hotels, restaurants, and wineries [13].

The study addresses this gap by focusing on the operational realities of these facilities through Participatory Action Research (PAR). The objective of the research is to investigate the current circularity potential and the challenges and barriers [8] for resource-intensive public facilities. It seeks to prove that implementing CE practices in resource-intensive public facilities strengthens their operational efficiency.

The transition towards a circular economy (CE) in the built environment is a pressing necessity. Across the globe, the construction sector continues to exert tremendous pressure on natural resources, energy systems, and waste management infrastructures. At the same time, it holds untapped potential for CE [1].

For asset-heavy public facilities, circular value creation relies heavily on maintaining the built environment, extending the lifespan of physical assets, and optimising resource streams to lower operational expenditures (OPEX) [3].

Given these organisations' high resource consumption, the complexity of their infrastructure, and their potential to advance the practical implementation of circular economy principles, the study analysed the integration of circular economy principles into organisational management using a multidimensional approach to data collection and analysis.

2 Methodology

Study uses Participatory Action Research (PAR) to investigate resource-intensive public facilities. This study applies the PAR methodology to analyse the needs and challenges of tourism SMEs in their transition towards the circular economy. PAR is widely used in the tourism sector and in circular economy projects and involves stakeholders in the research process [13].

PAR is highly effective because it directly connects research to real-world actions, enabling researchers and institutional stakeholders to generate practical knowledge collaboratively. Furthermore, applying PAR within a multi-case framework allows researchers to identify shared systemic barriers that interact with unique operational realities and respondents' knowledge [4].

Within the current research, the PAR process consisted of 3 phases. First ("Preparation"), organisations were selected (with limitations set on certain regions and tourism-related sectors according to NACE, and through on-site visits and in-depth interviews to track company readiness and willingness to collaborate). Second ("Data collection"), Excel data sheets were prepared, and organisations collected data on CE practices, including exact data, additional comments, and bi-weekly information in a CE practices diary according to the 9R framework adapted from Potting [11]. Third ("Analysis and Implementation") involved evaluating, validating, and cleaning data, aligning with available public financial reports, and holding a joint workshop with organisation representatives to identify further development potential.

The organisation's CE maturity level was assessed on an ordinal scale: Basic, Growth, and Professional. Basic maturity describes where CE practices are not yet embedded in daily management areas; Growth maturity shows where CE practices are successfully integrated but lack a systematic approach; and Professional maturity describes CE practices that are highly systematic and integrated into both daily operations and long-term strategies. The maturity evaluation was based on combining qualitative and quantitative data collected during the one-year PAR period.

By applying the same model to all participants, the goal is to gather comparable data that reflects the real operational situation and context. As part of a scientific research project (see Acknowledgement), a PAR study was conducted across 10 different organisations. To address the current literature gap, this article focuses on public, resource-intensive facilities; therefore, three specific institutional case studies - a National Museum, a National Zoological Garden, and a National Sports Event Facility, which have been selected for further research.

The study used a mixed-methods approach and data triangulation to assess how circular economy (CE) principles are integrated across management areas. The organisation performed a self-assessment of CE principles in business management areas (see Fig. 1). At the same time, representatives kept structured diaries documenting the timing, context, and rationale of daily activities and decisions aligned with the 9R principles, capturing detailed insights into CE-related actions. We also reviewed financial indicators to assess investment opportunities and potential financial constraints for launching and developing CE initiatives. All data were cross-referenced to compare the organisation's self-reported CE practices with its actual operations and financial capacity. This process improved the reliability and validity of the study's results.

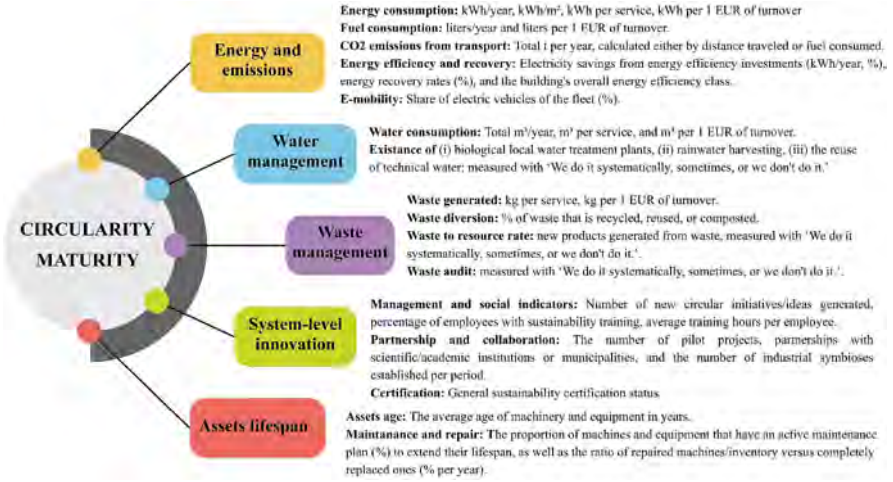

Fig. 1. Circularity Maturity Assessment: Dimensions and indicators. Study limitations: The study investigates three highly specialised, national-level public facilities in Latvia.

3 Results

Based on the Participatory Action Research (PAR) data gathered during the one-year study of the three facilities:

- The Turaida Museum Reserve is a state-accredited museum and a highly protected cultural monument of state significance, operating directly under the Ministry of Culture of Latvia. The facility maintains and restores historical monuments, buildings, and landscapes across 43.63 ha, offering insights into over a thousand years of local history, ethnography, and archaeology. This natural monument or national museum is located in the Gauja National Park area. The museum holds a European heritage label. Institutional web page: https://turaida-muzejs.lv/en/.
- The Riga National Zoological Garden, a 20-ha municipal institution located in Mežaparks, is the only national zoological garden in Latvia. Housing around 3,400 animals across 410 species, RigaZoo's core missions are fauna demonstration, ex situ species conservation, ecological education, and recreation. RigaZoo is an active participant of the European Endangered Species Program (EEP) and the European Association of Zoos and Aquaria (EAZA). Institutional web page: https://rigazoo.lv.
- The Bobsleigh and Luge Track "Sigulda" is located in the Gauja National Park area. It is a specialised winter sports facility. The Latvian Ministry of Education and Science owns the institution through the state enterprise "Latvijas Nacionalais sporta centrs". Built in 1986, this unique Eastern European sports facility features a 1,200 + 220 m artificial ice track. The track has 16 curves across 6,330 m^2. As a highly capital- and energy-intensive infrastructure, it consistently has service costs that exceed turnover. The Track remains heavily dependent on government support and the availability of EU structural funds for capital investments. Institutional web page: (https://www.bobtrase.lv/).

Grouping by management areas allows for evaluation of the system rather than of separate indicators. Overall, studied organisations operate at a "Growth" stage, meaning circular practices are integrated into daily operations but lack a common, unified, and systemic strategic framework. For example, regarding waste management, all three facilities have practical daily practices (such as composting bio-waste on-site, reusing branches for animal feed or as wood chips, and using reusable containers). However, despite these efforts, they lack systematic data, and no one conducts regular waste audits. The results of the case study are summarised in Table 1.

Table 1. Circularity maturity assessment of case studies

Circularity Trait	National Sports Facility	National Zoological Garden	National Museum
Resource Efficiency	Growth	Growth (Energy)/Basic (Water)	Growth
Extending Asset Lifespan	Professional	Professional	Growth (Near Professional)
Waste Prevention	Growth	Growth	Growth
System-Level Innovations	Growth	Growth-Professional	Basic - Growth
Overall Maturity Level	Growth	Growth-Professional	Basic - Growth

Water management at the National Zoological Garden scores the lowest. Upgrading from traditional consumption to a circular system (e.g., rainwater harvesting and greywater reuse for animal enclosures) requires substantial capital-intensive infrastructure modifications. The facility cannot self-fund these changes.

All three institutions incur high infrastructure costs and strongly depend on state or municipal funding. They demonstrate their highest maturity by extending asset lifespans and embracing a strong repair culture. Public funding constraints drive this practice. Since they lack free capital to purchase new equipment or undertake major infrastructure overhauls (such as replacing the refrigeration units at the sports track), maximising the lifespan of current assets is an economic survival mechanism. This approach coincidentally aligns with high-circularity practices.

None of these facilities can independently achieve an overall "Professional" maturity level. They are locked into unprofitable public-service models. Achieving systemic circularity, like renewable energy installations or water recycling systems, strongly depends on external funding (EU or state/municipal). Table 2 presents further analysis of circularity potential, strengths, and barriers in the context of CE practices.

Table 2. Circularity potential: identified strengths and barriers

Circularity Potential	National Sports Facility	National Zoological Garden	National Museum
Strength	Longevity of professional equipment	Infrastructure lifespan extension and "repair and reuse" culture	Asset longevity and a strong "repair and reuse" culture
	Targeted operational efficiency	In-house grown food loops, potential for organic waste loops	Exhibition items from recovered materials
	Data tracking of resources	Strong systemic vision	Educational program integrated
Barriers	Resource-consuming ice maintenance	Historical water management system	Heritage conservation regulations
	High infrastructure intensity	Capital-intensive, infrastructure	Strict climate regulations
	Structural financial deficit	Low-waste diversion practices	Regulated state procurements

4 Conclusions and Discussion

This study reveals the potential for circularity and sector-specific aspects for three resource-intensive public facilities. To improve circularity, zoological gardens must prioritise advanced water management and organic waste loops. Sports facilities require significant infrastructure modernisation. Museums need to focus on digitalisation and cross-sectoral resource sharing. This approach addresses the unique challenges posed by strict heritage conservation regulations.

State public procurement laws and strict cultural or natural conservation mandates heavily restrict institutional operations. These institutions lack the internal capital to fund massive, systemic infrastructure modifications. It is typical for them to try to solve major challenges on their own. Such challenges include high demand, seasonal fluctuations, and inefficiently managed infrastructure. This supports only basic, surface-level circularity rather than true, systematic transformation.

Transitioning resource-intensive public facilities to circularity requires strategic financing [2, 9], such as utilising the Energy Service Company (ESCO) model, in which efficiency upgrades are paid for through energy savings. [15].

Applying such energy optimisation models within sprawling cultural heritage sites like Turaida Museum Reserve requires a more selective approach. Strict mandates for temperature, humidity, and cultural conservation are in place. Comprehensive energy retrofits in delicate historical structures are virtually impossible. Following successful operational examples from European open-air museums such as Skansen [14] and Maihaugen [7], heritage facilities should implement centralised, real-time energy monitoring. Efforts should focus strictly on optimising newer, non-historical administrative buildings while leaving heritage assets untouched.

Zoological gardens face unique barriers driven by strict animal welfare regulations and high energy consumption. This is especially true in tropical houses and aquariums. These factors complicate ESCO investment returns and increase financial risk. Integrating advanced energy-efficiency models in these facilities is hindered by systemic barriers. These include a lack of precise historical consumption data, the complexity of state public procurement laws, and institutional inexperience with long-term contracts. Overcoming these challenges requires blending private financing models with municipal co-financing and national support programs. The success of Finish Korkeasaari Zoo [6] demonstrates a strong commitment to circularity. This institution prioritises carbon-neutral operations, green procurement, organic waste recovery, and closed-loop feeding.

For highly energy-dependent infrastructure like the Sigulda Bobsleigh Track, modernising compressors and recovering heat from its 1,200-m artificial ice track offer massive potential. This is similar to the 20% electricity savings achieved at the Innsbruck track. However, the Sigulda facility is technologically ageing and highly capital-intensive. Deep modernisation cannot rely solely on private ESCO partnerships. It must also have crucial backing from state and EU structural funds, which are already available in Latvia.

For the ESCO model to work effectively in the public sector, stable, measurable energy consumption data is needed. Accurate historical records are also necessary to forecast savings. Clear legal conditions must be in place. In Latvia, barriers may include complex public procurement processes, a lack of experience and distrust of long-term contracts, restrictions on historical buildings, and the absence of precise consumption monitoring. Therefore, in Latvia, the ESCO model for resource-intensive public facilities should be supplemented by EU funding, state support programs, and municipal co-financing.

Acknowledgments. The research is supported by the project "Assessment of Resources and Processes for Implementing Circularity and the Green Deal in the Tourism System (CirToS)" No. lzp-2023/1-0478.

Data-Driven Inverse Design of a Material-Efficient CAR1 Friction-Yielding Damper

Magdalini Titirla(✉) and Walid Larbi

Mécanique, Acoustique, Contrôle et calcul Scientifique (MACS), Conservatoire National des Arts et Métiers (CNAM), Paris, France
magdalini.titirla@lecnam.net

Abstract. This study presents a data-driven inverse design approach for the development of a material-efficient CAR1 friction-yielding damper, a passive energy dissipation device used to enhance the seismic performance of structures. The damper is composed of simple and potentially recyclable materials, and its axial control force and energy dissipation capacity depend on the appropriate selection of its design parameters. The CAR1 damper is characterized by thirteen design variables, resulting in many possible configurations. Traditional design approaches rely on predefined parameter combinations, which may lead to non-optimal material use. To address this limitation, a global sensitivity analysis is first performed to identify the most influential parameters affecting the damper's performance. Based on the generated dataset, an Artificial Neural Network (ANN) model is developed to approximate the relationship between design parameters and damper performance. The trained ANN is then used in an inverse design framework to identify parameter combinations that achieve target performance levels while minimizing material usage. The proposed methodology supports data-driven decision-making for the design of efficient seismic dampers, contributing to the development of resilient and resource-efficient structural systems

Keywords: Material-efficient design · Damper CAR1 · Fourier Amplitude Sensi- tivity Test · Data-Driven design · ANN inverse optimization

1 Introduction

Seismic risk encourages the installation of passive energy dissipation devices to mitigate earthquake damage [1–4]. Friction dampers are successful because of their simplicity, durability, and independence from power. They transform kinetic energy into heat, which reduces forces and displacements. Their performance is determined by interactions among geometric, material, and frictional characteristics [5–9]. Optimising these parameters to satisfy seismic performance targets remains a hard task.

The objective of this study is to optimize the mechanical behavior of the CAR1 friction damper [10], a representative passive energy dissipation device, using an integrated approach combining FE modeling, ANN-based surrogate modeling, global sensitivity

L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 839–847, 2026.
https://doi.org/10.1007/978-3-032-34930-9_98

analysis, inverse identification, and optimization. The validated FE model [11] serves as the reference to predict nonlinear damping behavior and generate a simulation dataset for training the ANN model, which reproduces the damper response at a much lower computational cost. Global sensitivity analysis identifies the most influential parameters and filters out negligible ones [12]. The trained ANN is then employed in an inverse design framework to discover parameter combinations that reach desired performance levels (while minimizing material consumption.

2 Damper Configuration

Figure 1 presents the configuration of the device proposed by Papadopoulos et al. [10], highlighting the external tube (Element A), inner shaft (Element B), and multiple groups of superimposed blades (Elements C) that make up the device. An elastoplastic flexural deformation of the stacked blades connecting elements A and B allows for the relative movement between the external tube and the internal shaft. The constitutive law of diagonal bracing under axial stress is determined by the total number, size, and elastoplastic characteristics of the superimposed blades. Thirteen parameters in the CAR1 damper alter its mechanical behavior (Table 1).

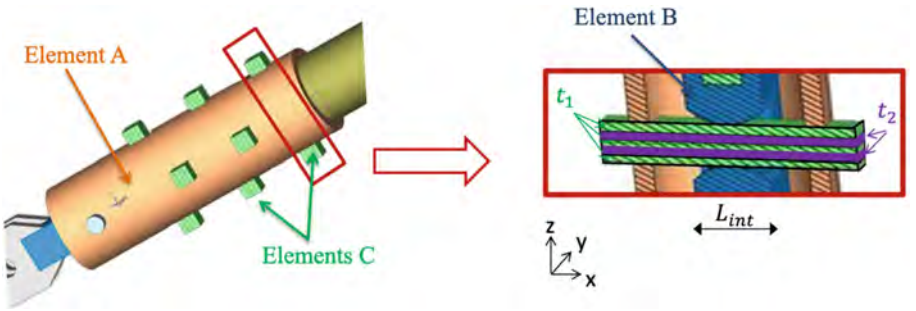

Fig. 1. Damper CAR1.

Table 1. Description of the investigated parameters.

Parameters	Definition	Unit	Min-Max value
t_1	Thickness of a main material blade.	mm	1–20
t_2	Thickness of a secondary component blade.	mm	0–10
N_1	The main material's blade count.	–	2–10
N_2	The secondary material's blade count.	–	0–10
μ	Friction coefficient in the contact area.	–	0.01–0.70
L_{int}	The inner shaft's length.	mm	40–90

(*continued*)

Table 1. (*continued*)

Parameters	Definition	Unit	Min-Max value
E_1	The fundamental material's Young's modulus.	GPa	100–201
E_2	The secondary material's Young's modulus.	GPa	100–201
v_1	Primary material's Poisson's ratio.	–	0.3–0.34
v_2	Poisson's secondary material ratio.	–	0.3–0.34
σ_1	The fundamental material's yield stresses.	MPa	170–215
σ_2	The secondary material's yield stresses.	MPa	170–215
U	Midspan deflection of the blade group.	mm	0–34

3 Artificial Neural Network

The finite element (FE) model was employed in previous studies to analyze the behavior of the device under the individual and combined effects of multiple parameters, demonstrating the importance of numerical simulations in obtaining results that are difficult to achieve experimentally [13, 14]. However, this approach involves a high computational cost. To address this limitation, an artificial neural network (ANN) was developed as a surrogate model to approximate the FE results [15–17]. The ANN was trained to capture the nonlinear relationship between 13 input parameters (Table 1) derived from FEM simulations and a single output variable representing the axial load. A dataset of 3200 simulations was used, with 70% allocated for training and 30% for testing. Several network architectures were evaluated through a parametric study to optimize performance, using standard error metrics such as mean squared error (MSE), root mean squared error (RMSE), mean absolute error (MAE), correlation coefficient (COR), and coefficient of determination (R2) [18, 19]. Figure 2 represents the chosen architecture (13–10–4–2-1), where the three hidden layers consist of 10, 4 and 2 neurons, respectively [12] (Fig. 3 and Table 2).

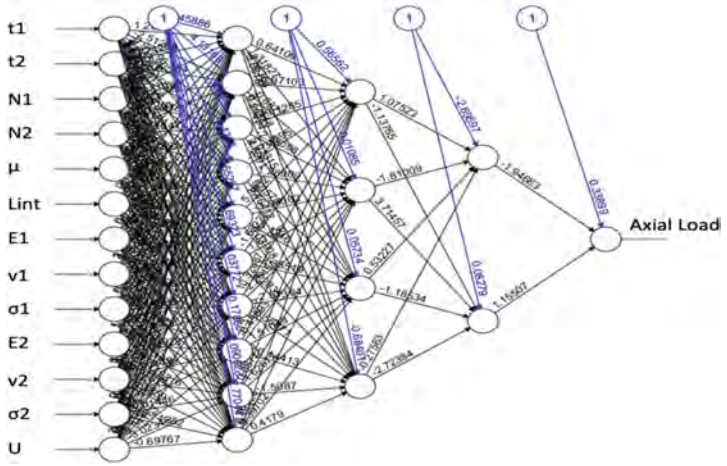

Fig. 2. Artificial Neural Network Model capable of predicting the axial load on the CAR1 damper.

Table 2. Standard error metrics used to evaluate the performance of the ANN.

0.99416	0.00025	0.016	0.01179	0.98674

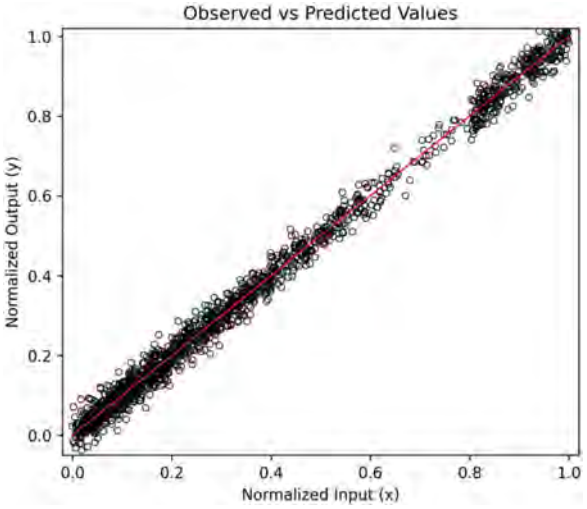

Fig. 3. Graph of Actual vs. Predicted values from ANN.

4 Inverse ANN to Material-Efficient

Based on previous global sensitivity analyses, the device exhibits strongly nonlinear behavior. The parameters exerting the most significant influence on its response are the coefficient of friction, the contact surface area, and the number and thickness of the superimposed blades [12]. The blade material—either a single material or a combination of two different materials—is selected according to the specific structural requirements and characteristics of the building. Notably, this damper has been designed using simple, cost-effective materials such as steel and/or brass. The target displacement and axial load are also dependent on the building's characteristics and are therefore treated as known quantities. Consequently, in the ANN-based inverse problem, eight values are considered known, while the optimization focuses on determining the combination of six parameters ($t_1, t_2, N_1, N_2, \mu, L_{\text{int}}$) that achieves the target axial load (stage 1 of optimization) while minimizing the quantity of material (stage 2 of optimization).

The inverse problem was solved using a genetic algorithm (GA) due to the nonlinear and potentially ill-posed nature of the ANN mapping [20]. While the forward model used 13 input variables, the inverse analysis estimated six unknowns, with the remaining variables fixed from sensitivity analyses. The GA minimized the discrepancy between the ANN output and the target response by performing a global, derivative-free search, making it well suited for complex error landscapes with multiple local minima where gradient-based methods may fail. Figure 4 shows the two-stage optimization methodology with an emphasis on material-efficient. Reducing material volume enhances sustainability in the built environment by lowering raw material use, embodied energy, and waste generation. It also increases resource efficiency and may simplify the reuse, transport, and recycling of the damper at the end of its lifecycle, supporting circular economy objectives.

To validate this study, the authors examined whether the device configuration proposed by Titirla [21] provides an optimal solution in terms of material used. That study investigated an existing building and suggested several damper arrangements to strengthen the first floor in the Y–Y direction. A single CAR1 damper required 325 kN for a target displacement of 23 mm, using five groups of superimposed blades. The proposed configuration used three steel plates (8 mm thick) and two brass plates (3 mm thick) with internal length 30 mm and friction coefficient 0.34. The study does not aim at optimizing the number of groups, but rather at evaluating the performance of the existing configuration (target Axial Load for a target displacement) while minimizing the material used.

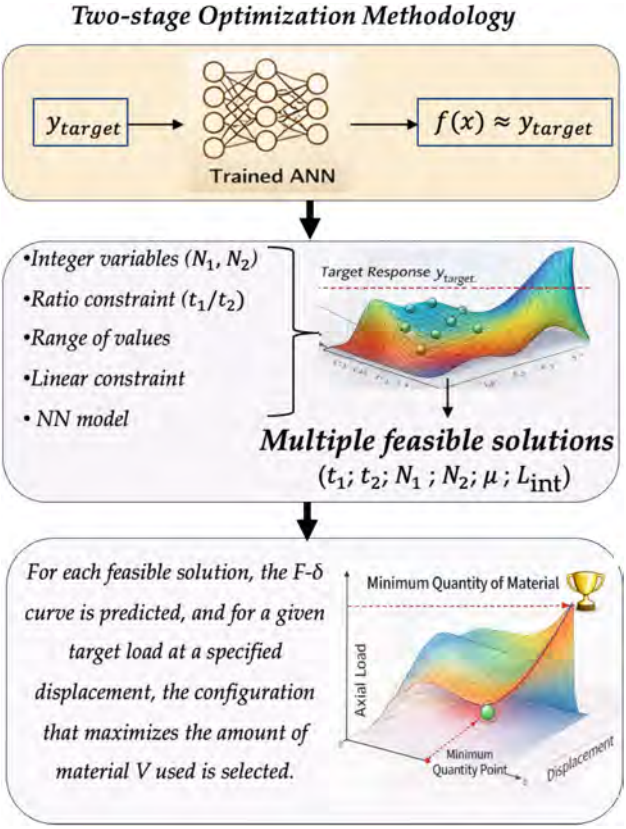

Fig. 4. Two-stage optimization methodology of inverse ANN with an emphasis on material-efficient.

Table 3 presents four possible solutions based on the Stage 1 configuration and the optimal Stage 2 configuration. The indices "1" and "2" denote steel ($E_1 = 201$ GPa, $\nu_1 = 0.3$, $\sigma_1 = 215$ MPa) and brass ($E_2 = 100$ GPa, $\nu_2 = 0.34$, $\sigma_2 = 170$ MPa). Configuration No. 2 is the best solution for the least material volume while achieving the axial load at the specified target displacement.

Table 3. Description of the investigated parameters.

Codename	t1 (mm)	t2 (mm)	N1	N2	μ	Lint (mm)	V (m^3)
No. 1	5.3	1.1	3	2	0.16	50	0.01849
No. 2	8	3	3	2	0.34	27	0.00915
No. 3	7.7	5	4	3	0.1	22	0.0095
No. 4	7.9	2.8	3	2	0.20	48	0.0275

Reducing the material volume is particularly significant from a sustainability perspective, as it directly lowers raw material consumption, and the associated embodied energy and carbon emissions linked to extraction, processing, and manufacturing. In the context of the built environment, a lighter and materially efficient damper contributes to resource efficiency by achieving the required structural performance with fewer inputs, thereby supporting circular construction principles. Moreover, minimizing the quantity of material can facilitate future reuse and disassembly, since smaller and lighter components are generally easier to transport, replace, inspect, and reintegrate into new structural systems. Reduced material complexity and quantity may also improve recyclability at the end of the component's service life (after an earthquake) by decreasing waste generation and simplifying material recovery processes. Consequently, the optimization strategy not only enhances mechanical efficiency, but also aligns the damper design with broader sustainability objectives in contemporary construction, including waste reduction, lifecycle performance improvement, and responsible resource management.

5 Conclusions

The following are the main scientific accomplishments and conclusions:

(i) Based on previous FE datasets [11] that was valided by experimental set-up, an artificial neural network (ANN) was trained as a computationally efficient surrogate, achieving a strong balance of complexity and accuracy. The optimized architecture was 13–10–4-2-1 with three hidden layers of 10, 4, and 2 neurons.
(ii) The device's response is nonlinear, with the main influencing factors being the friction coefficient, contact area, and the number and thickness of superimposed blades.
(iii) Using an ANN-based inverse model, six input parameters were optimized to achieve a target axial load while minimizing the volume of material used in the damper. A two-stage approach was employed: first, a genetic algorithm generated feasible solutions under integer and ratio constraints; second, the resulting configurations were evaluated based on both load–displacement performance and total material volume to identify the optimal design.
(iv) Minimizing material volume supports sustainability in the built environment by reducing raw material consumption, embodied energy, and construction waste. It also improves resource efficiency and can facilitate reuse, transportation, and recyclability of the damper at the end of its service life, aligning the design with circular economy principles.

On the Decay Potential of Wooden Components Exposed to Outdoor Environment in Greece: Enhancing Existing Estimations and Examining their Temporal Trend

Georgia Nikolitsa and Christina Giarma(✉)

Laboratory of Building Construction and Building Physics, Department of Civil Engineering, Aristotle University of Thessaloniki, Thessaloniki, Greece
chgiarma@civil.auth.gr

Abstract. The estimation of the degradation potential of building materials and components induced by the climatic conditions in a region, is a major step towards climate adapted, durable and resilient structures. The investigation of this potential's evolution in time supports, in view of the advancing climate change, the design of building elements able to respond to future conditions. Such efforts are very important when wood-based components, the use of which can be highly beneficial regarding circularity and sustainability in the built environment, are concerned. In this study, the decay potential of above ground wooden elements in Greece is examined. Building on the findings of a previous study, which provided such estimates based on daily climatic data over the period 1985–2004 for 33 locations in Greece, this work expands the calculations' basis with the inclusion of daily climatic data for the period 2005–2022. The studied sites are slightly lower in number but still distributed across Greece. The index proposed by Scheffer is used to provide estimations of the decay potential at these sites. An existing dose-response model is additionally applied for some of them. The calculations are performed based on the available data for larger periods between 1985–2022, and for successive smaller intervals within it. Hence, estimations for the examined potential are produced using a broadened climatic database, and its temporal trend over the last decades is identified.

Keywords: Above Ground Wooden Components · Decay Risk · Hygrothermal Conditions · Scheffer Index · Variation of Decay Potential in Time · Greece

1 Introduction

The design and construction of durable, resilient and adaptable to future climatic loads building components lie in the core of circular and sustainable practices in the building sector. The efficient implementation of the relevant strategies depends heavily on the reliable estimation of the actual and foreseen deterioration potential induced by the exposure and working conditions.

The degradation risk is obviously material-dependent, as different materials are not equally susceptible to every climatic factor. Wood has been the focus of many studies in this regard, e.g. [1–12]. In the context of these studies, various approaches have been adopted, including the calculation of decay potential indices and or the employment of dose-response models for the quantified estimation of the decay potential of wooden components that are exposed to the outdoor climatic loads. On this basis, the risk for the above ground wooden components has been approached for several areas in the world, and maps have been produced for specific countries or broader regions (e.g. [1–7, 9, 10]). In several of the relevant works, the impact of the differentiation of climatic conditions over time has been included to various degrees (e.g. [5–7]).

Recently, relevant results have been produced for several sites in Greece [5] based on daily climatic data for the period 1985–2004 and employing the widely recognized and used Scheffer Index (SI) [1], as well as two dose-response models [8–12].The present work builds upon the existing estimations by extending the climatic database with the addition of more years. The presented SI values are calculated on the basis of daily climatic data ranging from 1985 to 2014 for 25 sites in Greece. For 6 out of those sites, the calculations extend to 2022 using the available climatic data, complemented by the results derived from the implementation of one dose-response model for the entirety of the 38-years period. These results extend the database for the decay potential estimation at the examined sites, including more recent periods, and further support the derivation of conclusions on the timely evolution of the estimated risk.

2 Materials and Methods

2.1 Approaches Adopted for the Estimation of the Decay Potential of Wood

Scheffer Index. A widely used index for the representation of the decay potential of wooden elements above ground is Scheffer Index (SI) [1], based on which relevant maps have been produced for several regions. SI indicates the "*relative potential of a climate to promote decay of off-the-ground wood structures*" [1] and is calculated via Eq. (1) [1]:

$$SI = \frac{\sum_{i=Jan}^{Dec}[(T_i - 2)(D_i - 3)]}{16.7} \quad (1)$$

where Ti [°C] stands for the average monthly temperature for each month of the year (i = January,…,December), and Di [−] represents the average number of days with considerable rainfall (height ≥ 0.25 mm) for each month of the year. Negative values of the product [(Ti-2)(Di-3)] are excluded from the calculation [1]. In this work, SI is the main metric used for the estimation of the decay potential at all the examined sites and for the analysis of the appearing temporal trends.

Dose-Response Model. A dose-based approach [11–12] combined with a simplified dose-response model for the estimation of the decay potential at any site [8–9], have been employed, as a complementary metric to Scheffer index, for a small number of sites. In the core of this model lies the expression of the impact of the moisture content and temperature of wood to its decay process as daily doses (adoption of a dose-response

approach, based on experimental measurements [11]). The temperature and the moisture content of timber are derived on the basis of the main relevant factors characterizing the local climate. This way, the daily dose approach indicates the local climate-induced influence on the potential wood decay process. The calculations are based on daily data, and for each day of the examination period the daily dose is derived from Eqs. (2), (3), (4) [8–9]:

$$D(t_i) = D(T(t_i)) \times D(u(t_i)) \tag{2}$$

$$D(T(t_i)) = \begin{cases} 0, \, if \; T(t_i) < 0°C \\ T(t_i)/30, \, if \; 0°C \leq T(t_i) \leq 30°C \\ 1, \, if \; 30°C < T(t_i) \end{cases} \tag{3}$$

$$D(u(t_i)) = \begin{cases} (u(t_i)/30)^2, \;\; if \; u(t_i) \leq 30\% \\ 1, \, if \; u(t_i) > 30\% \end{cases} \tag{4}$$

In this set of equations, $T(t_i)$ [°C] and $u(t_i)$ [%] represent the daily temperature and moisture content of the studied element, respectively. $T(t_i)$ is assumed to be equal to the daily global air temperature (i-th day) [9], while the daily moisture content of the wooden element is calculated according to the process used in, among others, [9, 10] and shown in Fig. 1. $D(t_i)$ represents the total daily dose calculated for the i-th day of the examined period, with $D(T(t_i))$ and $D(u(t_i))$ standing for the temperature and the moisture-content contribution to the daily burdening for day i, respectively. For any period of analysis, the total dose equals the sum of the daily doses calculated for this period. It is interesting to note that, in this model, also the air relative humidity (i.e. not only data relevant to rainfall) at a site contributes to the final estimations (Fig. 1).

2.2 Climatic Data and Examined Sites

The calculations of SI and of the total daily dose with the use of the equations that are presented in Sect. 2.1 are based on climatic data of daily time resolution, provided by H.N.M.S. (Hellenic National Meteorological Service). Specifically, the average daily air relative humidity and temperature, as well as the daily rainfall for each day of the examined time period are used in the calculations.

The examined period extends from 1985 to 2022, covering more than 3 decades. The respective calculations, along with additional ones, have been performed for the years 1985–2004 in a previous study [5]. The expansion of the calculation basis in the present work serves to both consider a broadened and more recent time period, as well as to investigate the patterns, if any, of the decay potential's variation with time.

In this study, the decay potential for wood exposed to outdoor conditions is examined at 25 sites, spatially distributed over Greece (Table 1). The selection of these sites, less in number than those included in [5], is based on an effort to examine the conditions prevailing in areas of various topographical and climatic characteristics, and on the availability of the required climatic data mainly for the period 2005–2014.

Specifically, in the provided records of daily climatic data for each site, there were days with missing information. The days with at least one of the three variables (temperature, relative humidity, rainfall) missing were excluded from the calculations. The

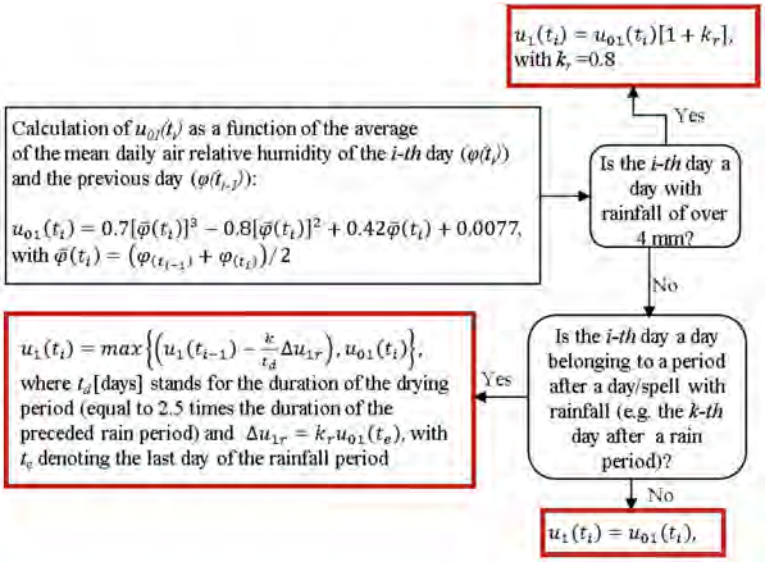

Fig. 1. Process for the calculation of wood's moisture content. All the elements included in the figure (equations, assumptions, etc.) are those ones used in [9, 10]. The figure is based on a relevant one appearing in [5].

Table 1. The investigated stations/sites, spatially distributed across Greece.

Site/Station	Latitude	Longitude	Site/Station	Latitude	Longitude
Agrinio	38.61	21.38	Kerkyra	39.61	19.91
Alexandroupolis	40.86	25.95	Larisa	39.65	22.46

Ioannina	39.69	20.83	Tripoli	37.52	22.40
Kalamata	37.07	22.02	Volos (Aghialos)	39.22	22.79
Kavala (Chryssoupoli)	40.92	24.62			

calculation of SI is based on averaging daily data over years per month; in order to ensure the representativeness of results and the comparability of the index' values that

are calculated for the examined sites, months and years having several days with missing data were not taken into consideration as a whole. This approach led to the exclusion of 8 sites examined in [5] from the current study, as the information on the climatic conditions at them for 2005–2014 was not complete or adequate in this context. For the 25 examined sites, SI is calculated based on data for the years 1985–2014. Out of these 25 sites, 6 were selected to be examined with the use of climatic data extending also to 2015–2022. These are the 6 sites for which the dosimetric model was also applied. Their selection was mainly based on data availability and completeness for both the periods 2014–2022 and 1985–2022, and on their distribution across the country (so that they can serve as a basis for future research efforts).

3 Results and Discussion

3.1 Scheffer Index Values for the Examined Sites

In Table 2, the calculated values of SI at the examined sites based on daily data for the periods i) 1985–2004 [5] and ii) 1985–2014, are presented.

Table 2. Scheffer Index values calculated for the examined sites based on the available daily data for the years 1985–2004 (as published in [5]), and for the years 1985–2014.

Site/Station	1985–2004	1985–2014	Site/Station	1985–2004	1985–2014
Agrinio	30.74	31.38	Kerkyra	37.83	44.59
Alexandroupolis	12.79	16.52	Larisa	23.07	24.91
Araxos	31.06	33.60	Mytilini	18.87	19.90
Argostoli	39.58	41.77	Naxos	18.33	20.12
Arta	36.51	37.46	Rodos	24.96	25.00
Athens (Hellinikon)	14.37	14.63	Samos	20.62	22.72
Chania (Souda)	29.58	29.87	Serres	28.71	32.22
Chios	13.83	14.56	Skyros	13.39	15.14
Drama	33.20	38.87	Tanagra	18.78	20.40
Heraklion	27.44	30.57	Thessaloniki (Mikra)	23.04	30.28
Ioannina	37.52	38.09	Tripoli	22.79	24.70
Kalamata	32.86	33.22	Volos (Aghialos)	21.50	23.80
Kavala (Chr/poli)	17.80	21.47			

Table 2 shows a consistent increasing trend for the decay potential across all examined sites when the climatic data for the years 2005–2014 are included in the calculations. While the recorded increase is borderline in some cases (e.g. Rodos), it reaches very

high percentages for some sites. For example, Thessaloniki's SI value that is derived considering the years 1985–2014 is by more than 30% higher than the one based on the period 1985–2004. An interesting observation is that the inclusion of the decade 2005–2014 in the calculations leads to a percentage increase of more than 20% for three sites, all belonging to the northern part of the country. Furthermore, the values of SI that had been derived for these three sites based on the data for the years 1985–2004 belong to the lower half of the respective ones that had been calculated for the list of the examined sites considering the same time period [5].

Notably, this increasing trend must be evaluated also in absolute numbers. As reported in [1], based on the index' value, the severity of the exposure conditions can be ranked in 3 classes: for values lower than 35 the decay potential is considered low; SI higher than 65 corresponds to high decay potential; all other cases indicate intermediate potential. At one site (Drama), the class of the decay potential changes from low to intermediate when the data for the decade 2005–2014 is included in the calculations. In some other cases, although the severity of exposure remains in the same category as before, the increase in the index' value is significant, reaching 6–7 units.

These results outline an increase in the decay potential for wood across the country when more recent data are included in the calculations. In order to further investigate whether this trend is consistent and continuing in time, a second series of calculations was performed taking into consideration also the period 2015–2022. This set of calculations was performed for 6 sites. Evidently, the calculation basis for these sites is even more expanded and the derived results outline the decay potential also for very recent periods. It must be highlighted that this analysis is not exhaustive in terms of the examined sites, but it serves as an indications' basis. The SI values calculated for different intervals in the period 1985–2022, and for its entirety, are listed in Table 3.

Table 3. SI values at 6 sites, based on the available climatic data for 1985–1994 [5], 1995–2004 [5], 2005–2014 and 2015–2022; the results for the period 1985–2022 are also presented.

Site/Station	1985–1994	1995–2004	2005–2014	2015–2022	1985–2022
Alexandroupolis	13.56	13.30	24.82	38.79	20.71
Heraklion	24.44	30.84	37.05	22.98	28.96
Ioannina	34.66	40.16	41.21	97.33	48.23
Kavala (Chryssoupoli)	17.78	19.27	29.17	33.79	23.21
Larisa	23.05	24.21	29.18	48.21	29.62
Mytilini	16.01	21.84	23.10	22.65	20.47

The results shown in Table 3 should be interpreted in combination with the ones listed for these 6 sites in Table 2. For all 6 sites, the SI values based on the expanded climatic base are higher than the respective ones derived for the years 1985–2004. This indicates a shift towards increasing values as time passes. In fact, the expanded database provides a more representative image for each site, enhancing the observation of the increasing decay potential. It is interesting to investigate whether this increase is due to

the increase in the number of days with rainfall, temperature or both. An initial calculation for Ioannina shows that both parameters are increased in 1985–2022 compared to 1985–2004, but this finding is location specific; the relevant investigation must be expanded to more sites for a safer general conclusion to be derived.

At least for the 6 sites listed in Table 3, the increase is not linear or uniform in the individual intervals constituting the larger periods. At one site (Heraklion), the value based on years 2015–2022 is lower than the one for 2005–2014. This trend is marginally the same for Mytilini, while it is strongly reversed for the other stations. Notably, these calculations can be treated only as indications since, among others, the period 2015–2022 is not even 10-years long, i.e. very short for the respective results to be considered as more than indications. Also, this analysis should be accompanied with results for more stations in Greece.

3.2 Application of the Dosimetric Model and Derived Results

In order to account for the different number of days considered for each site, for each station the mean daily dose is calculated. It is derived by dividing the total dose at each site by the number of days that were considered within its calculation. Since the analysis in this work does not aim at the doses themselves as an element of the actual decay estimation, the presented results focus on the study of the mean daily dose variations when the more recent data are also included in the calculations. The mean daily doses that are calculated based on the data for 1985–2004 [5] are compared with those derived for 1985–2022 for each site. Their percent variations are shown in Table 4.

Table 4. Percent variation of the mean daily doses at the 6 examined sites considering the period 1985–2004, when the data for the years 2005–2022 are also included in the calculations.

Site/Station	Alexandroupolis	Heraklion	Ioannina	Kavala (Chr/poli)	Larisa	Mytilini
[%] variation of mean daily dose	16.8%	20.0%	24.0%	15.0%	14.9%	−1.1%

The values shown in Table 4 enhance the image of a general trend of increase introduced by the SI values. The borderline decrease for Mytilini may not be considered to represent a major “breach” to the trend, due to its very low value. The findings for SI suggest similar trends for the majority of the 6 sites; for Mytilini, the respective variation is positive (contrary to the result of the dosimetric approach), but the increase is very low. Notably, even when relative humidity is included in wood’s moisture content estimations, the indicated increase pertains. The differentiations from SI results should be further investigated, considering the impact of relative humidity and the actual model for the calculation of wood’s moisture content on the derived values.

4 Conclusions and Future Research

In this study, the decay potential for wood above ground in Greece has been investigated based on daily data provided by H.N.M.S. for recent decades, with the use of primarily the SI and, secondarily, a dosimetric approach. The analysis focused, apart from analysing the SI results as autonomous values, on the temporal trend of the decay potential. It appears that this trend is generally increasing, suggesting that the change of the climate may indeed induce more severe strains on wooden elements even in areas of generally moderate exposure levels. Generally increasing SI values across Greece had already been indicated in [5], while this tendency of increase in SI values over the years has been identified for other countries as well (e.g [6]).

For this indication to be enhanced, several research steps must be made, including the study of the impact of various calculation parametres on the results (e.g., the mathematical models themselves, the assumptions for the values of the involved quantities). Specifically for Greece, the prevailing conditions at more sites should be investigated with the use of as recent and extended climatic databases as possible, while relevant experimental measurements under the actual prevailing conditions (as performed for various areas of the world) could lead to more reliable estimations.

Abstract. Traffic noise is one of the most persistent environmental stressors in urban and interurban corridors, making low-noise and resource-efficient pavements essential for sustainable mobility. This study investigates how the incorporation of several recycled materials—textile fibres, steel slag aggregates, recycled asphalt pavement (RAP) and residual plastics—modifies the acoustic behaviour of two porous mixtures designed for 80 km/h (interurban) and 50 km/h (urban) traffic. The work provides a mechanistic assessment by linking each residue to the functional parameters governing tyre–pavement noise, namely texture spectrum, air flow resistivity and acoustic absorption, integrated through the SPERoN prediction model. In the interurban double-layer mixture, replacing aramid fibres with 0.1% textile fibres preserved mechanical performance, while steel slag—when properly tamised—enhanced absorption ($\alpha \approx 0.60$) and reduced flow resistivity (≈ 400 Pa·s/m), achieving a noise reduction of -6.2 dB, comparable to the virgin mixture (-6.8 dB). In the urban mixture, slag increased texture but improved overall reduction (-2.0 dB), whereas partial binder replacement by plastics raised texture excessively, limiting performance (-0.9 dB). RAP-based mixtures showed balanced behaviour (-1.5 dB). Results demonstrate that residue-induced changes in macrotexture dominate the acoustic response, while increased porosity and absorption can only partially compensate. The study delivers practical design insights for developing sustainable, circular and acoustically optimised asphalt mixtures

Keywords: low-noise asphalt · recycled materials · steel slag · tyre–pavement noise · acoustic absorption · sustainable pavements

1 Introduction

Road-traffic noise is linked to sleep disturbance, stress and heart disease, with more than 12,000 premature deaths annually and more than 113 million people exposed to $>=$ 55 dB(A) due to road traffic in Europe [1].

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 857–865, 2026.
https://doi.org/10.1007/978-3-032-34930-9_100

Road-vehicle noise has two main contributors—engine noise and rolling noise—and rolling noise becomes dominant above an already moderate speed [1]. For speeds of 30 km/h and above, the road surface is regarded as the most important influencing factor [3].

The pavement's macrotexture strongly influences tyre–road noise, and texture wavelengths map into the sound spectrum even though the overall response is non-linear [1]. A noise reducing asphalt design must also consider porosity, airflow-related resistance (flow resistance or permeability indicators) and acoustic absorption, where higher absorption generally lowers rolling noise when tuned to the tyre emission spectrum and operating speed [1, 2]. A model that combines those factors to predict the noise reduction of a mixture is the hybrid SPERoN model, which combines a physical sub-model with a statistical sub-model [4, 5].

Porous asphalt provides source control by using high air-void content to absorb sound through air-pore-wall interaction, wave-pore interaction and pore-wall resonance [2]. Reported reductions reach up to 5 dB(A) versus dense asphalt and up to 8.5 dB(A) at construction in CPX comparisons, while optimized urban mixtures can achieve around 3 dB compared with conventional roads [1, 2].

However, porous asphalt can lose acoustic efficiency as voids deform or clog with fine particles and debris [2]. Low-noise mixtures must therefore balance noise reduction with rolling resistance and mechanical durability [6]. At the same time, studying the environmental feasibility of new solutions has become a common practice in the construction sector [7] what leads to the need of circular-economy based low-noise asphalt mixture design and validation practices.

This paper evaluates low-noise asphalt mixtures incorporating recycled materials by relating tyre–pavement noise to surface texture, flow resistance (airflow resistivity) and acoustic absorption, with the aim of identifying the influence of different waste materials on noise reduction and providing a knowledge base for the design of sustainable noise-reducing asphalt mixtures.

2 Materials and Methods

2.1 Reference Asphalt Mixtures

Two reference low-noise asphalt mixtures were designed to represent interurban (80 km/h) and urban (50 km/h) traffic while balancing acoustic performance, durability and construction feasibility.

The interurban surface was a double-layer porous asphalt with PA4 as the upper layer and PA8 as the lower layer. Each layer was approximately 20 mm thick (40 mm total), with about 22–23% voids, combining high interconnected porosity with controlled texture to promote absorption and air flow.

The urban surface was a 20 mm dense low-noise mixture with 4 mm maximum aggregate size and about 9–12% voids, selected to reduce texture while maintaining mechanical resistance under braking and acceleration.

Both mixtures used PMB 45/80–65 bitumen and conventional aggregates; they were the baseline for assessing the acoustic influence of the recycled materials.

2.2 Recycled Materials Evaluated

Five recycled-material configurations were assessed as substitutes for conventional mixture components (Table 1). **Recycled textile fibres** from post-consumer waste replaced aramid fibres used to stabilise binder in porous asphalt and prevent drainage.

Steel slag, evaluated as received and after sieving, replaced natural aggregates; sieving was used to better adjust gradation and mixture porosity.

Residual plastics from post-consumer streams partially replaced bitumen in the urban mixture, and **recycled asphalt pavement (RAP)** replaced part of the aggregate fraction while contributing aged binder.

The tested configurations and residue functions are summarised in Table 1.

Table 1. Mixtures and recycled materials evaluated.

Mixture	Traffic environment	Residue incorporated	Function of residue
PA4 + PA8 porous mixture	Interurban (80 km/h)	Textile fibres	Replacement of aramid fibres
PA4 + PA8 porous mixture	Interurban (80 km/h)	Steel slag	Replacement of natural aggregates
Urban low-noise mixture	Urban (50 km/h)	Steel slag	Replacement of natural aggregates
Urban low-noise mixture	Urban (50 km/h)	Residual plastics	Partial binder replacement
Urban low-noise mixture	Urban (50 km/h)	RAP	Replacement of aggregates and aged binder

2.3 Specimen Preparation

The mixtures were produced at laboratory scale following a conventional hot-mix asphalt procedure. Aggregates were batched according to each target gradation and mixed with PMB 45/80-65; hydrated lime and fibres were added to the porous interurban mixtures to improve cohesion and prevent binder drainage. The reference mixtures were composed of coarse and fine aggregate fractions, mineral filler, polymer-modified bitumen and fibres when required. In the recycled mixtures, the corresponding secondary material replaced the conventional component: textile fibres for aramid fibres, steel slag for natural aggregate, plastics for part of the binder and RAP for aggregate/aged binder.

Functional acoustic tests were performed on cylindrical specimens reproducing the layer configuration relevant for surface-related acoustic behaviour. The interurban specimens reproduced the in-service double-layer system, with a PA8 lower layer and a PA4 upper layer of 20 mm each, resulting in a total thickness of 40 mm. The PA8 layer was placed first and the PA4 layer was subsequently added in the same mould, so that the acoustic tests were performed on the final two-layer configuration rather than on isolated layers. The urban mixtures were prepared as single-layer specimens with a

nominal thickness of 20 mm for acoustic and surface-related testing. In all cases, the mixture mass was adjusted to obtain the target thickness and void content of each formulation. Mechanical characterisation, when required, was carried out on specimens prepared according to the corresponding EN 12697 test methods, in order to assess the mixture formulation under standardised laboratory conditions.

Specimens used for ISO 10534-2 had a nominal diameter of 100 mm to fit the impedance tube and maintain plane-wave conditions within the frequency range of pavement-acoustic interest, below approximately 1.8 kHz. The exposed test surface was the tyre-contact surface: the PA4 upper layer for interurban specimens and the compacted wearing surface for urban specimens.

2.4 Acoustic Characterization of Mixtures

The acoustic behaviour of the mixtures was evaluated through the functional parameters governing tyre–pavement noise generation. Three key properties were measured: surface texture spectrum, air flow resistivity and acoustic absorption.

The **surface texture spectrum** was measured on the exposed surface of the specimens using a high-resolution laser scanning device. The resulting surface profiles were processed according to ISO 13473-4 to determine texture levels over the wavelength range relevant for texture-induced rolling noise. For the interurban double-layer specimens, the measured surface corresponded to the PA4 upper layer, whereas for the urban mixtures the surface corresponded to the single compacted layer.

The **air flow resistivity** was determined following DIN EN 29053 by relating the pressure difference generated by air passing through the surface to the flow velocity. The parameter reflects pore connectivity and the ability of the mixture to reduce air-pumping noise.

The **acoustic absorption coefficient** was measured according to ISO 10534-2 using a 100 mm impedance tube. The specimen was placed at the tube end, a loudspeaker generated a plane wave, and two microphones separated the incident and reflected waves to calculate the normal-incidence absorption coefficient as a function of frequency. The coefficient represents the ratio between the sound energy absorbed by the specimen and the incident sound energy. For double-layer specimens, the wave was applied from the PA4 surface to reproduce the in-service orientation.

The maximum absorption coefficient and its peak frequency were recorded. Particular attention was given to the peak frequency, since high absorption is acoustically effective only when it is aligned with the dominant rolling-noise frequency range. Therefore, mixtures with similar absorption coefficients may lead to different predicted noise reductions if the peak occurs outside the most relevant frequency band.

2.5 Noise Prediction Model

The acoustic performance of the mixtures was estimated using the **SPERoN model** [4, 5], which predicts tyre-pavement noise from surface texture, air flow resistivity and acoustic absorption. The measured texture spectra, flow resistivity values and absorption parameters described above were used as input data to estimate the expected noise reduction relative to a reference pavement surface.

In this study, the predicted noise reduction was calculated relative to conventional reference surfaces: SMA11 for interurban mixtures and AC16 for urban mixtures. By combining the measured functional parameters with the SPERoN model, it is possible to evaluate how the incorporation of recycled materials modifies the acoustic performance of the asphalt mixtures.

3 Results and Discussion

The main acoustic results obtained for the studied mixtures are summarised in Table 2.

Table 2. Acoustic performance and predicted noise reduction of the analysed mixtures.

	Speed (km/h)	Air flow resistivity (Pa·s/m)	Acoustic absorption coefficient (−)	Peak absorption frequency (Hz)	Predicted noise reduction (dB(A))
Interurban reference	80	820	0.40	–	−6.8
Interurban with sieved slag	80	398	0.60	656	−6.2
Interurban with unsieved slag	80	1139	0.32	498	−4.8
Urban reference	50	29166	0.10	–	−1.6
Urban with slag	50	11592	0.61	1517	−2.0
Urban with slag and plastics	50	3705	0.73	1743	−0.9
Urban with RAP	50	5256	0.65	1517	−1.5

The reference interurban porous mixture achieved the best overall acoustic performance (−6.8 dB(A)), confirming the effectiveness of double-layer porous asphalt surfaces where interconnected porosity and limited macrotexture contribute to sound absorption and reduced air pumping.

The replacement of virgin aramid fibres with recycled textile fibres did not produce significant changes in the acoustic response of the interurban mixture, while mechanical performance remained acceptable. This result indicates that recycled fibres can successfully perform the stabilising role of conventional fibres without compromising the functional behaviour of the porous surface.

The incorporation of steel slag aggregates had a more pronounced effect on the interurban mixtures. The mixture produced with sieved slag showed the most favourable combination of acoustic parameters, with a relatively low air flow resistivity (398 Pa·s/m) and a high absorption coefficient (0.60), resulting in a predicted noise reduction of −6.2 dB(A).

In contrast, the use of unsieved slag increased air flow resistivity to 1139 Pa·s/m and reduced the absorption coefficient to 0.32, lowering the predicted noise reduction to −

4.8 dB(A). These results indicate that the acoustic benefit of steel slag depends strongly on gradation control and the resulting pore structure.

The surface texture spectra obtained for the interurban mixtures are shown in Fig. 1.

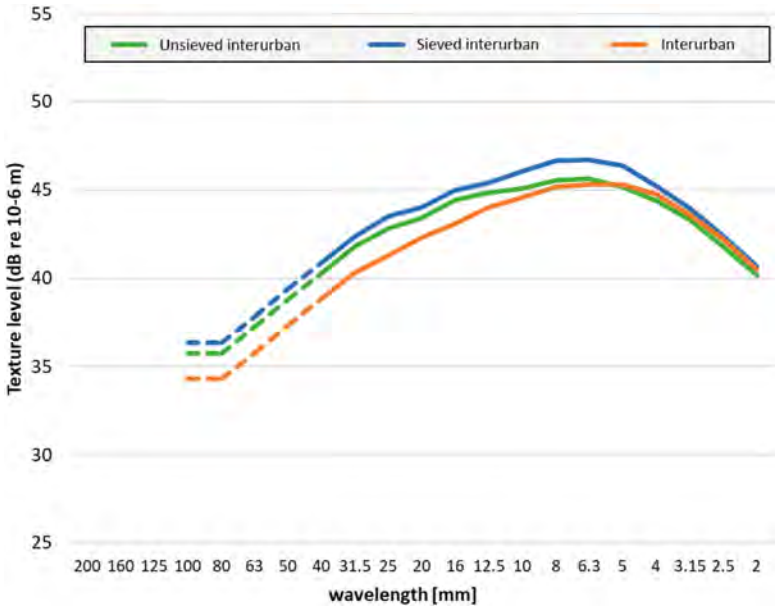

Fig. 1. Texture spectrum of the analysed interurban mixtures.

As illustrated in Fig. 1, the mixtures incorporating steel slag exhibit slightly higher macrotexture levels than the reference porous mixture, particularly in the wavelength range between approximately 10 and 50 mm. The mixture produced with sieved slag presents a more controlled texture spectrum, whereas the mixture with unsieved slag reflects the wider aggregate size distribution and a less homogeneous surface structure. These differences are consistent with the variations observed in air flow resistivity and acoustic absorption.

This comparison shows that the influence of slag cannot be interpreted from texture alone. The sieved slag mixture retained a texture spectrum close to the reference while maintaining a more favourable pore network, whereas the unsieved slag mixture combined higher resistivity with lower absorption. The acoustic penalty is therefore linked to the simultaneous modification of surface texture and internal connectivity.

In the **urban mixtures**, the overall acoustic performance was lower than in the porous mixtures due to the reduced void content and the more closed internal structure. The reference urban mixture achieved a predicted noise reduction of approximately **−1.6 dB(A)** relative to the AC16 reference surface. The higher peak absorption frequencies observed in the urban mixtures are consistent with their lower thickness and different pore structure, which shifts the absorption response towards higher frequencies.

The mixture incorporating **steel slag aggregates** slightly improved the predicted noise reduction to **−2.0 dB(A)**. This improvement suggests that the modified internal structure of the mixture still provides a favourable balance between macrotexture and sound dissipation mechanisms.

However, the incorporation of **residual plastics as a partial binder replacement** produced a different effect. Although the mixture showed increased acoustic absorption (**0.73**) and reduced air flow resistivity (**3705 Pa·s/m**), the predicted noise reduction decreased to approximately **−0.9 dB(A)**. This result indicates that the increase in surface macrotexture associated with the reduced workability of the plastic-modified mixture dominates the acoustic response, offsetting the benefits of the improved absorption.

The mixture incorporating recycled asphalt pavement (RAP) exhibited an intermediate behaviour (−1.5 dB(A)), remaining close to the reference urban mixture and indicating that RAP can be incorporated without a strong acoustic penalty.

Overall, the results demonstrate that the acoustic behaviour of asphalt mixtures incorporating recycled materials depends primarily on how these materials modify the **surface texture spectrum and pore connectivity** of the mixture. Increased acoustic absorption and reduced air flow resistivity can contribute to improved noise mitigation, but only when they are not accompanied by excessive macrotexture. In this sense, the results indicate that **macrotexture is the dominant parameter controlling the final noise response**, while acoustic absorption and air flow resistivity act as secondary compensating mechanisms.

These findings highlight the importance of considering functional acoustic parameters when introducing recycled materials into low-noise asphalt mixtures. Proper control of aggregate gradation, pore connectivity and surface texture is therefore essential to ensure that circular pavement solutions maintain or improve their acoustic effectiveness, providing practical guidance for the design of sustainable low-noise pavements incorporating recycled materials.

4 Conclusions

The results demonstrate that several recycled materials can be incorporated into low-noise asphalt mixtures without necessarily compromising acoustic performance. The acoustic behaviour of the analysed mixtures was interpreted through the functional parameters governing tyre-pavement noise generation: surface texture, air flow resistivity and acoustic absorption.

The replacement of virgin aramid fibres with **recycled textile fibres** proved to be technically viable, maintaining both the mechanical stability and the acoustic response of the porous mixture. This result highlights the potential of recycled fibres as a circular alternative for binder stabilisation in porous asphalt mixtures.

The incorporation of **steel slag aggregates** showed promising results, particularly when the material was properly sieved. The sieved slag mixture presented favourable air flow resistivity and acoustic absorption values, resulting in a predicted noise reduction comparable to that of the reference porous mixture. In contrast, the use of unsieved slag led to poorer acoustic performance due to a less controlled pore structure.

For **urban mixtures**, the influence of recycled materials was more limited due to the lower porosity of the mixture. Steel slag slightly improved the predicted noise reduction,

while mixtures incorporating **residual plastics** showed a decrease in acoustic performance despite increased absorption. This behaviour indicates that excessive macrotexture may dominate tyre–pavement noise generation, offsetting potential benefits associated with improved acoustic absorption.

The **RAP** mixture exhibited intermediate behaviour, indicating that reclaimed materials can be used without significantly affecting pavement acoustic response.

Overall, successful integration of recycled materials in low-noise pavements depends mainly on how they modify **surface texture and pore connectivity**. Proper control of aggregate gradation and mixture design is therefore essential to ensure that circular asphalt solutions maintain or enhance acoustic effectiveness.

Abstract. This paper is based on the preliminary phase of a larger project to develop a version of the ITACA Protocol specifically for university campuses in Italy. This phase is divided into two stages: theoretical and implementation. In the Theoretical part, 44 thematically relevant papers were reviewed in full text, and the indicators used in them were extracted, resulting in 258 unique indicators. The indicators were classified according to the SNTool's categories. Then, their units and frequency of occurrence, defined as the number of papers in which each indicator appeared, were recorded. In the Implementation part, 20 of the most frequently used indicators- for which there was enough data from the Politecnico di Torino (POLITO) - were selected, and the sustainability score of POLITO was calculated based on them. In the next step, a Q-sort analysis was conducted to prioritize 10 SWOT-based actions, and 3 future scenarios were identified. Finally, for all the scenarios, feasibility studies were conducted to assess the improvement and corresponding sustainability scores. The scenario with the highest score was identified as the best option

Keywords: SNTool · ITACA Protocol · SBTool · iiSBE · Sustainability Assessment Framework · Campus Indicators

1 Introduction

1.1 Aligning the National Sustainability Protocol with University Campuses

A university campus is viewed as a "small city", with flows of people and resources, and a wide range of services—making it an ideal living laboratory where sustainability solutions can be tested before being scaled up to urban and national levels. The ITACA Protocol [1] serves as Italy's green building rating system. ITACA is based on the international model, SBTool [2], which is primarily designed for the assessment of individual buildings. To align this national framework with the scale of a campus, instead of SBTool, its neighborhood/urban counterpart, SNTool [3], was applied. Both tools share the same underlying iiSBE [2] methodology, based on local customization. This work is built upon research conducted in the author's master's thesis [4].

2 Methodology

Figure 1 a and b show the methodology in the theoretical and implementation phase, respectively.

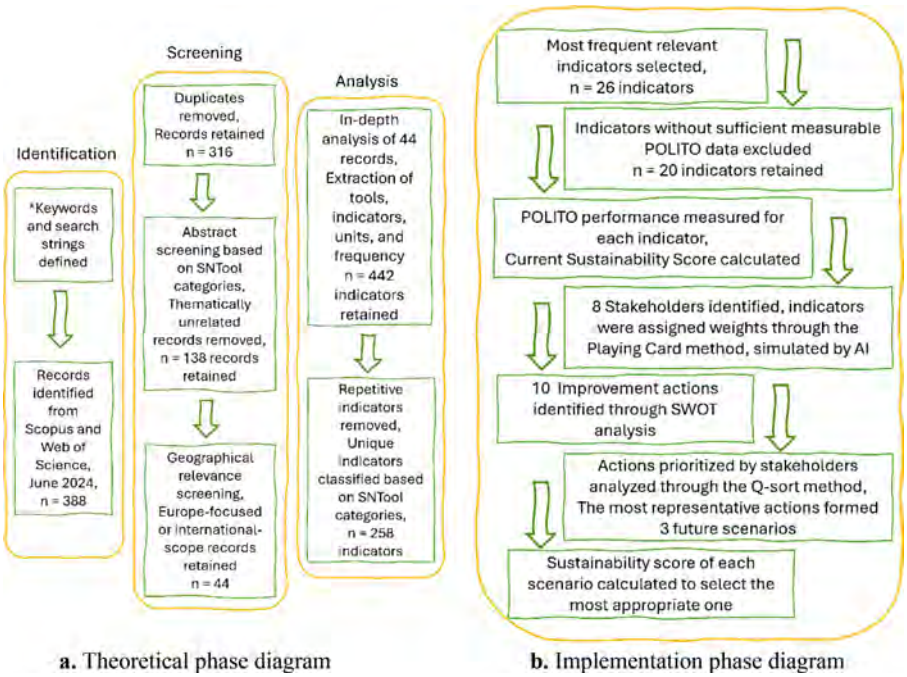

Fig. 1 a. Theoretical phase diagram. b. Implementation phase diagram. *Search strings combined terms related to sustainability assessment tools, university/campus contexts, and sustainability indicators/performance using Boolean operators.

2.1 Implementation Phase

Forming the Indicator Set and Calculating the Categories' Score. The implementation phase began with selecting the most frequently used indicators identified in the literature. Frequency was defined without any fixed numerical threshold, but simply as the number of articles in which each indicator appeared. From this phase, 26 indicators were initially selected. Among them, 20 were retained because sufficient measurable data were available for Politecnico di Torino (POLITO). For each indicator, the performance value was calculated, using formulas or assessment procedures derived from literature, and normalized according to the SNTool scale from −1 to 5. In this scale, −1 indicates performance below the minimum benchmark, 0 corresponds to the minimum benchmark, and 5 represents the maximum benchmark. The benchmark values were not locally calibrated for the Italian context; they were extracted from the source or assessment tool from which they were derived, mainly STARS or UI GreenMetric. Finally,

category scores were calculated as the mean value of the normalized indicator scores within each category (Table 1).

Assigning Weight to the Indicators. The weight assignment was done through the playing-cards method. In total, eight stakeholders were identified. In this preliminary phase, the preferences of eight stakeholders were simulated using AI-generated stakeholder profiles. Therefore, the weighting process should be considered an exploratory step rather than the result of direct stakeholder engagement. To set the indicators in the stakeholders' order of preference, the stakeholders' average rankings for indicators were considered (Fig. 2). The ranks were then converted to a final consensus table, placing the indicators in an ascending order of importance. Based on the differences in average ranks, the following rule was applied:

- If the indicators had exactly equal ranks → they were placed in the same row, and were divided by + (shared ranking).
- If the difference > 1→ a white card was inserted between them. (Each one unit of difference was equal to one white card)
- If the difference ≤ 1→ indicators were placed successively without a white card. To compare indicators on a relative scale, the weights were also normalized to a sum of 100% (or 1).

Area for water absorption / total open area
Area on campus covered in planted vegetation
Users using more sustainable commuting options
Open space area / total campus population + Publicly shared facilities
Total vehicles (cars & motorcycles)/ campus population
% of university budget for sustainability efforts

Organic waste treatment + Inorganic waste treatment + Availability of containers for sorted waste + Water consumption (per person) + Water conservation program & implementation
Annual electricity consumption / m2 + Annual heat energy consumption / m2
White Card
Annual GHG emissions (electricity/m2) + Annual GHG emissions (thermal/m2) + Share of renewable electricity consumption (E-renewable / E-total)
Annual scope 1 & 2 GHG emissions (per person)

Fig. 2. Final consensus of implementation indicators

Current Performance Score of POLITO. The weight of each category is the sum of the weights of its indicators. The performance score in each category is calculated by multiplying the category's score by the category's weight. Finally, the overall sustainability performance score is obtained as the sum of all category performance scores divided by 100.

Future Scenarios. The next step focuses on improving the current situation. Based on a SWOT analysis, 10 actions were identified. As with the indicators, these actions were

ranked by AI-simulated stakeholders according to their preferences, and a Q-sort analysis [5] was then used to identify converging opinion trends. This process resulted in three future scenarios, each including the same ten actions arranged according to stakeholder preference. To reduce complexity, only the first three actions in each scenario, or the most representative ones, were selected for further analysis. For each future scenario, a feasibility assessment was then conducted to determine whether the proposed actions were feasible and to estimate the expected improvement in the corresponding indicators. Tables 2, 3 and 4 summarize these improvements.

3 Results and Discussion

3.1 Theoretical Results

Theme. Figure 3 shows the 138 thematically relevant studies according to SNTool's categories. Since most studies adopt a comprehensive approach in their assessment there is no significant difference among most categories. Still three categories emerge as the most addressed: Energy Climate Change Mitigation and Social Aspects aligning with two pillars of sustainability assessment topics: People and Planet. The third pillar economy however is the least regarded. Firstly because in comparison with education research or social involvement economy is not the priority of universities in general. Secondly since many of the Higher Education Institutions regarded are state universities their financial stability is guaranteed through the state budgets. Finally because there is no standard methodology to assess financial sustainability [6]

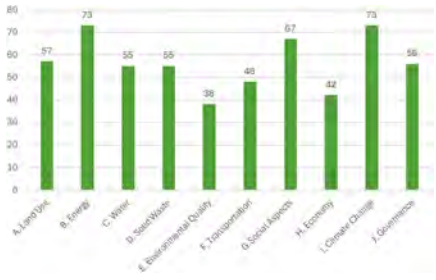

Fig. 3. 138 thematically relevant studies according to SNTool's categories

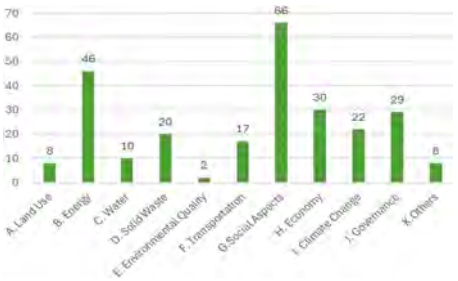

Fig. 4. 258 unique indicators according to SNTool categories

Indicators. Figure 4 illustrates the 258 unique indicators according to the SNTool's categories. It shows that "Social Aspects" and "Energy" account for the largest share. The surge in Social Aspects is due to a structural issue: campuses are not neighborhoods, and some campus-specific themes do not map neatly into urban categories [7, 8]. Similarly, in neighborhood-scale frameworks, such as SNTool, there is no specific category for academic and research-related aspects. Indicators, on the other hand, have been collected from campus sustainability studies, with many of them belonging to research-related

categories. These indicators are consequently classified under "Social Aspects", in addition to the original social indicators. The very small number of environmental quality indicators also suggests the same issue: environmental quality (e.g., particulate matter in the air) is considered essential in neighborhood/urban studies, but appears much less in campus studies, at least among the 44 studies reviewed.

3.2 Implementation Results

Table 1. Final list of 20 sustainability indicators

Category	Indicator	Performance Score	Low Benchmark	High Benchmark	Normalized Score	Normalized Weight	Category's Score	Category's Weight	Category weighted score
Use of Land	Area on campus covered in planted vegetation (%)	7.00	10	40	-1.0	0.88	-1	2.86	-2.86
	Open space area/total campus population (m^2 per capita)	4.3	10	70	-1.0	1.98			
Energy	Annual heat energy consumption (kWh per m^2)	51.77	130	50	4.9	7.27	2.65	23.35	61.96
	Annual electricity consumption (kWh per m^2)	57.88	180	30	4.1	7.27			
	Electricity-Renewable/Total (%)	6.15	10	30	-1.0	8.81			
Water	Water use (L/person/day)	16.09	54	14.5	4.8	5.73	3.65	11.46	41.83
	Water conservation program and implementation (%)	25	0	50	2.5	5.73			
Waste	Organic waste treatment (%)	100	0	85	5.0	5.73	4	17.19	68.76
	Inorganic waste treatment (%)	100	0	85	5.0	5.73			
	Availability of containers for sorted waste (n/1000m^2)	0.3	0	0.8	2.0	5.73			
Transportation	Bicycle parking spaces /total campus population (n/person)	0.03	0.01	0.07	2.3	3.96	3.98	7.92	31.52
	Total vehicles (cars & motorcycles)/total campus population	0.01	1	0.045	5.0	2.64			
	Users using more sustainable commuting options (points)	5.57	0	6	4.6	1.32			

Final Sustainability Score for the Current Situation. Table 1 shows a representative selection of the 20 final indicators, while the complete set was used in the assessment. The sum of all categories' weighted scores amounts to 328 points, which, when divided by the total weight (100), yields an overall score of 3.28 out of 5, representing POLITO's sustainability performance across the twenty indicators (Fig. 5).

Future Scenarios. Performing the Q-sort methodology on the actions, prioritized by the stakeholders, revealed three clear structures named as future scenarios. Tables 2, 3 and 4 summarize the first three actions in these scenarios and how they affect their corresponding indicators. The overall sustainability score for each scenario is shown in Figs. 6, 7, and 8, respectively.

Table 2. First future scenario, focusing on governance, investment, and long-term transition measures, represented mostly by institutional actors.

Actions	Annual electricity per m^2	Renewable electricity share	Containers for waste	Sustainability courses/total	GHG operations per person	GHG (electricity) per m^2
By 2030, double the PV share	−6.63%	100%			−5.6%	−8.7%
By 2030, increase the share of sustainability courses to 80%				26%		
By 2030, double the sorted-waste collection points.			100%			

Table 3. Second future scenario, focusing on users' daily needs and comfort, represented mostly by Students and Technical Staff.

Actions	Planted vegetation area	Bicycle parking spaces per capita	Users using more sustainable commuting options	Publicly shared facilities
By 2030, upgrade and expand campus facilities				63.2%
By 2030, double the share of green areas within the total open area	100%			
By 2030, enhance sustainable mobility: reducing daily trips by private cars to 0, increasing the bicycle parking spaces to at least 50%		50%	7.7%	

Table 4. Third future scenario, capturing minor differences as a secondary nuance rather than a fully distinct viewpoint.

Actions	Annual electricity per m^2	Renewable electricity share	Water use per person	Bicycle parking spaces per capita	Users using sustainable commuting	GHG operations per person	GHG (electricity) per m^2
By 2030, double PV share	−6.63%	100%				−5.6%	−8.7%
By 2030, 10% reduction in water consumption			−6%				
By 2030, enhance sustainable mobility				50%	8%

Fig. 6. Final assessment of the first Future Scenario. **Score: 3.58**

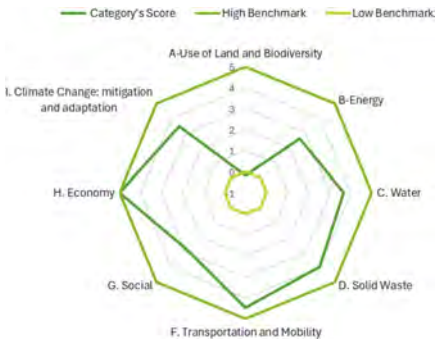

Fig. 7. Final assessment of the second Future Scenario. **Score: 3.37**

Fig. 8. Final assessment of the third Future Scenario. **Score: 3.48**

3.3 Discussion and Concluding Remarks

The results show that adapting sustainability assessment tools to university campuses requires more than transferring building- or neighborhood-scale indicators. Several campus-specific aspects, especially those related to education, research, participation, and everyday campus life, are not fully captured by existing SNTool categories. This confirms the need for a tailored framework for university campuses.

A limitation of this preliminary application is that stakeholder preferences were simulated through AI-generated profiles and were not collected through direct stakeholder participation. Future development of the framework should involve real campus stakeholders in the weighting and scenario-building process and test the proposed approach on other Italian university campuses.

Another limitation concerns the benchmark values, which were taken from the original assessment tools rather than calibrated specifically for the Italian or regional context. This limitation also highlights one of the main reasons for developing a campus-specific sustainability assessment framework: existing benchmarks are often available at the building, urban, or neighborhood scale, while university campuses represent a more specific institutional and spatial context that is not yet sufficiently covered by localized reference values. Future development of the framework should define locally adapted benchmarks for Italian university campuses.

Demand-Responsive Transport (DRT) for Sustainable Rural Tourism: A Participatory Action Research Case Study in Latvia

Mara Grinberga-Silaua(✉), Dace Dance, and Sarmite Rozentale

Vidzeme University of Applied Sciences, Valmiera, Latvia
mara.grinbergasilaua@va.lv

Abstract. High dependency on private automobiles threatens ecological integrity and the transition to sustainable transportation in rural tourism, notably in Latvia's Gauja National Park. The economic inefficiency of fixed public transit and connection concerns creates a "mobility paradox" of unused infrastructure and dependence. Tourists also face major "last mile" connectivity problems. In a participatory action research (PAR) case study, 10 entrepreneurs from heritage manor hotels, beverage companies and nature conservation agencies participated between April 2025 and January 2026. Seven entrepreneurs found demand-responsive transport relevant to their companies, and the remaining three participated in the PAR process on transitions towards sustainable mobility and the circular economy. Within this partnership, sustainable growth is hampered by systemic logistical barriers, including empty movements, challenging planning and a lack of digital tools for SMEs. Authors propose Demand-Response Transport (DRT) to address these challenges. The goal is to combine minimal planned service provision with flexible, demand-oriented mobility by simulating infrastructure distribution using GIS-based data processing. The primary result is strategic recommendations through DRT, a publicly run, digitally enabled (PMDE) system that turns underutilised bus stops into valuable assets and removes barriers to SME collaboration. With synchronous logistics and digital gig-economy platforms, SMEs become active moderators of mobility, thereby making the system cost-effective. The study concluded that there is a need for a Regional Mobility Agency with a single digital platform to manage smooth booking and tracking, and to guide tourists toward sustainable "silent mobility" solutions

Keywords: Sustainable rural mobility · Demand-Responsive transport · Policy planning · Transport poverty · Active mobility

1 Introduction

The transition to sustainable mobility is a cornerstone of European rural mobility and nature tourism, as well as the European Green Deal; however, rural regions, such as Latvia's sparsely populated areas, including nature parks like Gauja National Park (GNP), face a significant "mobility gap" that threatens their ecological integrity [1,

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 875–882, 2026.
https://doi.org/10.1007/978-3-032-34930-9_102

2]. This gap is a key driver of transport poverty, which, in the context of rural tourism and mobility, is defined as the inability of individuals—both tourists and locals—to access essential services, transport hubs, or employment opportunities due to a lack of affordable, reliable, or physically accessible public transport [3]. While urban centres have greater access to dense public transport networks, rural tourism remains heavily dependent on private vehicles, as traditional fixed-route public transport is not economically viable in Latvia's countryside and GNP. This situation creates a mobility paradox: visitors seeking "unspoiled nature" indirectly contribute to carbon emissions and noise pollution due to fragmented "last-mile" connectivity.

Studies and interviews with local small and medium-sized enterprises (SMEs) indicate that regional transport faces several systemic challenges. The "last-mile" problem stands out, as public transport routes often end several kilometres from the destination, necessitating additional private transport [4, 5]. A lack of information often compounds this physical barrier, as complex schedules make it difficult for modern tourists to navigate. Furthermore, infrastructure limitations, such as a lack of charging stations and "parking fees" for car-sharing in non-designated zones, hinder sustainable mobility. In terms of operations, SMEs observe inefficiencies, such as "empty runs", and lack the financial and human resources to implement digital tools, such as GPS tracking or AI-driven logistics, necessary for route optimisation.

The proximity of existing transport infrastructure, e.g., stations and stops, is often seen as a logistical obstacle rather than an advantage. This situation creates an unused competitive advantage for rural tourism service providers. To address these shortcomings, this study proposes a demand-responsive transport (DRT) strategy – a flexible, technology-based service that operates without fixed routes or schedules [6]. The study uses participatory action research (PAR) (a collaborative approach to inquiry that combines research, action, and education) with 10 tourism-related organisations to show how tourism operators can move from passive observers to active mobility enablers [7]. By demonstrating a possible "publicly managed, digitally enabled" (PMDE) model, this study outlines a collaborative problem-solving process, including coordinated transport and digital ride-sharing, that uses distance as a strategic advantage.

2 Context

The study was conducted as action-oriented research from April 2025 to January 2026. Its main objective was to assess the resources and processes that facilitate the transition to a circular economy and the Green Deal within the regional tourism system and tourism-related organisations. The organisations involved in the study represented various segments of the industry, including rural manor hotels, event organisation, and beverage producers who combine manufacturing with tourism. The study also included large-scale government agencies involved in nature conservation and environmental education, as well as the largest regional public transportation provider.

Through this initial study and interviews with rural SMEs, several systemic issues were identified that hinder regional mobility and are primarily related to the "last-mile" problem. In many cases, public transport routes end several kilometres before the final destination (Fig. 1), thereby forcing reliance on private transport and creating a "mobility gap" that threatens the region's ecological integrity due to a lack of connectivity. In

some areas, there are no taxis or similar services, which makes mobility without private vehicles even harder. A lack of information often exacerbates this physical barrier, as travellers find existing schedules too complicated or insufficiently tailored to facilitate travel without a car. Infrastructure constraints further hinder the transition to sustainable and active mobility; for instance, the lack of electric vehicle charging stations discourages "green" travellers; car-sharing users often incur additional costs because their destinations are not designated as official drop-off areas. Service providers face inefficiencies. That leads to unnecessary fuel consumption and emissions when picking up guests on extra rides. In addition, many organisations lack the financial and human resources to implement modern digital tools, such as GPS tracking and AI-driven logistics, which are necessary to optimise regional routes and reduce the environmental impact of rural tourism.

3 Literature Review

The theoretical framework explains the transition from traditional, high-capacity infrastructure and services to a flexible, decentralised network designed to address specific logistical challenges in sparsely populated rural areas. This transition is grounded on the last-mile theory, which states that the main obstacle to sustainable travel is the separation between transit hubs and destinations [4, 5]. In rural settings, this gap often leads to transport poverty, defined as the systematic inability of individuals to access essential services or destinations due to a lack of affordable and reliable transport options [3, 8]. This theory explains why tourists in the Gauja National Park (GNP) rely on private vehicles, as the current fixed-route system remains economically disadvantageous for both service providers and users. To address these challenges, the study uses the demand-responsive transport (DRT) paradigm, which is based on a flexible, technology-driven approach with no fixed routes or schedules. As supported by the DRT theory, this approach enables the development of a model that transforms underused infrastructure, such as bus stops, into functional assets by dynamically directing smaller vehicles only when needed, achieving cost efficiencies where traditional routes have not been cost-effective [6, 9].

The Resource-Based View (RBV) of the firm anchors the solution of SMEs, transforming passive stakeholders into active mobility moderators. RBV management theory states that firms achieve sustainable competitive advantage by acquiring and utilising internal resources that are Valuable, Rare, Inimitable, and Organised (VRIO) [10–12]. In this study, SMEs apply strategic agency to manage the "last mile", converting physical distance into a competitive asset by internalising guest transport logistics. Finally, the framework integrates sharing economy principles that allow a diverse cross-section of stakeholders to leverage localised resources, such as community drivers, through platforms like Abillio, where freelancers could more easily and legally be paid for their services, to bridge connectivity gaps without the high capital costs of private fleet ownership [13, 14]. While the primary focus remains on connectivity and agency, this framework allows for the future integration of the Energy Loop model, where decentralised renewable energy could eventually fuel electric mobility to guarantee long-term operational resilience in GNP or similar areas [15, 16].

4 Methodology

The study focuses on the Gauja National Park (GNP) area, particularly investigating the operational integration of tourism SMEs, including hotels, cafes, and museums.

The methodology was structured into three levels to address challenges identified by the entrepreneurs:

1. Qualitative Engagement (PAR): At this stage, the primary focus was on helping organisations see the transition from structural passivity regarding transport constraints to strategic agency. By taking control of transportation in-house, SMEs were able to address the "last-mile" problem and the lack of tailored information by creating their own "travel prescriptions" for guests. Data were gathered using two complementary methods across all 10 tourism-related organisations from April 2025 to January 2026. The first involved a structured survey instrument on organisational sustainability practices across thematic blocks, including waste management, water use, energy, transport, green investments, circular economy readiness, and biodiversity. Second, in-person semi-structured interviews were conducted with organisational representatives to deepen and contextualise survey responses. Qualitative and quantitative data were analysed using a structured coding framework based on two analytical dimensions. Responses were initially categorised according to the business processes defined as data entry points for each organisation. Second, responses were assessed on five circular economy characteristics: (1) resource efficiency, (2) supply chain transparency, (3) product and service life extension, (4) waste prevention, and (5) system-level innovation. This two-dimensional matrix enabled a systematic comparison of organisational practices across entrepreneurs and the identification of both barriers and enablers of circular, sustainable mobility. Conclusions were drawn through interpretive synthesis, by cross-referencing the coded qualitative findings with the quantitative spatial and financial modelling results described in steps 2 and 3 below.
2. Quantitative spatial analysis: Using geographic information system (GIS) data, the study modelled the distribution of underused public transportation infrastructure to identify where the "bridge" between high-capacity hubs and destinations was missing.
3. Socio-technical modelling: To address the shortage of financial and human resources, stochastic financial modelling was used to assess the feasibility of utilising third-party digital platforms, such as Abillio. The results indicate that freelancers could be a missing part of the model, and the economic model can provide the necessary digital tools and tax compliance without the additional costs of traditional employment.

5 Results

The results of this study indicate a significant shift in the functional role of rural tourism SMEs, which are transforming from passive observers of transit restrictions into active promoters of mobility. By implementing "last-mile" control, these organisations effectively take over the final part of the guest's journey. This solution is achieved by implementing demand-driven transport services that are coordinated with the company's existing logistics—such as supplier procurement or employee shifts—thereby reducing "empty runs" and maximising resource efficiency. "Last-mile" control can be

influenced by entrepreneurs, who cannot change state policies but can improve local transport. As shown in the spatial analysis of the region (Fig. 1), the basic infrastructure for this multimodal transition already exists; however, the most significant shortcoming is not coverage but rather intermodal connectivity. Specifically, there is a critical need to improve signage and information and ensure a seamless physical transition from major transport hubs to tourist routes, such as Mežtaka, which is part of the European long-distance hiking route E11 [17]. The results show that offering specific "travel recipes", such as predetermined train and minibus departure times, reduces the psychological barrier caused by rural isolation and significantly improves car-free travel.

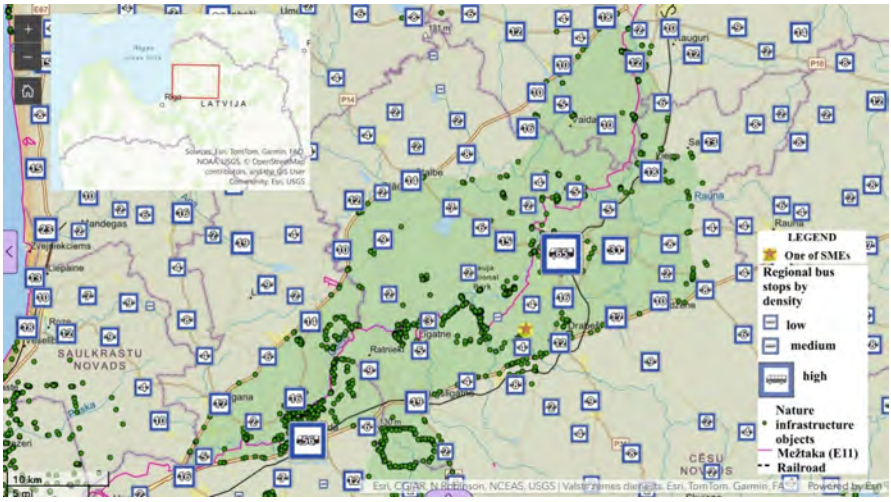

Fig. 1. Map of Gauja National Park public transport infrastructure and natural objects. Source: M.Grīnberga-Šilaua, cartographer M.Ķibers, 2025

The study showed that a collaboration and car-sharing model is essential for reducing the capital investment required to establish a fleet of specialised vehicles. The seasonal minibus route, which operates from May to September, has been recognised as an effective solution when costs are shared among a network of local businesses. Localised sharing economy is further facilitated by digital service economy platforms, such as "Abillio", which allows SMEs to legally hire individuals as on-demand drivers while complying with tax requirements and avoiding the complexities of traditional employment. Digital integration is a significant factor of this connectivity, using QR codes for instant access to schedules, event-specific ride-sharing platforms, and Google Maps to simplify the tourist experience. This is supported by other research indicating that psychological factors, such as perceived ease of use and behavioural control, are fundamental drivers in the successful adoption of pro-environmental mobility choices [18]. Strategic partnerships with shared mobility service providers, such as Bolt Drive and CityBee, further enhance the ecosystem by providing official drop-off zones, effectively reducing the need for private vehicles in the region.

6 Discussion and Conclusion

The study demonstrates that the mobility gap in rural protected areas, such as Gauja National Park, is not a geographical barrier but rather a logistical one that can be overcome through SME-led initiatives. Based on the theory of competitive advantage and the resource-based view, this model demonstrates that integrating transport management within organisations enables them to achieve outstanding sustainability results. By transitioning from passive observers to active mobility facilitators, tourism service providers can turn physical distance into a competitive advantage. This transition demonstrates that demand-responsive transport (DRT) offers a viable alternative to the current car-centric tourism dilemma. As indicated by the infrastructure mapping in Fig. 1, the presence of an existing but disconnected network suggests that the main problem is the lack of a "bridge" between high-capacity transit hubs and destinations along nature trails. The effectiveness of this strategy relies on the collaboration between social responsibility and digital innovation.

For instance, platforms such as "Abillio" reduce high labour costs by engaging the local community, thereby creating a more flexible and accessible workforce. Ultimately, the psychological transformation of tourists is closely linked to the issuance of "travel prescriptions", which give visitors the confidence they need to opt out of private vehicles in favour of the park's quiet mobility. The proposed publicly managed, digitally enabled (PMDE) system offers a scalable governance model in which regional bodies act as mobility coordinators to promote these seasonal "quiet mobility" routes. While the primary focus remains on connectivity and digital coordination, the energy cycle model is recognised as a potential future driver of sustainability by reducing long-term energy costs. Looking ahead, future implementation should prioritise the expansion of zero-emission protected areas models. In these models, transportation serves both as a logistical necessity and as an enjoyable, sustainable service that enhances the nature park's overall ecological integrity. Ultimately, sustainable circular transport is a key component in rural and urban areas and must be prioritised more strongly to ensure long-term resilience and environmental balance, not only in the context of natural resources but also in social aspects, to establish a human-oriented system.

Use of Emissions Control Indicators as a Tool to Guide NZEB Carbon Retrofits in Brazilian Public Universities: A Case Study

Natália Galvão dos Santos(✉), Mauricio Carvalho Ayres Torres, and Ruane Fernandes de Magalhães

Universidade Federal do Rio Grande do Sul, Porto Alegre, RS, Brasil
arq.nataliagalvao@gmail.com

Abstract. In view of the global warming trend and the increase in CO_2 emissions, largely driven by the construction sector, the development of low-carbon strategies for buildings has become increasingly urgent, such as the nZEB carbon trend. This need is particularly pronounced for existing buildings, where extending service life through environmentally responsible retrofit solutions plays a key role in emissions reduction. Among building typologies, Higher Education Institutions (HEIs) present specific challenges due to their functional complexity, high occupancy levels, and stringent comfort requirements, particularly in the public sector. *Low-carbon* indicators for retrofits were developed to monitor and control emissions. This research adapt an existent management method, with fifteen indicators for monitoring and controlling CO_2 emissions in public buildings, through a case study of a public HEI in Brazil, aiming to simplify the decision-making process, typically based on life cycle assessments, which are often complex and time-consuming The study proposes a framework that reallocates responsibility for decarbonization from individual designers to university management, thereby democratizing knowledge, strengthening institutional governance and refining the original method to reflect the context of Brazilian public HEIs better. The indicators are used to structure a systematization of low-carbon management within the university. The proposed framework indicates a high potential for a medium to long-term transition towards low-carbon and circular practices within the university. Furthermore, it highlights the effectiveness of involving professionals, students, and stakeholders not traditionally engaged in retrofit-related decision-making, positioning the university as a living laboratory and integrating emissions management into institutional processes

Keywords: Educational Public Buildings · Sustainable Transition · Low-Carbon Retrofitting · Management Strategies · Resource Efficiency

1 Introduction

The construction sector is a major contributor to global CO_2 emissions and energy consumption. In 2023, buildings accounted for 32% of global energy demand and 34% of CO_2 emissions, with operational emissions reaching 9.8 Gt and embodied carbon

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 883–891, 2026.
https://doi.org/10.1007/978-3-032-34930-9_103

around 2.9 Gt [11]. In response, increasing research has focused on strategies to mitigate emissions, among which sustainable retrofitting stands out as an effective approach to reducing greenhouse gas emissions and climate impacts [7].

This challenge is particularly relevant for Higher Education Institutions (HEIs), which comprise large and complex building stocks with diverse functions such as classrooms, laboratories, libraries, and service areas. Their high occupancy density, strict comfort requirements, and extended operating hours make campuses important targets for energy efficiency and carbon reduction initiatives [5, 13]. In Brazil, the higher education system includes hundreds of institutions, many operating large campus infrastructures that resemble small urban systems [10].

Several Brazilian universities have already implemented sustainability initiatives, including carbon inventories, institutional sustainability plans, renewable energy projects, and research programs focused on low-carbon strategies. However, managing emissions in university buildings still requires structured decision-making tools capable of guiding retrofit processes, which should be easy to use, unlike the more well-known tools, which require specific knowledge and only one team in charge, as Life Cycle Assessment. To deal with it, Liu [8] developed a methodological framework with 15 measures to guide carbon reduction in public buildings, based on sustainability certification criteria and emission-control indicators to support retrofit planning, while there is no focus especially on HEIs, nor a clear division of responsibilities.

In this context, the study evaluates the applicability of Liu's framework to a public HEI in Brazil through a case study at the Federal University of Rio Grande do Sul (UFRGS), aiming to develop indicators that distribute decarbonization responsibilities between designers and university management.

2 Method

2.1 Case Study Context

The Faculty of Architecture and Urban Planning (FAU) of UFRGS, inaugurated in 1958, is one of the oldest and most qualified institutions for teaching architecture and urbanism in Brazil [12]. For several years now, the course has included subjects in sustainability and environmental education, aiming to increase skilled professionals in these areas. Despite the interest in the school curriculum, the HEI has not yet undergone improvements to meet sustainability and environmental metrics.

Considering the operation of universities and the constant need to adapt spaces to accommodate new demands, this work will focus on adapting an existing framework for carbon emissions control, aiming to distribute decision-making responsibilities, democratizing knowledge on the subject, and favoring process control by stakeholders who are naturally involved for longer in the context of the building. Additionally, the study seeks to systematically understand the main metrics to be adopted within the chosen scope and evaluate their replication for other public HEIs in Brazil, with a view to proposing a useful tool for retrofits of various kinds within the context and making the university environment a true living laboratory.

2.2 Regulatory and Normative Framework

The management of public educational institutions in Brazil is governed by federal legislation and institutional regulations. The Federal Constitution of 1988 grants universities administrative and financial autonomy, although they remain subject to public administration rules. Law No. 14,133/21 establishes national procedures for public procurement, including the possibility of performance-based remuneration linked to quality and environmental sustainability criteria.

At the institutional level, universities operate through statutes, regulations, and management plans, which must comply with national standards such as the Normative Instruction for the Energy Efficiency Class of Commercial, Service, and Public Buildings (INI-C). The INI-C establishes the methodology for assessing the energy efficiency of new public buildings, including envelope, lighting system, HVAC, water heating, renewable energy generation, and efficiency indicators [6].

Although policies promoting sustainability exist in public HEIs, their implementation remains limited due to barriers such as high initial costs [13], bureaucratic complexity arising from fragmented policies [2], and insufficient awareness or training among professionals regarding performance targets [9]. These challenges highlight the need for additional measures to strengthen sustainability-oriented actions through an analytical framework for decision-making assessment.

Based on a review of research related to decarbonization in existing public and institutional buildings, which mainly includes studies that propose a deeper analysis of the building life cycle [1, 5, 9] and energy simulations [3, 4, 13], we chose to work with a simplified tool focused on sustainability indicators, proposed by Liu et al. [8]. The aim is to simplify decision-making to reduce carbon emissions in public buildings as a method for devising strategies for the case study.

The tool is divided into six scopes: materials, energy, management, innovation, location, and water, comprising 15 measures (Table 1). It was developed by cross-referencing and summarizing CO_2 emission control indicators from international databases to build a framework that meets different needs worldwide, comparing the indicators characteristics of the following certifications: LEED (USA), BREEAM (United Kingdom), GM (Singapore), and ASGREB (China). Within the certifications, each measure has a different weight, according to its relevance, and the maximum score in Liu's [8] framework is 84.2%, as it is based on systems that also address other aspects of sustainability beyond carbon emissions control, totaling 100%.

To improve the method's efficiency, the decision-making process at FAU will be evaluated, and a reorganization will be proposed to increase flexibility in applying the method and partially reduce project bureaucracy, in addition to developing an inventory framework to support the standardization proposed by the method. This measure aims to simplify decarbonization tools and streamline decision-making, which currently operates as shown in the Fig. 1.

Table 1. Summary of scopes and measures. The sum of the weights is equal to 84.2%, accounting for the maximum score of the framework. Source: Adapted from [8].

Scope	Mandatory measures	Recommended measures	Scope weight
Materials	Safety and durability	–	18,3%
	Waste recycling		
	Material Location		
	Green materials		
Energy	Energy saving in buildings	Use of energy from renewable sources	17,7%
	Energy saving of equipment		
Management	Intelligent operation	Political and institutional orientation	14,9%
Innovation	Calculation of carbon emissions in the building	–	14,9%
	Historical and cultural heritage		
Location	Low-carbon transportation	Reduction of the heat island effect	10,5%
Water	Reduced consumption	Non-traditional water use	7,9%

3 Results and Discussions

3.1 Indicator Assessment across Management Domains

Based on the application of Liu's [8] model to the FAU UFRGS case study, the results were translated into an adapted framework presenting decision priorities at project and management levels. The framework supports both building users and designers in making

informed decisions that can be maintained throughout the bidding process. This organization helps identify not only estimated environmental impacts, but also the institutional constraints affecting implementation.

The scopes in Table 1 were reformulated by the author to find decarbonization opportunities, including items within each measure (in italics), with scores equally redistributed for each of them (in bold), and it is mandatory to comply with at least one item within each of the mandatory measures, as summarized in Table 2. The safety measure was excluded from the scope because it is not directly related to decarbonization.

Table 2. Measures adapted to the case study. The weights are estimated to scope sum (Table 1). Source: Developed by author.

Mandatory measures	Recommended items (at least 1 item by each measure)	Weight
Durability	*Materials durability* (1)	**4,575%**
Waste recycling	*Prioritize materials that have been produced through recycled raw material* (2)	**4,575%**
Material Location	*Prioritize materials for shorter distance, not exceeding 500 km* (3)	**4,575%**
Green materials	*Prioritize materials that are or have reusable or recyclable packaging* (4)	**1,525%**
	Prioritize brands that have reverse logistics (5)	**1,525%**
	Prioritize materials with abundant raw materials in the region (6)	**1,525%**
Energy saving of buildings	*Prioritize equipment with an A grade in the PROCEL seal* (7)	**8,85%**
Energy saving of equipment	*Carry out equipment operation plans, involving students and employees of the HEI* (8)	**8,85%**
Intelligent operation	*Installation of IoT (Internet of Things) elements and equipment* (9)	**3,725%**
	Smart glazing in all build (10)	**3,725%**
	Installation of presence sensors (11)	**3,725%**
	Automatic stand-by mode equipment (12)	**3,725%**
Calc. of emissions	*Hiring of specialized staff* (13)	**7,45%**
Historical and cultural heritage	*Maintain a team specialized in historical heritage* (14)	**3,725%**
	Involve HEI users in reform decisions (15)	**3,725%**
Low-carbon transportation	*Installation of paracycles in IES* (16)	**2,625%**
	Policies to encourage the use of low-carbon transport (17)	**2,625%**
	Inclusion of building users in decision-making for incentives (18)	**2,625%**
	Constant improvement of universal accessibility on campus (19)	**2,625%**
Reduced water consumption	*Installation of water-saving elements* (20)	**3,95%**
	Creation of consumption reduction policies (21)	**3,95%**

Regarding the measures recommended by Liu [8], this research allows the inclusion of additional sustainability measures when there is a link between maintenance inputs and project specifications. The University score will not have a minimum score, as the aim is to promote nZEB carbon retrofits. Instead, the focus is on gradually increasing the number of measures over time, according to local feasibility, ensuring continuous improvement in the HEI's score, preventing setbacks, and maintaining results for up to four consecutive years, corresponding to the average rectoral administration term.

3.2 Implications for Retrofit Decision-Making

Renovation requests at the University follow a hierarchical decision-making process involving multiple stakeholders. Currently, decisions are made through a bottom-up system with limited involvement from university administration and bureaucratic procedures that may halt projects even after completion, overburdening the infrastructure department, as shown earlier in Fig. 1.

Thus, effective decarbonization in public HEIs requires not only technical and environmental performance but also compatibility with purchasing processes, standardization of specifications, and logistics, ensuring operational viability and continuity over time. However, there are still barriers that compromise this relationship, such as budget, bureaucracy, or human resources.

Lean Governance advocates reducing bureaucratic waste to optimize workflows, accelerate decision-making, and improve responsiveness to institutional demands [2]. In this context, implementing decarbonization measures requires streamlining bureaucratic processes and reducing the number of actors involved in decision-making, facilitating coordination and improving control over retrofit actions in public HEIs. To support the replicability of this study, a proposed organizational flow for retrofit projects in public higher education institutions is presented below (Fig. 2).

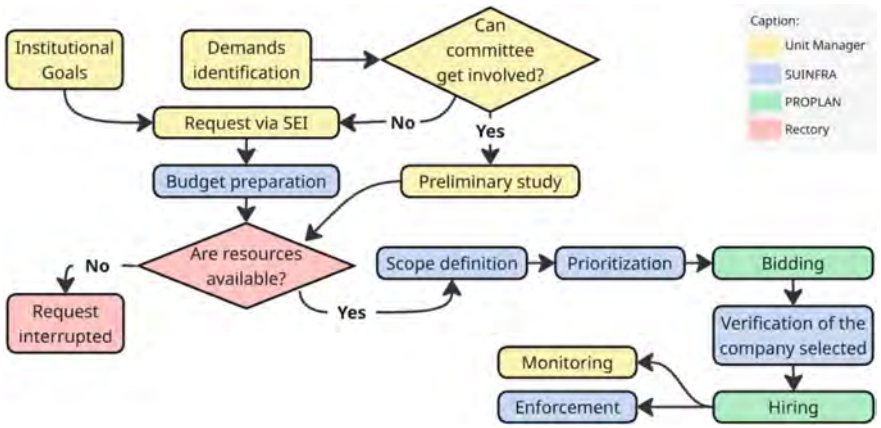

Fig. 2. Flowchart of the proposed decision-making structure. Source: Developed by author.

Under the proposed new decision-making structure at FAU, each department involved will have its responsibilities allocated as described below:

1. **Unit Manager:** Institutional demands should be organized and supported by internal policies that promote user awareness and guide sustainability act ions. (Table 2, items 8, 15, 18, 21);
2. **PROPLAN:** Mediates bids and legal procedures without getting involved in technical aspects or decision-making that requires specific knowledge;
3. **SUINFRA** Conducting inventories, developing projects, prioritizing demands, and supervising construction works, while ensuring compliance with decarbonization measures, guaranteeing standardization and alignment with sustainability requirements (Table 2, items 1, 2, 3, 4, 5, 6, 7, 9, 10, 11, 12, 16, 20);
4. **Rectory:** Creates public policies for decarbonization, ensures the necessary human resources for their implementation, and coordinates the funds available for maintenance and renovations (Table 2, items 13, 14, 17, 27, 19).

Implementing bottom-up decision-making in HEIs requires organizational change, but it can reduce bureaucracy, strengthen stakeholder engagement, and improve trust. Integrating decarbonization decisions before retrofit interventions also encourages user involvement with the built environment. In this context, renovation commissions are essential to involve students in institutional decision-making and experimentation, especially in architecture schools, where innovative solutions can later inform practice, teaching, and institutional policies.

For the measures mentioned to be appropriate to the FAU context, it is very important that the university management, together with the technicians, conduct a comprehensive inventory of all relevant aspects of the site to the proposed framework. This document should be updated periodically and cover the university's environments and their current uses, as well as the state of each construction system that makes up the site, the equipment that integrates these areas, their uses and maintenance, and events that may have caused degradation at the site, as shown in Fig. 3, in order to obtain a better perspective for the decision to standardize future purchases.

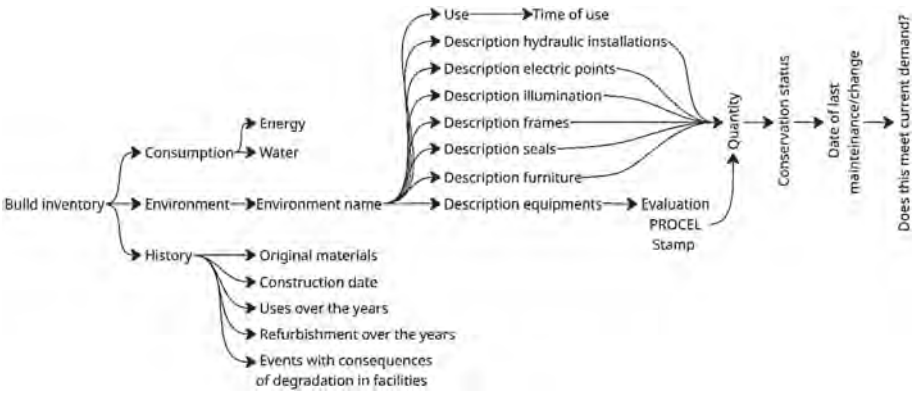

Fig. 3. Inventory proposal for HEIs low-carbon retrofitting. Source: Developed by author.

4 Conclusions

By adapting Liu's [8] tool, it was possible to develop a progressive decarbonization plan that enables HEIs to establish benchmarks and targets for specific scores. Revising the university decision-making process also helped reduce bureaucracy in renovation demands, empower building users, and reduce the workload of the infrastructure sector. The proposed organization is promising due to its easy replication across public HEIs, which often share similar administrative structures.

The inventory model further improves internal facility management by incorporating data such as energy and water consumption and construction materials. This tool supports future decarbonization metrics and enables simplified comparisons between existing conditions and renovation proposals.

Another important contribution is the creation of a culture of sustainable responsibility among students, staff, and faculty through their participation in building-related decisions. In this context, the renovation committee plays a key role, especially in architecture schools, where innovations can be tested and later disseminated through university practices, teaching, and internal policies. However, given the current asset management structure at UFRGS, transferring sustainability and decarbonization decisions directly to building managers remains complex, requiring a holistic approach at the university level.

Abstract. Adaptive reuse of existing buildings is a needed strategy for reducing resource consumption and improving the sustainability of the building. However, many evaluation models adopted in decision-making processes are based only on characteristics of properties, relying on static representations of obsolescence and providing limited support for evaluating the effects generated by the reuse on surrounding urban context. The aim of the work is to propose a methodological framework for assessing adaptive reuse potential based on relevant obsolescence categories and including the potential impacts generated by the intervention of reuse. The proposed framework is structured into two modules: the first one, is intended for determining the intrinsic potential of the abandoned building through Analytic Hierarchy Process (AHP) weights system of obsolescence indicators; the second one, is aimed at assessing (ex-ante) the impacts that could be generated on neighborhoods. The study contributes an original two-module decision-support framework combining building reuse potential and ex-ante urban impact assessment. Through multidimensional indicators and AHP weighting, it improves transparency and traceability in circular adaptive reuse evaluation for supporting optimal and efficient circular economy's decisions. Future developments will concern the application of the proposed framework into a real case study by testing the validity of results with the comparison of compensatory and non-compensatory multicriteria techniques

1 Introduction

Adaptive reuse of existing buildings is recognized as a strategy for promoting sustainability in the built environment. In contrast to demolition and new construction, adaptive reuse substantially reduces material consumption, embodied energy, construction waste, and land-use pressure, often avoiding 50-75% of embodied carbon emissions by preserving carbon-intensive structural elements like foundations, frames, and envelopes [1]. It also diverts substantial materials from landfills by minimizing demolition activities, considering that construction and demolition waste represents around 38–40% of total waste generation in the EU and similar shares globally [2]. Within the circular economy paradigm, and under the umbrella of the European Union (EU) Circular Economy Action Plan, adaptive reuse is increasingly recognised as a key strategy to transform the construction value chain and to reduce the sector's environmental impacts. Beyond environmental benefits, adaptive reuse supports social inclusion, urban regeneration and value creation within existing urban fabrics, reinforcing its role in achieving circular and climate objectives at building and neighbourhood scales. In this context, robust assessment models capable of capturing circularity, impacts and risks of adaptive reuse interventions are essential to support evidence-based decision-making. Despite the growing recognition of adaptive reuse as a sustainable and circular strategy, decision-makers still face challenges in prioritising reuse interventions within complex urban systems. Existing assessment approaches often focus on building-level characteristics while overlooking broader socio-economic, cultural and environmental impacts on the surrounding neighbourhood. Furthermore, the lack of transparent indicator systems limits the replicability and implementation of many existing tools. Addressing these gaps requires integrated, multi-criteria and impact-based approaches aligned with circular economy policies and sustainability assessment frameworks [3]. This paper develops a multi-criteria framework for assessing adaptive reuse potential of buildings, aiming to enhance the importance of evaluating the potential impacts on the surrounding neighbourhoods through decision-making transparency. The approach focuses on three key aspects: first, it suggests the use of an obsolescence dashboard system by defining environmental, social, cultural, and economic (ESCE) level of obsolescence; second, it takes into account through Analytic Hierarchy Process (AHP) the relevance of obsolescence into the determinants of useful life of abandoned buildings; third, it creates analysis of impacts according to different isochrones and scenarios intervention of reuse. The remainder of the paper is as follows: Section no.2 describes each step of the proposed framework; Section no.3 concerns main pros and cons of the work and its future directions with a real case study application.

2 Methodology

2.1 Framework Overview

The proposed framework builds upon previous developments of the Adaptive Reuse Potential Index (ARPI) model proposed by Anelli et al. [4] and inspired by Langston's Adaptive Reuse Potential (ARP) model [5, 6]. The contribution of the paper is an operational extension of previous ARP-based approaches, structured in two modules to estimate: (A) the intrinsic potential for reuse of an existing building through a dashboard

of obsolescence indicators, with their relevance objectified via the AHP (e.g., as applied in related multicriteria adaptive reuse assessments [7, 8]; and (B) an Ex-ante Impact Potential (EIP), designed to assess potential impacts in the urban environment associated with alternative reuse scenarios, while keeping the intrinsic component distinct from the territorial impact component (aligned with ex-post/ex-ante impact evaluations and multidimensional extensions in heritage reuse frameworks [9]).

In summary: Module A returns a synthetic measure of the "intrinsic reuse potential" of the asset; Module B, applicable only after the ARP estimation, allows to compare scenarios in terms of potential impacts in the Area of Influence (AoI) defined by isochrones. Figure 1 depicts the workflow of the proposed methodology.

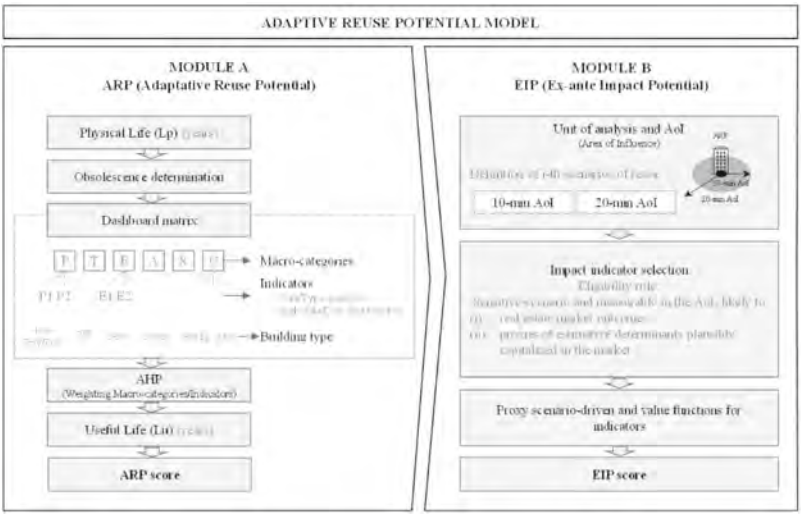

Fig. 1. ARP Model proposal of methodological framework.

2.2 Module A—ARP

2.2.1 Physical Life Assessment

In continuity with the model developed in Anelli et al. [4], the estimation of the physical life *Lp* is carried out by means of an improved physical life worksheet that compares the conditions of the context and the robustness of the asset for the purposes of the expected physical life. The result is expressed in years and constitutes input for the estimation of the useful life.

2.2.2 Obsolescence Dashboard: Core vs. Type-Specific Indicators

The determination of obsolescence is broken down into six families consistent with the literature on adaptive reuse and building obsolescence: Physical (P), Technological/Functional (T), Economic (E), Environmental (A), Social (S), Cultural/Heritage (C).

To ensure replicability and transferability to different uses, the dashboard is structured as a matrix of indicators × building types, distinguishing:

- Core set (Cr): essential and applicable to most types;
- Type-specific set (Ts): depending on the intended use (residential private/public, offices, public services, commercial/hospitality, mixed-use; with heritage module when relevant).
- (−): non-priority in the minimum dashboard

Each macro-category can be operationalized with a Primary measure (more informative) and a Proxy measure (low-data), associated with a level of "data effort/availability" -low (L) or high (H). Below is an excerpt from the dashboard (Table 1):

Table 1. Excerpt of dashboard matrix of obsolescence indicators.

Cat.	Obsolescence indicators	Building typology							Source
		Res-Priv	Res-Pub	Off	Serv	Com	Her	Mix	
P	Envelope/structure status	Cr	Cr	Cr	Cr	Cr	Cr	Cr	[10, 11]
T	Functional adequacy of layout/spaces	Ts	Ts	Cr	Cr	Cr	Ts	Cr	[11–14]
E	OPEX	Cr	Cr	Cr	Cr	Cr	Cr	Cr	[10, 11, 13]
Env	Operating CO_2 / emissions ($kgCO_2e/m^2a$)	Cr	Cr	Cr	Cr	Cr	Cr	Cr	[13, 14]
S	Accessibility/barrier-free	Cr	Cr	Cr	Cr	Cr	Cr	Cr	[13, 14]
C	Integrity, constraints, compatibility of use	–	–	–	–	–	Cr	–	[12, 14]
[…]									

2.2.3 AHP-Based Weighting of Obsolescence Macro-Categories

Previous applications of ARP-based approaches demonstrated the usefulness of multi-criteria methods for identifying adaptive reuse priorities in urban contexts [4, 15, 16]. In the present work, the choice to weigh the obsolescence categories is formalized to replace Langston's assignment by range (0–0.20) with a transparent and verifiable procedure. Let $k = 1,2... k$ the set of obsolescence macro-categories (P, T, E, A, S, C). A matrix of pairwise comparisons is constructed using the Saaty scale based on expert judgments, and the weight vector is obtained as the principal eigenvector (or, alternatively, by means of a normalized geometric mean). The consistency of the judgments is verified through the Consistency Ratio (CR). When quantitative indicators are used, the pairwise comparison matrix is instead constructed based on the ranking of their values. In this case, the implied transitivity ensures that the consistency requirement is always satisfied. The resulting weights are then used to aggregate the indicators (core and type-specific) into a synthetic measure of overall obsolescence.

2.2.4 Useful Life

The useful life *Lu* is calculated as "discounted physical life", according to the Langston-based approach already adopted in Anelli et al. [4]:

$$Useful\ life = \frac{Physical\ life}{1 + \sum_{i=1}^{n} O_i} \tag{1}$$

where $\sum_{i=1}^{n} O$ represents the overall annual rate of obsolescence deriving from the aggregation (weighted) of the obsolescence households. Unlike Langston's range approach, in this paper $\sum_{i=1}^{n} O$ is obtained by combining: (i) indicator scores for each macro-categories (core/type-specific) and (ii) weights *wk* from AHP.

2.2.5 ARP Score

The ARP score is then calculated as a function of the *ELu* and the effective age of the building, *ELb,* according to the formula:

$$ARP\ SCORE = \frac{\frac{100 - ELu^2}{100 \cdot ELb}}{ELu} \tag{2}$$

In the setting proposed here, ARP is a building-intrinsic output: it returns a synthetic measure of the potential for reuse of the asset regardless of the scenario and the surrounding context and is used as an ex-ante "filter/priority" to decide whether the building is a candidate for further scenario-based analysis (EIP, module B).

2.3 Module B—Ex-ante Impact Potential (EIP)

2.3.1 Unit of Analysis and AoI Definition Through Isochrones

The unit of analysis of Module B is the i-th scenario of reuse of the building whose calculation of the reuse potential is expressed by ARP score. The Area of Influence (AoI) is set ex-ante to ensure comparability between scenarios: a 10-minute pedestrian isochrone (alternately buffer 700–800 m) is assumed as the main AoI for proximity impacts; a secondary AoI (20 minutes or ~1.5 km) can be used for sensitivity analysis or more common impacts. The time horizon is defined in a way that is compatible with the ex-ante nature: short (1–3 years) and medium term (4–10 years), where necessary.

2.3.2 Impact Indicator Selection Rule: Intervention Sensitivity and Real Estate Market-Mediated Relevance

To ensure that the assessed impacts reflect the changes plausibly induced by the intervention, the EIP protocol imposes a scenario-sensitive selection rule based on a minimum causal chain: scenario → output/services → proxy impact mechanism measurable in the AoI. In this contribution, in line with the evaluation approach, the eligibility of the indicators is further linked to a market-mediated relevance: indicators are selected that constitute (i) real estate market outcomes (e.g. potential changes in prices/rents, vacancy, liquidity) and (ii) proxies of estimative determinants plausibly capitalized in the market

(e.g. accessibility/amenities, perceived environmental quality, safety/supervision, footfall), provided that they are sensitive scenario and measurable in the AoI. Formally, for a Si scenario, the EIPSi set is defined as a J subset of candidate indicators:

$$EIP_S = \{I_j \in \mathcal{J} | \mathcal{S}(I_j, s) = 1, \mathcal{A}(I_j) = 1, \mathcal{M}(I_j) = 1, \mathcal{F}(I_j) = 1\} \quad (3)$$

where S represents sensitivity to intervention (ToC-link), A spatial attribution to AoI, M market-mediated relevance, and F ex-ante feasibility (Primary/Proxy and data-effort).

2.3.3 Proxy Scenario-Driven and Value Functions

For each selected indicator *Ij*, the method defines a proxy dependent on the scenario drivers (e.g. potential users, opening hours including evening slots, intensity of events/activities, equivalent employees, generation of movements). To transform heterogeneous proxies into comparable values, each indicator is mapped to a score using anchored value functions, favouring interpretative anchors (0; 0.5; 1) based on policy criteria or technical plausibility, instead of purely statistical normalizations that require large samples. For cost indicators (e.g. mobility externalities), the value function is decreasing.

2.3.4 Aggregation, Compensability Policy, and Robustness

The EIP for a given scenario S_i is calculated as a weighted aggregation of indicator scores across intervention categories (K). The model combines two levels of weighting: category weights w_k and indicator weights v_{jk}. For each scenario, the performance of a given indicator j is transformed into a normalized value-function score $u_j(S_i)$. Considering J_k as the number of indicators in each category k:

$$EIP(S_i) = \sum = 1^k \; w \left(\sum = 1^J \; v \cdot u(S_i) \right) \quad (4)$$

Indicators are first aggregated within each category using the local weights v_{jk}, and the resulting category scores are combined using the global weights w_k. This aggregation ensures that the relative importance of categories and the contribution of individual indicators are considered [15]. The resulting EIP(S_i) provides a measure of the intervention potential of a given scenario S_i, allowing comparison among alternative strategies. Future applications may also incorporate sensitivity analyses to evaluate the stability of rankings under alternative weighting configurations

2.4 Preliminary Validation of the Proposed Framework

A preliminary validation of the proposed framework was carried out by checking its methodological consistency with previous ARP based applications. In particular, Module A builds on the Adaptive Reuse Potential model developed by Langston [4, 5] and on the ARPI model proposed by Anelli et al. [9]. The extension proposed in Module B was preliminarily validated through a conceptual consistency check with previous multicriteria and impact-oriented approaches to adaptive reuse assessment [6–8].

3 Conclusion and Future Directions

This paper proposes a methodological framework to support the assessment of the adaptive reuse potential of existing buildings, based on a structured and sustainability-oriented multicriteria approach. The methodological robustness of the framework is supported by the integration of validated ARP-based formulations structured indicator systems, and established multicriteria procedures widely adopted in adaptive reuse assessment literature.

Among the main strengths of the proposed framework is its continuity with previous ARP-based models and applications, which have demonstrated the feasibility of estimating adaptive reuse potential through physical life, useful life and obsolescence conditions [5, 6]. The framework is also consistent with studies that interpret adaptive reuse as a sustainability-oriented strategy capable of reducing demolition impacts, preserving existing building stock and supporting urban regeneration processes [15, 16, 18, 19]. In this perspective, the distinction between Module A and Module B allows the assessment to move from the intrinsic characteristics of the building to the potential impacts generated by reuse scenarios in the surrounding urban context. Although this preliminary validation does not replace a full empirical application, it supports the internal coherence and operational applicability of the framework. Future research will test the model on real case studies, including sensitivity analysis and comparison between compensatory and non-compensatory multicriteria techniques.

At the same time, the framework presents some limitations. AHP-based procedures remain sensitive to expert judgement, pairwise comparison consistency and weighting assumptions, thus requiring sensitivity and robustness analyses [20]. Moreover, the weighted additive aggregation adopted in the framework may generate compensatory effects among criteria. This issue is particularly relevant in sustainability-oriented assessments, where poor performance in one dimension should not always be offset by high performance in another [21]. Finally, the operational implementation of the framework depends on data availability and quality, especially when proxy indicators are used to estimate obsolescence or ex-ante urban impacts.

In conclusion, the proposed framework advances adaptive reuse assessment by expanding ARP-based methods from building-intrinsic reuse potential to ex-ante evaluation of territorial impacts of alternative reuse scenarios. Though needing full empirical validation, the framework is operational, grounded in established ARP/ARPI and multicriteria procedures, serving as a preliminary decision-support tool for public administrations and urban regeneration actors. Future case studies will enable calibration of indicators, testing of weighting assumptions, and comparison of aggregation methods.

Abstract. This paper examines the architectural repurposing of decommissioned wind turbine blades (WTBs) as primary building envelope components through a design-led, material-driven research project. The study focuses on the segmentation of glass fiber–reinforced polymer (GFRP) blade components and their integration into modular wall and roof assemblies. WTB segments are treated as architectural elements, with geometry and material properties that directly affect the design.

The research is aided by the design and fabrication of a 1:1 physical mock-up to facilitate the testing of constructability, connection detailing, assembly sequencing, and the integration of non-standardized waste streams in the built environment. Through hands-on evaluation, the study demonstrates that blade segments can be cut, drilled, and mechanically connected without delamination, enabling blade-to-blade and blade-to-wood assemblies within modular wall and roof systems. At the same time, the research identifies critical constraints, including geometric variability between blades, transport and storage barriers, labor-intensive processing requirements, and the absence of established certification frameworks governing structural reuse of GFRP composite segments in building applications.

The findings highlight key enablers and barriers for scaling blade repurposing within architectural practice and inform future pathways for embedding decommissioned infrastructure materials into circular building systems. By characterizing WTBs as an urban mining resource instead of waste, this study shifts blade repurposing toward a transferable design framework for future circular construction applications, while outlining the technical, logistical and regulatory challenges that remain.

1 Introduction

1.1 Problem Statement

Wind energy accounts for 29% of the Netherlands' electricity mix [1] and 18% across the European Union, with further expansion driven by EU renewable energy targets and long-term decarbonization strategies. While this transition reduces operational carbon

© The Author(s) 2026

emissions, it simultaneously generates a growing end-of-life (EoL) waste stream from wind turbine blades (WTBs) [2].

Unlike turbine towers and foundations, which are primarily steel and concrete and benefit from established recycling systems, WTBs consist largely of glass fiber–reinforced thermoset polymers (GFRP). These composites are irreversibly cured [3, 4], materially heterogeneous [5], and geometrically complex, making high-value recycling difficult. Consequently, landfilling and incineration – which rank lowest within the EU waste hierarchy – remain common disposal routes [6, 8]. Although landfill bans and industry commitments signal regulatory progress, they do not offer a solution to the increasing stock of decommissioned blades [9, 10].

While recycling technologies continue to develop, the systematic integration of WTB segments as primary structural components in building systems remains underexplored. In particular, segmentation logic, connection strategies, and envelope compatibility lack validation at an architectural scale.

This study investigates whether decommissioned WTB segments can function as structurally viable, mechanically connectable, and envelope-compatible components within modular building systems. Using a design-led experimental methodology combining digital modeling and full-scale prototyping, the research evaluates material processability, structural integration, and scalability.

1.2 The Waste Stream and End-of-Life Management

Current EoL pathways include landfilling, incineration with energy recovery, co-processing in cement kilns, recycling, and repurposing. Landfilling remains the simplest disposal strategy but performs poorly in environmental and resource-efficiency terms. Incineration and co-processing recover limited energy or mineral value but generate emissions and do not preserve structural integrity [3, 4].

Recycling strategies attempting to recover material value usually result in fiber degradation or require energy-intensive thermal or chemical processes. Mechanical grinding typically downcycles blades into filler materials with reduced structural performance [6]. Thermal and chemical processes can recover higher quality fibers, yet remain economically and energetically uncertain at scale.

Repurposing, by contrast, preserves structural integrity and extends service life. Structural reuse retains mechanical properties and embodied energy, enabling load-bearing applications and higher-value outputs [7, 12]. Existing precedents have demonstrated whole-blade reuse in infrastructure, playgrounds, and urban installations, however, these applications are often bespoke and limited in systemic scalability.

2 Methodology

This study adopts a design-led experimental methodology in which architectural prototyping functions as a research instrument to evaluate the structural reuse potential of decommissioned WTB segments.

The research unfolded in three phases. First, literature analysis established blade material composition, structural behavior, and EoL pathways. Second, geometrical mapping of a WTB and iterative development of a building design informed a segmentation

strategy aligned with architectural load paths. Third, a 1:1 prototype showcasing a key envelope detail was fabricated, to test assembly sequencing, cutting behavior, fastening performance, and resistance to delamination using standard tools.

A pragmatic approach was adopted in this study by focusing on a single blade typology. However, the principles that determine the design and the examined manufacturing techniques can be adapted across different blade types.

2.1 An Overview of Material Selection

In line with the project's circular design approach, the prototype building envelope was designed and built using almost exclusively reclaimed and recycled materials.

Wind Turbine Blades. WTBs are composite structures designed to maximize strength, stiffness, and durability while minimizing weight to ensure efficient energy generation and fatigue resistance. Although configurations vary between manufacturers, blades generally follow consistent material and geometric principles. They are characterized by a non-symmetrical, multi-cellular heterogeneous cross-section, split into the spar caps, edges, shell panels and shear webs, the material configurations of which are illustrated in Fig. 1. Approximately 80% of a blade's total mass consists of glass or carbon fiber reinforced polymer, composed of 60–70% structurally reinforcing fibers that are embedded in a thermoset polymer matrix which binds the structure and protects the fibers [3, 4, 5]. The Netherlands has 3,553 wind turbines [11], equal to 10,659 blades, representing a substantial and recurring local waste stream as turbines are decommissioned each year.

Fig. 1: Geometry and material composition of a WTB section showing: Spar Caps: Unidirectional (UD) glass/carbon fiber, supported by epoxy/UPR/VE/PUR matrix, Leading/Trailing Edge: Triaxial glass/carbon fiber, supported by structural adhesive, Shear Webs and Shell Panels: Triaxial GFRP sandwich laminates using balsa/PVC/PET matrix, Web and Edge Bonding: Epoxy/PUR-based structural adhesive, Surface Coating: PE/PUR-based lacquer

Other Secondary Materials. While the WTBs provide the main load-bearing structure, additional materials were required for framing, openings, connections, and insulation. Research and mapping of locally available resources confirmed availability for: reclaimed timber for framing, windows from specialized suppliers, steel bolts from demolition contractors for connections, and recycled materials for insulation. For this case study, the insulation is manufactured from recycled cotton textile waste.

3 Design

The design phase explored how WTB segments can inform an architectural system, translating their geometry and structural configuration into multiple building elements. All components are derived from a single blade, simplifying fabrication while enabling adaptable, repeatable designs.

A small-scale floating office demonstrator (Fig. 2) is developed as a speculative application in which blade segments define roof, walls, and platform components. Spatial organization and structural orientation are driven by blade curvature, thickness variation, and fiber distribution.

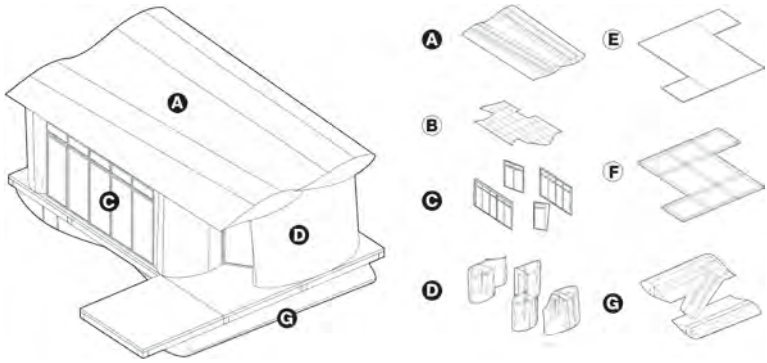

Fig. 2. Design overview for the proposed 'floating office', showing exploded elements with primary components made from WTB(*) labelled in black: Roof*, Ceiling panels, Timber fittings, Walls*, Floor System, Steel grid structural platform, Floating raft base*.

3.1 Building System and Blade Segmentation

The segment used for the mockup derived from a 30 m-long Fraunhofer-type WTB. However, for digital modeling, technical drawings of an NREL/5 MW/61.5 m WTB were used, as this WTB is one of the few with publicly available properties.

Segmentation follows the blade's internal structural logic. Spar caps, designed to resist high bending moments are reassigned as primary load-bearing zones within roof and wall elements. Their fiber continuity is maintained to preserve structural capacity. Shear webs inform internal stiffening strategies and contribute to local rigidity within assemblies. Shell panels and sandwich sections, characterized by lighter composite layups, are proposed as enclosure components where stiffness, durability, and surface continuity are required without high load demand. Through this approach, each blade region retains a role aligned with its original mechanical behavior, optimizing material utilization across the building system.

Blade segments form the exterior structural shell of roof and wall assemblies, functioning simultaneously as load-bearing structure and weather-resistant finish. To address waterproofing at exposed edges, a fiber-reinforced adhesive made from the same materials as the WTB is used to provide a robust seal and enable recyclability at the EoL.

This approach allows the project to ensure a high-performance barrier against moisture infiltration.

A lightweight timber substructure mediates between the curved composite surface and planar interior components, supporting insulation, vapor control layers, and reclaimed window interfaces. Openings are integrated through timber fittings that adapt to the blade's double curvature while allowing mechanical connection and disassembly. At the base of the proposal, blade segments are configured as buoyant elements within a floating platform system.

4 Manufacturing

4.1 Cutting, Assembly, and Connections

The 1:1 mock-up (Fig. 3) served as a functional validation of the proposed envelope system by focusing on the complex roof–wall–window interface to test structural integration, buildability, and reversibility alongside conventional construction logic. This full-scale prototype allowed for the simultaneous assessment of mechanical fastening and alignment at a critical convergence point, informing a production model that follows prefabrication strategy and on-site assembly.

The prototype starts with cutting the procured blade segment. A transverse cut that preserves the spar cap region to keep the structurally valuable portion intact and a longitudinal cut for a narrower segment suitable for vertical wall applications. This minimizes waste and maintains fiber continuity where possible.

Fig. 3. Annotated schematic of mock-up detail illustrating build-up and structural layers, alongside image of final finished prototype.

The segments are then connected using a dowel joint technique with stud bolts. This enables vertical load transfer, rapid on-site alignment, and reduces the need for specialized tools. This also supports reversible construction principles since the connection can be disassembled without damaging the building elements.

Timber battens, acting as an interface between the WTB's curved surface and the window frame, were precision-cut to match the blade's geometry and fixed with stud

bolts. This connection was enabled through geometric mapping of the selected WTB segment and its transfer into a computational tool that was designed to generate the exact batten profile required – allowing for rapid adaptation to varying curvatures and rotations of different blade segments, supporting design flexibility.

The wall build-up consists of interior finish panels, a service cavity, reclaimed timber framing, insulation, vapor barrier membrane, and the blade shell acting simultaneously as structure and exterior finish. The window frame is then installed into the opening using mechanical fasteners into the timber battens.

4.2 Scalable Manufacturing and Design Framework

Scalability is supported by the concept's processing simplicity and potential for large-scale deployment, whereby WTBs can be rapidly segmented and directly repurposed as building elements enabling high throughput. The blade-to-building design approach is also adaptable across multiple small-scale building typologies beyond offices. Finally, feasibility assessment of the prototype's results suggests a pathway toward a scalable manufacturing framework which the authors envision as a 'Design and Build' practice. This would entail holistic project coordination, a proprietary material-informed parametric design software and a centralized robotic fabrication and processing facility. Specialized tasks such as blade decommissioning, pre-processing and transport would remain subcontracted.

5 Discussion and Conclusions

5.1 Discussion

The successful execution of this project identifies material affordances that challenge assumptions regarding the inaccessibility and technical complexity of WTB repurposing. Their structural reuse demonstrated robustness and adaptability within a materially informed design approach.

At the material scale, blade segmentation was achieved using standard hand tools, demonstrating that specialized equipment is not essential for primary processing. The composite accommodates drilling and mechanical fastening without significant splintering or delamination, enabling blade-to-blade assemblies through overlaps and custom joints. The inherent curvature, initially perceived as a design constraint, proved structurally and formally advantageous when strategically deployed, including its use for load-bearing purposes. The geometric variability also highlighted the need for localized adjustments and parametric tools. Crucial enabler to the design development and execution of construction details was the implementation of a computational design workstream, as demonstrated for the blade-to-building segmentation strategy and the custom timber connection between the curved composite blade and the planar framing and openings.

Despite successful prototyping, constraints to broader implementation remain. Repurposing WTBs at scale introduces significant handling and structural challenges due to aggregated weight and geometry, necessitating specialized transport, storage, and

processing facilities. Material and geometric variability across blade models complicates standardization; however, the proposed workflow achieves an adaptable approach accounting for various typologies. Finally, the absence of established certification frameworks for reused GFRP components places this material outside existing building codes, restricting structural application without rigorous engineering validation.

5.2 Conclusions

Positioning WTBs as an urban mining resource reframes blade waste as a construction opportunity. This project demonstrates that decommissioned blades can support circular building practices through prefabrication, computational adaptation, and design-for-disassembly. By linking infrastructure decommissioning with architectural production, the research contributes to circular construction models that prioritize high-value reuse and extend material lifecycles.

Future research should address structural testing, long-term durability, and fire performance – particularly critical for GFRP composites – as well as comparative life cycle assessment to quantify environmental benefits relative to recycling pathways. In addition, the development of digital inventory systems, parametric design tools, certification pathways, and standardized testing protocols will be necessary to enable integration into regulated construction markets.

Overall, this study provides insight into the technical challenges and opportunities associated with structural WTB reuse and demonstrates a manufacturing practice that advances blade repurposing beyond a niche design experiment. The findings suggest that further research is warranted to determine whether this might be a transferable circular strategy for incorporating large-scale composite waste streams into regenerative building systems.

Acknowledgements. This project was part of TU Delft's Building Technology MSc course 'Circular Product Design,' coordinated by Olga Ioannou and Jan Jongert, to whom the team is extremely grateful for their guidance and support. The authors also thank the university's Lichen-Blades team for their collaboration and support, particularly Jelle Joustra and Israel Carrete for providing the WTB segment and for sharing their technical expertise throughout the development of the prototype.

The authors further acknowledge Octatube for providing workshop facilities, secondary materials, and technical assistance, as well as the support in the assembly process and handling of fabrication tools in realizing the full-scale prototype.

Lastly, the authors also thank Isolatie Garant (Den Haag) for supplying the Métisse® recycled cotton insulation used in the prototype.

Integrating Geospatial and Earth Observation Technologies to Assess Urban Sustainability: A Systematic Literature Review

Katherine Athié[1](✉), Bruno Rocha[1], Luís Bragança[2], and Cristina Alvarez[1]

[1] Federal University of Espírito Santo, Vitória, Espírito Santo, Brazil
katherineathie@gmail.com
[2] University of Minho, Braga, Portugal

Abstract. Research on urban sustainability and urban morphology has traditionally focused on anthropogenic attributes of urban form, while giving less attention to natural systems and the health of urban ecosystems. Recent studies indicate that landscape connectivity, biodiversity, vegetation cover dynamics, and the relationships between urban form and natural systems remain underexplored, particularly in integrated and long-term spatial analyses. In response to this gap, this article conducts a systematic literature review on Earth Observation technologies applied to urban sustainability, emphasizing the integration of Remote Sensing (RS), Geographic Information Systems (GIS), and geospatial analyses to understand urban transformations and environmental impacts. The theoretical framework draws on contributions from sustainable urban morphology, landscape ecology, and geomatics, integrating recent reviews and empirical studies based on Earth Observation data. Methodologically, the review includes studies using orbital and geospatial data to analyze land use and land cover, urban expansion, built density, vegetation cover, and climate-related risks. The results indicate that these approaches enable the identification of consistent patterns of urbanization, vegetation loss, and urban thermal intensification, with implications for urban sustainability, ecosystem services, and land-use management. As its main contribution, the article systematizes climate-oriented analytical approaches, highlighting the potential of geospatial technologies to connect urban morphology and natural systems while supporting evidence-based territorial management strategies

Keywords: Urban Sustainability · Remote Sensing · Geomatics · Climate Change · Urban Ecosystems

1 Introduction

Urbanization has intensified significantly in recent decades, transforming landscapes and generating complex environmental challenges for cities. Projections indicate that 68% of the global population will live in urban areas by 2050 (Wellmann et al., 2020), increasing pressure on natural systems and contributing to environmental degradation, biodiversity loss, and the intensification of climate-related risks. Although studies on sustainable

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 909–916, 2026.
https://doi.org/10.1007/978-3-032-34930-9_106

urban morphology have advanced in recent years, recent reviews highlight limitations related to the limited incorporation of indicators of natural systems and ecosystem health into analyses of urban form (Zhang et al., 2023).

Cities can be understood as Socio-Ecological-Technological Systems, in which the spatial configuration of built and natural elements influences environmental performance and the provision of ecosystem services (Wellmann et al., 2020). The increasing availability of satellite image time series and geospatial products has expanded the capacity to monitor these transformations, supporting more integrated and consistent urban environmental analyses (Wulder et al., 2019).

Satellite imagery enables the monitoring of land use and land cover changes, vegetation distribution, and urban thermal patterns, allowing the quantification of indicators such as Land Surface Temperature (LST), vegetation indices (NDVI), and Land Use/Land Cover (LULC) patterns. Recent studies have demonstrated that these approaches contribute to analyses related to outdoor thermal comfort and urban environmental performance (Manapragada et al., 2025).

Studies demonstrate the relevance of these approaches for understanding the relationships between urbanization and environmental change. Dessu et al. (2020) found that urban expansion associated with vegetation loss influenced local climatic conditions, and Qin et al. (2025) demonstrated that blue and green spaces contribute to regulating land surface temperature and improving urban microclimates. Other studies highlight the potential of Nature-Based Solutions (NBS) and ecosystem-based strategies for thermal mitigation and improving urban environmental performance (Santos et al., 2021; Zuo et al., 2022; Toscan et al., 2025).

Despite the growing number of empirical studies applying RS to urban environmental analysis, the literature remains fragmented across different thematic domains, often addressing urban climate, vegetation monitoring, and land use change separately. This study conducts a systematic literature review on the application of EO technologies, particularly RS and geomatics, to urban sustainability analysis under climate change conditions. The review aims to identify how these technologies have been employed to assess urban sustainability and to systematize recurring methodological trends and analytical approaches by organizing the literature around three dimensions: urban climate dynamics, urban vegetation and green infrastructure, and LULC changes associated with urban expansion. By integrating these dimensions, this study seeks to strengthen ecosystem-based and spatial approaches applied to sustainability-oriented urban planning, supporting more efficient and resilient territorial strategies.

2 Methodology

This study adopts a Systematic Literature Review (SLR) to identify and analyze recent scientific contributions on the application of Earth observation (EO) technologies, especially RS, to urban sustainability assessment. The review followed principles of transparency, traceability, and reproducibility widely adopted in systematic reviews, including the PRISMA protocol.

The bibliographic search was conducted in the Scopus and ScienceDirect databases, selected due to their broad coverage of journals in the fields of urban studies, environmental sustainability, geospatial technologies, and EO applications. The search strategy

was structured around three thematic axes — urban sustainability, EO technologies, and climate change — using the following Boolean search string: ("urban sustainability" OR "sustainable urban development") AND ("remote sensing" OR "satellite imagery" OR "Earth observation" OR "geospatial technologies") AND ("climate change" OR "climate crisis"). The search considered the occurrence of these terms in titles, abstracts, and keywords.

Peer-reviewed articles published between 2020 and 2025 were included if they explicitly addressed the application of RS, satellite imagery, or geospatial technologies in studies related to urban sustainability, urban planning, or environmental assessment in urban areas. Duplicate studies, research unrelated to urban contexts, studies in which RS appeared only marginally, and non-peer-reviewed publications were excluded. In the full-text review stage, studies lacking adherence to the proposed analytical dimensions or without a direct relationship between geospatial technologies and urban sustainability were also excluded.

The initial search identified 118 records (93 from Scopus and 25 from ScienceDirect). After removing 21 duplicates, 97 studies remained for screening. Title and abstract analysis resulted in the preliminary selection of 59 articles, which were subsequently evaluated through full-text review. After thematic refinement, the final sample comprised 42 scientific articles.

The selected studies were organized into an analytical matrix containing authors, year of publication, journal, research focus, type of RS data, and environmental indicators employed, including NDVI, LST, NDBI, and LULC dynamics. A thematic analysis was then conducted to identify recurring methodological trends and analytical approaches. Based on this analysis, the studies were grouped into three thematic categories: urban climate and urban heat islands (18 articles), urban vegetation and green infrastructure (13 articles), and land use changes associated with urban expansion (11 articles).

3 Results and Discussion

3.1 Overview of the Literature and Methodological Approaches

The reviewed studies demonstrate the growing use of RS and satellite data from open-access platforms, especially the Landsat and Sentinel missions, in the investigation of urban environmental processes. These approaches enable the monitoring of urban landscape transformations and support analyses related to climate dynamics, vegetation distribution, and land use change. According to Wulder et al. (2019), the integration between Landsat — an Earth observation program in continuous operation since 1972 — and Sentinel-2 expands the spatial and temporal coverage of data, strengthening multitemporal analyses.

Recent literature highlights the predominance of multispectral imagery associated with indicators such as Land Surface Temperature (LST), vegetation indices (NDVI and EVI), and Land Use and Land Cover (LULC) classifications. Studies also emphasize the growing integration between RS, GIS, LiDAR data, and ML techniques, reflecting a methodological trend toward integrated analyses of urban morphology and urban ecological processes. According to Manapragada et al. (2025), these approaches expand the

capacity to analyze urban thermal dynamics, outdoor thermal comfort, building energy consumption, and solar potential.

In addition to orbital imagery, several studies incorporate complementary geospatial datasets, including OpenStreetMap, the Human Settlement Layer, and cloud-based geospatial platforms, expanding the capacity to represent built density, urban configuration, and interactions between vegetation, and urban microclimates. These techniques support long-term analyses of territorial transformations and their environmental impacts. Dessu et al. (2020) demonstrated how urban expansion associated with vegetation loss contributed to local climatic changes in urban centers of southwestern Ethiopia. Similarly, Ruiz-Valero et al. (2026) integrated satellite imagery, LiDAR data, and Bayesian hierarchical models to analyze the cooling capacity of urban tree canopy cover in Málaga, Spain.

Overall, the reviewed studies indicate a growing integration between thermal metrics, vegetation indicators, and land use analyses, reinforcing the understanding that urban climate, green infrastructure, and urban expansion constitute interdependent dimensions of urban sustainability. Table 1 summarizes the main approaches, indicators, and applications identified in the reviewed literature. Nevertheless, limitations related to the spatial and temporal resolution of sensors, classification uncertainties, interoperability between platforms, and unequal data availability persist. These limitations hinder comparisons between studies and restrict the operational application of part of the environmental indicators derived from RS.

Table 1. Summary of the main RS approaches applied to urban sustainability

Dimension	Technologies	Indicators	Applications
Urban climate	Landsat, Sentinel-2, GIS	LST, NDVI NDBI	Thermal dynamics
Green infrastructure	Landsat, GIS	NDVI, LST	NBS
Urban expansion	Landsat, GEE	LULC, LST	Soil sealing

3.2 Urban Climate and Urban Heat Islands

A substantial portion of the reviewed literature investigates urban climate dynamics, particularly the relationships between UHI, urban morphology, and land cover transformation. These studies predominantly employ satellite-derived indicators such as Land Surface Temperature (LST), often combined with vegetation and imperviousness indices such as NDVI and NDBI.

Halder et al. (2021) investigated the impacts of climate change on urban heat islands using satellite-derived geospatial indicators. More recent studies expanded these analyses through thermal vulnerability and spatial modeling approaches. Pradeep Kumar et al. (2023) analyzed thermal comfort zones in semi-arid regions, while Li et al. (2024) integrated RS and ML to assess urban heat vulnerability.

Other studies examine the evolution of urban heat islands in rapidly urbanizing contexts. An et al. (2025) demonstrated that urban expansion and land cover transformations directly influence urban thermal patterns in Harbin, China. Similarly, Hasyim et al.

(2025) identified relationships between population density, land use, and increasing land surface temperature, highlighting the role of intensive urbanization in the intensification of urban heat islands.

Overall, the reviewed studies indicate a strong association between urban expansion, increasing impervious surfaces, and the intensification of urban heat islands, while vegetated areas and Nature-Based Solutions (NBS) present recurring mitigating effects. These findings reinforce the importance of incorporating thermal and vegetation-cover indicators into urban planning strategies aimed at climate adaptation and improving urban environmental quality.

3.3 Urban Vegetation and Green Infrastructure

Another group of studies examines the role of urban vegetation and green infrastructure in mitigating climate impacts and strengthening urban ecosystem services. These studies mainly employ satellite-derived vegetation indices to assess vegetation cover, cooling capacity, and the distribution of green infrastructure in cities.

Santos et al. (2021) used RS and GIS to model the potential of green roofs at different scales, highlighting their relevance for urban sustainability strategies. Kamal (2023) applied automated image extraction techniques from satellite imagery to estimate vegetation loss and support climate adaptation strategies. Other studies focused on the cooling effects associated with vegetation and Nature-Based Solutions (NBS). Zuo et al. (2022) quantified the thermal performance of green roofs under different urban configurations, while Shi et al. (2023) analyzed the relationship between urban parks and thermal comfort in industrial cities.

Recent research also demonstrates growing interest in the interactions between vegetation, water bodies, and urban microclimates. Qin et al. (2025) identified synergistic cooling effects associated with the integration of blue and green spaces in Fuzhou, China, demonstrating that spatial configuration and ecological complexity influence land surface temperature patterns. Similarly, Toscan et al. (2025) analyzed the impacts of NBS on land cover dynamics and urban temperatures in Guimarães-Portugal using multitemporal Landsat imagery and ML. Ruiz-Valero et al. (2026) also demonstrated the cooling capacity of urban tree canopy cover through the integration of satellite imagery and spatial modeling.

The reviewed studies indicate a growing trend toward the use of NBS and green infrastructure as spatially efficient strategies for thermal mitigation, climate adaptation, and strengthening urban resilience. In addition to microclimatic benefits, these approaches contribute to the preservation of ecosystem services and the more efficient use of urban land, reinforcing their relevance for sustainability-oriented urban policies.

3.4 Land Use Change and Urban Expansion

A third thematic group focuses on urban expansion and land use and land cover changes, investigating how territorial transformations influence urban environmental conditions. RS has played a central role in monitoring these dynamics, enabling the identification of patterns associated with urban growth, soil sealing, and vegetation loss.

Criado et al. (2020) conducted a multitemporal analysis of soil sealing and land use change in Salamanca, Spain, using Landsat imagery and historical aerial photographs between 1956 and 2018. The authors identified significant urban expansion over agricultural and environmentally sensitive areas. Dessu et al. (2020) documented similar trends in Ethiopian urban centers, demonstrating that accelerated urban growth was accompanied by reductions in vegetation and agricultural land.

More recent studies incorporate cloud-based geospatial platforms and ML techniques to expand the scale and accuracy of urban spatial analyses. Biswas et al. (2023) used Google Earth Engine and ML algorithms to map land use changes in Chattogram, Bangladesh, demonstrating the potential of these platforms for large-scale urban monitoring. Sonet et al. (2025) analyzed urban expansion patterns and thermal characteristics in rapidly growing megacities, highlighting relationships between intensive urbanization, land cover transformation, and increasing land surface temperature.

Overall, the analyzed studies demonstrate that LULC dynamics, vegetation loss, and urban thermal intensification constitute interdependent processes associated with accelerated urban expansion. These findings reinforce the importance of continuous spatial monitoring to support strategies aimed at more efficient land use, environmental impact mitigation, and preservation of urban ecological infrastructure.

The reviewed studies also indicate that the integration between RS, spatial modeling, and geospatial datasets expands the capacity to analyze relationships between urban morphology, ecological processes, and urban sustainability. Despite methodological advances, challenges related to the integration between RS, urban ecology, and territorial planning persist, as well as the translation of geospatial indicators into tools applicable to urban management. In this context, the results highlight the need for more integrated and operational approaches to sustainability-oriented urban planning, climate adaptation, and efficient land use.

4 Conclusion

The results highlight that EO technologies, especially RS and geomatics, enable the monitoring of land use and land cover change, vegetation distribution, and urban thermal dynamics, contributing to integrated analyses of urban morphology and ecological processes. The growing integration between RS, GIS, LiDAR data, and spatial modeling expands the capacity to represent interactions between the built environment, green infrastructure, and urban environmental conditions. The studies also demonstrate that urban climate, vegetation, and land use and land cover change constitute interdependent dimensions of urban sustainability, frequently associated with urban expansion, soil sealing, and thermal intensification.

Despite methodological advances, the literature remains fragmented across different thematic domains and still presents limitations related to the integration between RS, urban ecology, and territorial planning. Challenges associated with sensor resolution, interoperability between platforms, unequal data availability, and the institutional and operational complexity of EO systems—especially in contexts of the Global South—also persist. The reviewed studies highlight the relevance of Nature-Based Solutions (NBS) and green infrastructure for thermal mitigation and climate adaptation. In this

context, the results reinforce the potential of geospatial technologies to support evidence-based territorial strategies for efficient land use and ecosystem service preservation. Finally, future research may advance in the development of more integrated approaches capable of articulating EO data, urban morphology indicators, and ecosystem metrics into frameworks more applicable to sustainability-oriented urban planning.

Abstract.
Purpose The construction market in Kosovo is still dominated by linear traditional construction practices, which are not sufficiently environmentally friendly. Recently, urgent needs for sustainability, resilience and circularity have emerged, challenging these conventional methods. This study aims to analyze the emerging ecosystem of sustainable construction in Kosovo by examining industry initiatives, private sector competitors, and stakeholder collaborations that drive systemic change

Methodology This research employs a desk research-based approach combined with qualitative descriptive analysis. To gain primary insights, in-depth interviews were conducted with the founder/director of the Kosovo Green Building Council (KGBC). This methodology allows to evaluate how stakeholders coordinate and apply sustainable strategies within the local ecosystem

Findings and Discussion The paper identifies key actors within the ecosystem, such as the Kosovo Green Building Council (KGBC), a non-governmental organization dedicated to advancing green standards and professional development. KGBC aims to serve as a bridge connecting stakeholders from the public and private sectors. In the private sector, businesses like InstaBuilt illustrate the advanced techniques that are changing the construction industry. InstaBuilt is one of the largest construction factories in Southeast Europe, creating environmentally friendly, wood-based modular housing systems that reduce embodied carbon and improve resource efficiency

Conclusion The research concludes by assessing the level of coordination among stakeholders and the effectiveness of current techniques and strategies in fostering a sustainable ecosystem. By highlighting the synergy between NGO advocacy and private sector innovation, the paper underscores the necessary transition from traditional to circular construction practices in Kosovo

1 The Overview of Construction Sector in Kosovo

The industry of construction remains a cornerstone of Kosovo's economy, showing consistent growth during 2025 in tax contributions and business registrations. Based on data from the Kosovo Agency of Statistics, the GDP contribution from the construction sector reached €242.54 million in the third quarter of 2025 [1]. According to data from the Kosovo Business Registration Agency, there are approximately 12,684 construction businesses registered during 2025 [2]. However, based on data from the Tax Administration of Kosovo, only 4,258 construction companies are currently active tax declarants [3]. This indicates that a significant number of registered businesses are either not economically active or fail to declare and pay taxes regularly.

As reported in the annual report of the Tax Administration of Kosovo for 2025, the construction industry has been identified as a high-priority area for revenue collection and formalization [3]. Total tax revenues for the period January–August 2025 reached €713.3 million, an increase of €71.2 million (10.6%) compared to the same period in 2024 [3]. Hence, stricter reverse charge VAT applications have been enforced for construction services to prevent tax evasion [3].

2 Methodology

This study adopts a mixed-method approach, combining qualitative descriptive analysis with quantitative desk research to provide a comprehensive overview of the sustainable construction ecosystem in Kosovo. The study evaluates both the maturity of the sustainability transition in this sector and its economic scale.

The first part of the research is based on official reports and statistical databases published in 2025. Key sources include TAK, KBRA, KAS, and reports from international organizations such as EBRD, UNDP, and GIZ [1–3, 13–16]. To capture the green transition, the study conducted a semi-structured in-depth interview with a key pioneer actor within the local ecosystem, namely the founder and director of the Kosovo Green Building Council (KGBC). The selection was based on KGBC's central role in advocacy and private sector innovation.

The qualitative data was processed using thematic coding to categorize industry barriers and drivers. A cross-referencing method was applied to compare qualitative findings with quantitative data from TAK and KAS [1, 3]. This approach enabled identification of implementation and compliance gaps between sustainable certification practices and economic output.

3 Emerging Ecosystem of Sustainable Construction in Kosovo

Based on international funding support and private innovation, 2025 has seen a gradual shift toward green construction standards, although traditional practices still dominate in Kosovo [13, 14]. Kosovo's ecosystem for sustainable construction remains in an early stage of development [4]. Its key features include increasing awareness of environmental

regulations, energy efficiency, and sustainable building practices. Due to insufficient promotion, citizens remain relatively uninformed about the benefits of sustainable construction [4]. Sustainable construction offers economic, social, and environmental benefits such as energy savings, reduced operational costs, lower CO_2 emissions, and improved occupant well-being [4]. Utilizing resources more effectively is necessary to transition to a sustainable economy [5]. However, challenges remain largely organizational, structural, economic, and regulatory [4].

There are several interrelated actors in Kosovo's emerging ecosystem of sustainable construction (see Fig. 1). All of these actors work together to create a growing environment that facilitates the shift to sustainable building. The regulatory and policy framework for sustainable construction is mostly shaped by public institutions.

Fig. 1 Emerging Ecosystem of Sustainable Construction in Kosovo

3.1 Government and Public Institutions

Sustainable building practices are implemented by developers and construction businesses, while government institutions offer the policy direction and regulatory framework. A combination of institutional obligations and evolving legal instruments create Kosovo's regulatory environment for sustainable construction. The regulatory framework is shaped by public institutions that provide policy direction and legal instruments. Key institutions include the Ministry of Environment, Spatial Planning and Infrastructure [6] and the Ministry of Economy [7]. The framework is defined by the Law on Construction [8], the Law on Energy Efficiency [9], and the Law on Energy Performance of Buildings [10]. Additional support is provided by the Renewable Energy Law [11] and financial mecha-nisms such as the Kosovo Energy Efficiency Fund [12].

3.2 Universities and Research

Higher education institutions contribute through programs in civil engineering and architecture. The University of Prishtina and the University for Business and Technology integrate sustainability concepts such as energy efficiency and green construction into their curricula [4].

3.3 International Organizations

The construction sector started to progressively embrace green building concepts including better insulation, the integration of renewable energy, and resource-efficient materials thanks to donor-sponsored programs and compliance with EU standards. International actors play a key role in advancing sustainable construction. Helvetas promotes green materials and technologies through the RECONOMY program [13]. Establishing Green Building Councils is one strategy that promotes industry-wide standards and gives women and youth access to green jobs [13]. The World Bank and EBRD finance large-scale energy efficiency projects in public buildings [14, 15]. The European Union supports infrastructure and sustainability initiatives through programs such as the Western Balkans Investment Framework [16]. UNDP contributes through advisory support and capacity-building activities [17].

3.4 Private Sector

Private sector innovation is emerging but remains limited. InstaBuilt represents an advanced example of green construction, focusing on modular housing and embodied carbon reduction [18]. Similarly, the Innovation and Training Park (ITP) in Prizren has developed energy-efficient infrastructure and renewable energy capacity [19].

3.5 Financial Institutions

Financial institutions, particularly commercial banks, are increasingly supporting sustainable construction through green financing mechanisms. Some banks have introduced loan products that support energy-efficient construction and renovation, often in collaboration with international financial institutions [15].

3.6 NGOs

NGOs such as Balkan Green Foundation contribute through research, advocacy, and public engagement on environmental and climate-related issues [20]. These organizations often collaborate with international partners and institutions to support the development of standards, training, and awareness campaigns [20].

3.7 Industry Associations

The Kosovo Green Building Council (KGBC) is a non-governmental, non-profit organization that operates as a professional association promoting sustainable construction practices. It plays a key role in promoting sustainable construction practices and bridging the gap between policy and private sector engagement [21]. KGBC serves as the primary NGO advocate, facilitating the "Green Business & Industry Summit" and the "Green Business Expo 2025" in Pristina to bridge the gap between public policy and private green investment [22].

4 Analysis and Discussion

According to the data gathered in this study and presented in the Table 1, we can conclude that the transition toward a sustainable construction ecosystem in Kosovo is characterized by a significant gap between officially registered businesses and those actively participating in the market. The construction industry remains a primary economic driver, the qualitative data gathered from the Kosovo Green Building Council (KGBC) emphasizes that the market for sustainable building is still in its initial stage of maturity. The following analysis examines the systemic obstacles and barriers, and strategic drivers identified by key stakeholders.

According to the data gathered from the interview with the Founder and Director of KGBC to shift toward green building, the most important incentives and forces are: rising energy costs and EU standards. Hence, based on this suggestion, internal policy incentives are weaker in supporting and driving sustainability in Kosovo than immediate economic necessity and external regulatory pressure (EU Standards). On the other hand, the lack of government incentives and high initial capital costs remain the strongest barriers to widespread adoption. This financial barrier is accompanied by a technical skill gap in the local workforce, which has a direct impact on limiting the capacity of construction firms to implement complex green technologies.

Nevertheless, the construction industry is recognizing the necessity future of the green standards but is still hindered by short-term fiscal constraints. During the interview, the director of KGBC, emphasized that the private sector engagement is low, and on the other hand the long-term economic value is perceived as positive. "*We established KGBC to bridge the gap between outdated construction norms and the urgent need for energy-efficient urban development*" (K-01).

Table 1. Summary of semi-structured in-depth interview

Interview ID	**K-01**
Respondent Role	Founder & Director
Core Mission & Gap	Advocating for sustainable standards; filling the gap in energy efficiency regulations and green building certification.
Market Maturity (Early/Dev/Adv)	Early Stage
Main Drivers (1=EU Standards, 2=Energy Costs, 3=CSR, 4=Policy)	1, 2
Main Barriers	High initial capital costs, lack of government incentives, and limited technical expertise in the local workforce.
Notable Projects/ Initiatives	Green Building Weeks, Policy Advocacy, Certification Training
Private Sector Engagement (High/Med/Low)	Low
Perceived Economic Value (Pos/Neut/Neg)	Positive (Long-term)
Primary Stakeholder Partner	Government (Ministry of Environment) & International NGOs
Future Outlook (5-10 yrs)	Shift toward mandatory energy performance certificates and LEED/BREEAM alignment.
Key Quote	"We established KGBC to bridge the gap between outdated construction norms and the urgent need for energy-efficient urban development."

5 Conclusion

According to the data related to the Tax Administration of Kosovo [3], only 4,258 are active tax declarants, while there are 12,684 registered construction businesses. A critical compliance gap is reflected by the data, that extends from environmental standards to tax declarations. Meanwhile, the mission of KGBC is supported by international partners and not too much supported by any state legislative framework. However, the future of

this industry for the next 5–10 years remains optimistic, with a projected shift toward mandatory energy performance certificates. To achieve this, the cooperation between advocacy groups like KGBC and private sector innovators like InstaBuilt and other stakeholders, will be essential in moving Kosovo toward a circular economy.

Adaptive Natural Ventilation Strategies in Scotland's Office Building: Impact on Indoor Air Quality and Comfort

Ariakpoze Jessica Eyaefe(✉), Mina Jowkar, and Nirodha Fernando

Edinburgh Napier University, Edinburgh EH10 5DT, UK
40683718@live.napier.ac.uk

Abstract. This study assesses the effectiveness of adaptive natural ventilation (ANV) strategies in improving indoor air quality (IAQ) and thermal comfort in a Scottish university office building. A mixed-methods approach was used, including simultaneous environmental monitoring and occupant surveying. Results show that although the ambient environmental conditions generally aligned with adaptive comfort guidance in ASHRAE 55 (2023) and EN 16798–1:2019, low indoor air quality and thermal dissatisfaction were reported due to restricted airflow, inaccessible windows, and inconsistent operation during colder periods. Key barriers including spatial design limitations, limited user interaction, and climatic variability are also discussed. The findings highlight the importance of user-responsive ventilation systems that incorporate automated controls and adaptive design to enhance energy efficiency, occupant well-being, and climate resilience in office buildings

Keywords: adaptive natural ventilation · indoor air quality · thermal comfort · sustainable buildings · occupant perception · office environments

1 Introduction

The building sector contributes around 39% of global energy-related CO_2 emissions, with ventilation systems accounting for a significant share of operational energy use in non-residential buildings [1, 2]. In the UK, higher education buildings consume approximately 5.2 billion kWh of energy annually [3], highlighting the importance of improving indoor environmental strategies to reduce energy demand and associated greenhouse gas emissions. However, energy efficiency measures must ensure that occupant thermal comfort and indoor air quality are not compromised. In response to these energy saving strategies, Natural Ventilation (NV) is widely promoted as a low-energy strategy that can reduce reliance on mechanical systems while maintaining indoor air quality (IAQ) and thermal comfort through passive airflow [2, 4]. However, its effectiveness is highly climate dependent. In cold and variable climates such as Scotland, low temperatures, humidity, and fluctuating wind conditions can limit airflow and reduce ventilation efficiency [5, 6]. In addition, occupant reluctance to open windows during colder periods

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 925–933, 2026.
https://doi.org/10.1007/978-3-032-34930-9_108

and physical constraints such as single-sided ventilation in deep office spaces can result in low air velocities, stagnant zones, and poor perceived air quality despite acceptable CO_2 levels [7, 8]. Adaptive natural ventilation (ANV) adjusts airflow pathways and window operation in response to environmental conditions and occupant interaction [9]. Although simulation studies show that NV and ANV can reduce energy demand while maintaining acceptable indoor conditions [10], empirical evidence of their real-world performance in cold-climate office buildings remains limited. In regions such as Scotland, a key challenge is balancing heat retention and fresh air exchange [11, 12]. Highly airtight buildings designed for energy efficiency can lead to the accumulation of CO_2, moisture, and VOCs, increasing the risk of poor indoor air quality and Sick Building Syndrome (SBS) [2]. This issue may be further intensified by occupants' reluctance to open windows during winter, creating an indoor air quality–energy paradox [7]. This research gap is particularly relevant in Scotland, where many office buildings are historic or retrofit-sensitive and therefore constrained in terms of ventilation design [7, 13]. Understanding the relationship between measured environmental conditions and occupants' perception is essential for adaptive comfort evaluation in naturally ventilated office buildings.

This study evaluates the effectiveness of adaptive natural ventilation (ANV) strategies in improving indoor air quality (IAQ) and thermal comfort in a university office building in Scotland. Using in-situ environmental monitoring and occupant surveys, the research examines IAQ, thermal conditions, and window-use behaviour. The measured performance was evaluated using adaptive thermal comfort guidance in ASHRAE 55 -2023 [14] and EN 16798-1:2019 [15] to identify potential gaps between regulatory compliance and occupant perception, providing in-sights for climate-responsive and user-centred ventilation design in cold-climate regions.

2 Methodology

This study used a mixed-methods approach, combining in-situ environmental monitoring and structured occupant surveys in a naturally ventilated university office in Scotland (Fig. 1). Ventilation was provided through six high-level, single-sided operable windows along one façade. The partitioned office layout and a closed rear door limited cross-ventilation potential.

2.1 Environmental Monitoring and Data Collection

Environmental monitoring was conducted over a two-week period (14–28 March 2025, excluding weekends) during working hours (09:00–17:00)

Parameters Measured includes Carbon dioxide (CO_2) concentration, Indoor air temperature, Relative humidity (RH), Air velocity, Particulate matter ($PM_{2.5}$ and PM_{10}). CO_2 was used as an indicator of ventilation effectiveness. Temperature and RH were used to assess thermal comfort conditions. Air velocity was measured to evaluate airflow performance. All monitoring devices were strategically placed at a height of 1.1 m centrally within the office to avoid direct sunlight, draughts, and equipment interference, ensuring representative indoor readings. The parameters and their respective monitoring devices are summarized in Table 1.

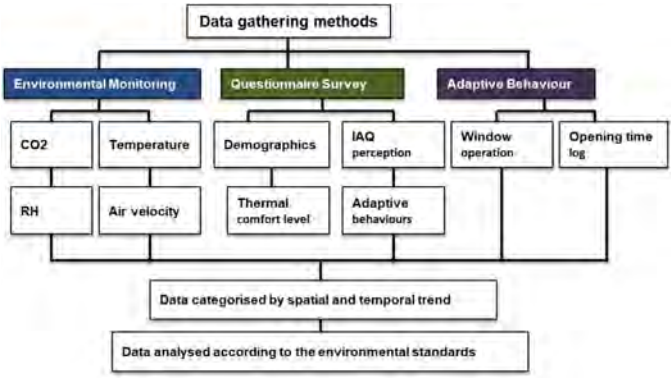

Fig. 1: overview of the data gathering methods

Table 1. Technical specifications of monitoring equipment

Measured Parameter	Instrument	Range	Accuracy
Air Temperature	INKBIRD IBS-TH3 PLUS	0–50 °C	±0.3 °C
Relative Humidity	INKBIRD IBS-TH3-PLUS	0–99 %RH	±3% RH
CO_2 Concentration	Qingping Air Monitor Lite	400–9999 ppm	±15%
PM2.5 / PM10	Qingping Air Monitor Lite	0–500 µg/m^3	Not specified
Air Velocity	Swema 03 Anemometer	0.05–3.00 m/s	±0.03 m/s

2.2 Questionnaire Survey (Table 2)

Table 2. Summary of participant

Office Type	Capacity	Group	Gender	Age Range	Mean Age	Activity Level
Shared research office	Designed for 24 occupants	Research students (N = 15)	8 Male and 7 Female	25–55 Years	32 Years	1.1–1.2met

3 Results

Carbon dioxide (CO_2) concentrations during the monitoring period ranged from 556 ppm to a peak of 1123 ppm, with an average value of 725 ppm. Mean concentration presented in Fig. 2a, remained below the commonly referenced 1000 ppm threshold for office environments [15, 16]. However, exceedance above 1000 ppm occurred during peak occupancy on 21 March 2025, indicating periods of insufficient ventilation. These fluctuations

indicate intermittent under-ventilation, particularly during afternoon occupancy peaks. Indoor temperature ranged from 18.4 °C to 26.6 °C (mean: 23.4 °C). These values fall within the acceptable adaptive comfort ranges recommended by ASHRAE 55 (2023) for naturally ventilated offices. Relative humidity ranged between 30.9% and 58.4% (mean: 41.4%), remaining within the recommended 30–60% indoor comfort range. Particulate matter concentrations ($PM_{2.5}$ and PM_{10}) remained between 0–3 μg/m^3, well below WHO guideline limits, showing minimal particulate-related air quality concerns during the monitoring period.

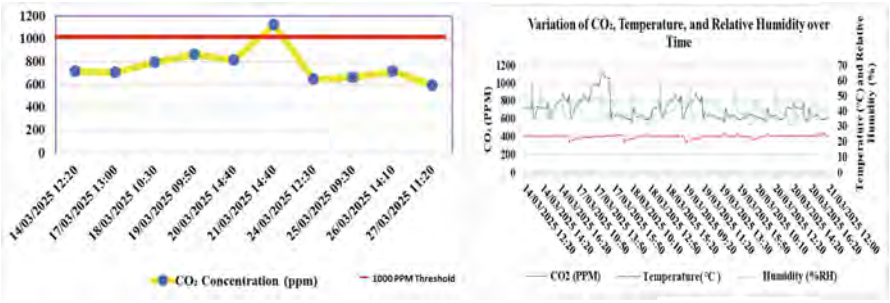

Fig. 2 **a**. CO2 concentration and **b**. IAQ Trend during monitoring period

In contrast to these compliant parameters, air velocity ranged from 0.013 to 0.051 m/s (mean: 0.048 m/s), substantially below the perceptible airflow threshold of 0.15–0.25 m/s recommended for naturally ventilated spaces (Fig. 3). This empirical value provides a scientific basis for the 73% dissatisfaction rate recorded in the surveys. While most environmental parameters complied with standards, extremely low air velocity indicates limited effective air movement within the space.

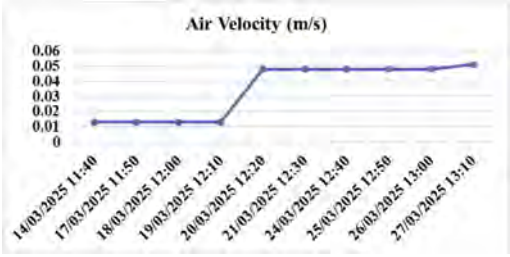

Fig. 3. Recorded air velocity during monitoring period

3.1 Occupant Comfort Perception

Following analysis of the environmental data, the occupant thermal comfort and perception of indoor air quality were analysed and the results provided in the following sections.

Thermal Comfort. Survey responses indicated that most occupants reported neutral to slightly warm sensations on the ASHRAE thermal sensation scale, with the mean TSV of 1.1. Despite measured temperatures falling within adaptive comfort ranges, several occupants reported discomfort associated with insufficient airflow and air movement which influenced perceived thermal conditions more strongly than temperature alone. To understand the relationship between these variables, a Pearson Correlation Matrix was utilized (Table 3).

Table 3. Pearson Correlation Matrix

	Temperature	Humidity	CO_2	Air Velocity
Temperature	1			
Humidity	−0.094	1		
CO_2 (PPM)	−0.089	0.239	1	
Air Velocity	−0.135	0.085	0.239	1

Perceived Indoor Air Quality. Forty percent (40%) of respondents reported experiencing "stuffy or stale air," while 13.3% reported dry air and 13.3% unpleasant odours. Although CO_2 levels were generally compliant, perceived air freshness did not fully align with measured concentrations. Reported symptoms included fatigue, headaches, and respiratory discomfort, consistent with mild SBS indicators (Fig. 4).

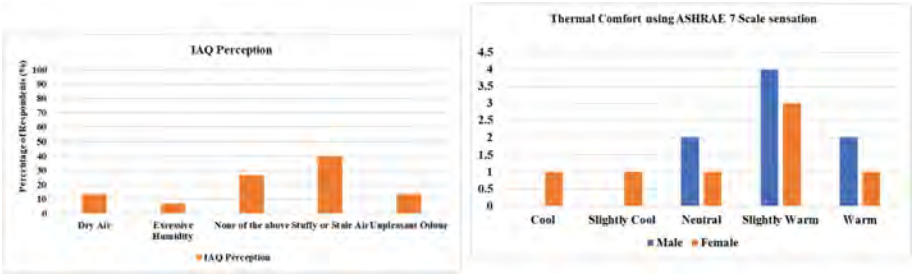

Fig.4 **a**. Perceived IAQ concerns, and **b**. TSVs reported by occupants

Window operation was inconsistent. 20% reported opening windows daily, 26.7% opened windows a few times per week, 33.3% occasionally, 20% rarely or never. Cold weather was identified as the primary barrier to window operation (53.3%), followed by external noise (20%) and lack of operable windows at individual workstations (20%). These demonstrate that climatic conditions and limited window accessibility reduced user interaction with the ventilation system. Despite windows being operable, the single-sided layout and high-level window positioning limited effective cross-ventilation, contributing to restricted airflow and reduced ventilation effectiveness during colder periods.

4 Discussion

This section presents a detailed analysis and interpretation of the findings obtained from the study. The results are examined to identify key trends and to discuss their implications in the context of occupant thermal comfort.

4.1 Measured IAQ and Perceived Comfort

Measured environmental parameters generally complied with thermal comfort and ventilation guidance for naturally ventilated buildings. Average CO_2 concentrations (725 ppm) remained below the 1000 ppm recommended thresholds, temperature (mean 23.4 °C) remained within the adaptive comfort range recommended in ASHRAE 55 (2023), and relative humidity remained within the recommended 30–60% range. However, air velocity (mean 0.048 m/s) was significantly below the perceptible comfort threshold of 0.15–0.25 m/s. Despite numerical compliance, 40% of occupants reported "stuffy or stale air," alongside symptoms such as fatigue and headaches, indicating a discrepancy between measured IAQ indicators and perceived comfort. The findings support adaptive comfort approaches in naturally ventilated buildings, where occupant perception and behavioural adaptation influence comfort beyond steady-state thermal parameters. This aligns with previous findings [7], who reported that ventilation performance in Scottish buildings may meet regulatory thresholds while still failing to satisfy occupants due to airflow distribution limitations. Similarly, occupant perception is strongly influenced by air movement rather than pollutant concentration alone [17].

In contrast to studies demonstrating significant IAQ improvements through optimized natural ventilation [17], this study shows that compliance with CO_2 limits does not guarantee perceived freshness when air velocity remains low. These findings reinforce the importance of airflow distribution and air movement as determinants of comfort in naturally ventilated office environments.

Window operation behaviour significantly influenced ventilation performance. More than half of respondents identified cold weather as the primary barrier to opening windows. This aligns with previous finding that observed occupants in cold climates are reluctant to open windows due to thermal discomfort concerns [6]. Fobiri et al. (2023) similarly reported seasonal behavioural reluctance as a key limitation. In cold and variable climates such as Scotland, maintaining thermal comfort often takes precedence over air exchange. The findings demonstrated that ANV systems that depend on manual interaction underperform during colder periods. Climatic variability, including low outdoor temperatures and fluctuating wind patterns, further complicates airflow predictability and consistency, reinforcing the context-dependent nature of natural ventilation performance. The spatial configuration of Office which is single-sided high-level windows, lack of cross-ventilation pathways, and internal partitions restricted effective airflow distribution. Window opening produced negligible changes in air velocity, demonstrating architectural limitations rather than operational failure. This aligns with Evola and Popov (2006), who demonstrated that cross-ventilation effectiveness depends heavily on façade orientation and airflow pathways. It also supports findings by Lei et al. [18], who emphasized the influence of building configuration on pollutant dilution. This finding highlights the importance of considering spatial airflow dynamics during the design or

retrofit of naturally ventilated office buildings, particularly in heritage-sensitive con-texts where façade modifications may be restricted.

The combined influence of restricted airflow, climatic variability, and inconsistent window operation demonstrates practical limitations of purely passive, occupant-dependent natural ventilation in Scottish office environments. To enhance both energy efficiency and occupant well-being, ventilation strategies must move beyond reliance on manual window operation. User-responsive systems incorporating automated controls, demand-based airflow adjustment, or hybrid support mechanisms may help compensate for behavioural and seasonal variability. Such adaptive natural ventilation design approaches can improve airflow consistency while maintaining thermal comfort, thereby supporting climate-resilient office environments in cold regions.

5 Conclusion

This study evaluated the real-world performance of adaptive natural ventilation (ANV) in a Scottish university office through a simultaneous environmental monitoring of temperature, CO2, relative humidity (RH), PM2.5 and PM10, air velocity, and occupant questionnaire surveys.

The results show that while measured parameters for temperature and CO_2 generally aligned with adaptive comfort guidance in ASHRAE 55 (2023), EN 16798–1:2019 and ventilation guidance in ASHRAE 62.1, the findings reveal a significant IAQ-Perception Gap. The technical root of occupant dissatisfaction was identified as stagnant airflow, with a recorded mean air velocity of 0.048 m/s well below the human perceptibility threshold of 0.1 m/s. This lack of air movement, coupled with 73% of respondents reporting Sick Building Syndrome (SBS) symptoms such as fatigue and headaches, confirms that regulatory compliance alone does not guarantee perceived comfort or healthy indoor environments. In the context of Scotland's cold climate, the IAQ-Energy Paradox remains a critical barrier. Occupant reluctance to operate high-level, single-sided windows during colder months to avoid localized draughts leads to localized dead zones and increased air age. To move toward a professional standard of climate-resilient ventilation, this research advocates a layered strategy that combines: 1) Automated Actuators that is sensor-driven window controls to bypass behavioural barriers; 2) User-Responsive Overrides to maintain occupant activity through manual controls; 3) Retrofit Interventions that Implement low-level windows or trickle vents to enhance airflow distribution in restricted heritage spaces. Future research should focus on long-term seasonal monitoring to further refine these automated triggers for optimal energy-efficiency and occupant well-being in cold-climate regions.

Understanding Zero Carbon Building Implementation Through Actor-Network Theory (ANT) Lens

Simin Tavajoh(✉) and Govert Valkenburg

Norwegian University of Science and Technology, Trondheim, Norway
simin.tavajoh@ntnu.no

Abstract. The construction and operation of buildings account for more than one-third of global carbon emissions, making low- and zero-carbon initiatives essential for climate change mitigation. However, the implementation of such initiatives remains inconsistent. This suggests that challenges lie not only in technical design but also in how sustainability measures are implemented and negotiated within real project settings. This study examines how sustainability-related artifacts—such as calculation tools, energy models, and policy documents—shape the implementation of low-carbon building practices. An integrative literature review was conducted, focusing on case-based studies that apply Actor-Network Theory (ANT). The findings show that artifacts do not determine results on their own. Their effects vary across contexts and depend on how they are interpreted, used, and connected to other actors within networks. The same tool may lead to different outcomes depending on local practices. Processes such as black-boxing can strengthen trust in certain actors while limiting others' influence. Overall, the study shows that sustainability outcomes in building projects emerge from the dynamic interaction between actors and artifacts rather than from technical solutions alone

1 Introduction

Climate change has made it essential to reduce greenhouse gas and carbon emissions across all sectors, particularly in building construction and use, which are major contributors and account for more than one-third of global emissions [1]. In April 2021, the European Union introduced a plan to replace the nearly zero-energy building standard with a zero-emission building target by 2030, supporting its broader aim of becoming climate neutral in the long term. As a result, all EU Member States are required to put in place and strengthen national laws and regulations to cut emissions from buildings and ensure that their countries reach carbon neutrality by 2050 [2].

Although many policies focus on sustainability, problems often arise during their implementation. There is often a gap between what is planned in policy and what is actually carried out in practice [3]. Research also shows that sustainable building is not

limited by a lack of knowledge, technology, or assessment tools. Instead, the main challenge is the difficulty of changing current practices and adopting new ways of working in order to apply these new technologies [4].

This shows that the challenge is not only technical but also social and organizational. This is where Science and Technology Studies (STS) can provide useful insights. One key point in STS is that it examines how scientific knowledge and technologies are shaped and formed within social contexts, and in turn contribute to the shaping of those contexts [5].

1.1 Theoretical Background

Actor-Network Theory (ANT) was developed within Science and Technology Studies in the late twentieth century. It is based on the idea that nothing exists outside the relations that produce it [6]. A network consists of actors, or "actants," both human and non-human, that shape processes such as innovation. Human actors influence networks through their interests and interpretations, while non-human actors shape them through their material properties and constraints [7].

Society and organizations are not made up of social relations alone; they also involve relations between texts, devices, buildings, and other material components and in our analysis, we should treat such relations as being of the same kind [8, 9]. Rather than offering broad explanations, ANT focuses on describing how these relations are formed in practice and how they hold together, or fail to do so [6].

A key concept in ANT is "translation," which refers to the process through which actors align interests, build connections, and create order. Through translation, actors and networks are transformed, and certain elements come to represent others [8]. Ideas and policies circulate more effectively when turned into artifacts, but these must align with new networks of actors and knowledge to lead to action. Whether this occurs depends on how problems are defined and whether actors can enroll others and gain support for the idea [10].

1.2 Research Question and Paper Structure

From ANT perspective, reality is produced through connections between human and non-human elements. To understand how these networks are formed and stabilized, it is important to examine how actants interact, enroll one another, and how intermediaries shape their relationships.

This paper examines how low-carbon building initiatives are implemented or constrained through the interactions among human and non-human actors. It explores how artifacts mediate sustainability in building projects, drawing on existing studies. Section 2 explains the search method and the criteria used to select and assess the material. Section 3 presents and categorizes the collected data according to the main artifacts identified, followed by a discussion of the key findings and concluding remarks.

2 Method

2.1 Research Design and Data Collection

Given the focus of this study on cases that examine the success or failure of sustainable practices through the lens of Actor-Network Theory, an integrative literature review was chosen as the most appropriate method for data collection and analysis. An integrative literature review is a research approach that examines, evaluates, and brings together key studies on a specific topic in a unified way [11]. This type of review does not aim to include every published study on the topic. Instead, it involves a more flexible and selective approach, bringing together insights from different fields and research traditions to build a broader understanding [12].

Scopus was chosen as the main database for this study because it is well known for its wide coverage and for offering reliable and high-quality research from different academic fields [13]. The research questions were translated into a search string using Boolean operators. The search included terms such as "actor network" combined with "sustainabl*" OR "low carbon" OR "zero carbon," and "building" OR "construction."

2.2 Searching Process and Selection Criteria

The process of identifying relevant materials was carried out in two main stages. First, structured search strings were used to search electronic databases. After this step, additional sources were added to strengthen the data collection. These included references from selected articles, studies already known to the author, and AI-based tools such as Research Rabbit, which supported forward and backward citation tracking by grouping related studies.

Papers were selected based on inclusion criteria developed to ensure relevance to the research question.

- First, the study had to use Actor-Network Theory as an analytical lens to examine real case studies or practical examples.
- Second, the case study needed to be related to the building industry, or the analysis had to be clearly applicable to it. Some publications were excluded because they used the term "construction" in a different context.
- Third, the practices discussed in the papers had to relate to sustainability-oriented changes or the analysis had to be clearly applicable to it.

In addition, only studies published within selected subject areas were considered, with the search mainly limited to the fields of environmental studies, social sciences, engineering, and business

After the final two screening stages, 17 papers were first selected based on the relevance of their abstracts—9 from the first stage and 8 from the second. However, 5 of these were later excluded as they were found to be irrelevant (not aligned with all three inclusion points above). This led to a final sample of 12 papers for detailed review and data extraction. The full process is illustrated in Fig. 1.

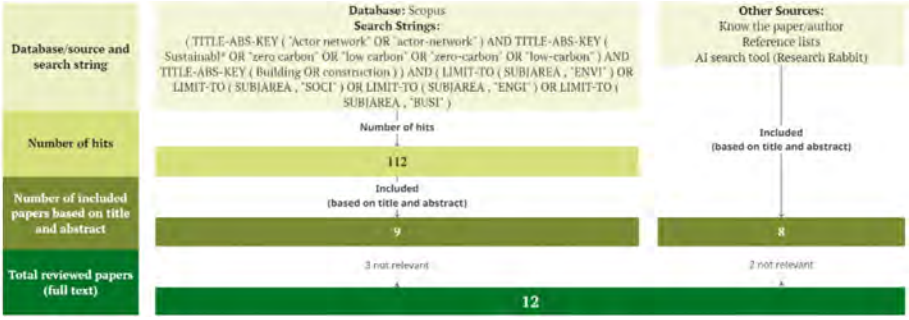

Fig. 1. Searching process

3 How Artifacts Meditate Low Carbon Initiative Implementation

The reviewed papers show that artifacts are crucial in shaping sustainable design work, both by enabling certain practices and limiting what actors can do. To clarify these patterns, the most frequently discussed artifacts are grouped into three categories in the next sub-sections.

3.1 Policy, Regulations, and Standards

Artifacts that comply with standards reinforce the dominant norms of a field because the value attached to compliance encourages others to follow, creating stability [14]. Based on the case study by Faulconbridge et al. [14] in commercial office design, this dynamic is evident in both the informal idea of Grade A offices—rooted in shared assumptions about what makes a marketable building—and the formal BCO (British Council for Offices) specifications, which translate these assumptions into detailed technical benchmarks. Together, these standards define what counts as a high-quality building, shape market expectations, and make designs comparable. At the same time, they restrict design agency by turning complex questions into fixed criteria, shifting attention away from how people actually work in offices and toward meeting predefined technical requirements. This promotes a uniform, one-size-fits-all approach, such as designing for occupancy levels far higher than most offices ever reach, which leads to oversized systems and limits the feasibility of low-energy solutions. In effect, those taken-for-granted standards "black-box" many aspects of design: they simplify complexity but also narrow professional judgment, diminish contextual knowledge, and lock in design choices that may not align with real patterns of use. In ANT terms, black-boxing means that certain objects, relations, and practices are made present while others become absent, forgotten, or displaced [15].

Relationships between artifacts and agencies vary between cases, and we see that different national policies engender different constellations. For example, in Cyprus [16], sustainability policies are broad and unspecific, giving building designers considerable interpretive freedom. Because formal criteria are limited, advances in areas such as energy performance or sustainable community design have largely depended on individual designers' expertise, motivation, and ability to persuade colleagues. However, Rydin

[17] showed in the context of planning for low-carbon urban development in London that planning documents influence how actors interact within the planning system, and this influence depends largely on the level of detail they contain. As policies specify exactly how to assess energy use, emissions, or technology options, they direct how planners interpret requirements and reduce the scope for discretionary decision-making. Such detail also strengthens the capacity of higher-level authorities to steer local planning practice from a distance. Rather than enabling flexible judgment, highly prescriptive wording can narrow planners' choices and limit the agency of those responsible for applying the policies.

3.2 Certificates and Database

Goulden et al. [18] show that the growing policy appeal of green building certification, as we saw in the Israeli case, stems from the assumption that certified buildings automatically reduce greenhouse gas emissions, even though actual environmental improvements are rarely measured. Israel's voluntary green building standard, SI 5281, awards points across categories such as energy, water, materials, health, waste, and transport, with buildings certified on a one- to five-star scale. This black-boxed understanding encourages adoption for reasons that extend beyond verified performance: the multi-category checklist makes certification a flexible and indirect indicator of environmental benefit, offering limited evaluation of performance in any single area, including energy. As a result, SI 5281 provides little evidence of real efficiency gains, yet its ambiguity enables it to circulate easily across governance settings, serving both energy-focused and broader environmental agendas.

Francart et al. [16] show a similar dynamic in Cyprus, where building designers rely on the single sustainability score provided in product databases rather than assessing underlying data themselves. This reliance leads many to assume that a high score signals low climate impact, even though the database primarily evaluates local environmental and human-toxicity indicators and includes energy use and climate impact only as optional information. Because the assessment is simplified and outsourced, it shapes which aspects of sustainability are considered and which are overlooked, turning the database into a black-boxed authority that effectively defines which materials are treated as "sustainable." In practice, users engage with the score much like they engage with a certification manual: its apparent clarity and ease of use guide decisions, while the criteria behind it remain largely invisible.

As mentioned earlier, applying for a sustainability certificate does not directly improve a building's environmental performance, but, according to Frank et al. [19], in Denmark, it indirectly encourages more sustainable choices throughout the design process. Economic incentives—such as reduced energy use and the durability of long-lasting materials—reinforce this effect, while costly analyses can be replaced with templates and checklists to keep certification accessible, which was introduced in the study as an added intermediary to reduce costs and make the process more standardized. The certification manual functions as a key non-human actor: its clarity and usability shape how homeowners, architects, and builders engage with the scheme. A manual that is too dense discourages participation, while one that is too flexible leaves less experienced builders vulnerable to pressure from actors motivated more by cost than environmental

goals. For this reason, the criteria must be strict enough to ensure genuinely sustainable outcomes, yet flexible enough to allow innovation within the standardized system and avoid black boxing.

3.3 Assessment Tools and Energy Modeling

The case study by Eidenskog [15] demonstrates how design challenges arose from the project's reliance on energy consultants and the limited transparency of their modeling tools. The initial energy model (IDA ICE), although presented as accessible, effectively functioned as a black-boxed instrument, since the consultant provided only simplified outputs that prevented other professionals from examining underlying assumptions. When a new energy consultant later introduced a spreadsheet-based model, its results diverged significantly from those of IDA ICE despite using identical input data. This discrepancy created uncertainty about which model was credible and revealed, at a late stage, that the building's projected energy performance was insufficient. Since the earlier modeling process had not allowed the team to scrutinize or test assumptions independently, they were unable to identify these issues during the phase when design parameters were still flexible. The resulting design challenges thus stemmed from the interplay between opaque modeling practices and the professionals' dependence on consultants for understanding and validating energy performance. This dynamic reflects a broader concern identified by Rydin [17]: planners and other professionals must possess, or have access to, sufficient modeling competence to challenge results when necessary. Without such capacity, they become dependent on consultants' interpretations, increasing the likelihood that modeling practices will become fully black-boxed and reducing their influence over how energy performance is defined and negotiated in development processes.

Georg [10] examined how an assessment tool shaped professional practice, which was developed with the aim of translating the idea of a sustainable city. The study shows that such calculative instruments influence collaboration and decision-making by defining what counts as relevant knowledge. Under tight competition deadlines, teams divided the tool's indicators along disciplinary lines, which turned it primarily into an intermediary for coordinating tasks rather than a shared analytical framework. While some professionals viewed the numerical scores as persuasive, most used the tool pragmatically as a checklist to ensure compliance with client requirements, without allowing its benchmarks to guide their design vision. A smaller number of teams engaged with the tool more strategically, using its parameters to reassess priorities and revise design concepts, whereas others dismissed it as too restrictive for more qualitative ambitions. Across these varied uses, the tool functioned mainly as an intermediary that facilitated coordination, but in some cases also acted as a mediator that reshaped knowledge, design choices, and professional interactions.

4 Discussion and Conclusion

Sustainability requirements, definitions, and calculation methods are often inscribed in artifacts, and these elements can shape sustainable design and create opportunities to advance it. However, their influence depends on how they connect with the everyday

practices of local actors. From an Actor-Network Theory perspective, the focus is not on providing general explanations, but on examining how relations between actors and artifacts are formed, how they are stabilized, and how they sometimes weaken or fail. This helps explain why sustainability policies do not automatically lead to consistent outcomes in practice.

The reviewed studies indicate that the effects of artifacts differ across contexts and depend on their interaction with other actors and actants within the network. Even the same tool, used within the same national setting, was applied and interpreted in different ways [10]. This suggests that outcomes are not determined by the artifact itself, but by the network of relations in which it operates. Georg [10] argues, focusing only on professionals overlooks how artifacts enable or challenge collaboration. Flexibility in the use of artifacts may allow room for interpretation, but it can also leave less experienced actors exposed to pressure from others.

The concept of black-boxing illustrates how tools and documents can shape power relations. When artifacts such as energy models are treated as closed systems, they may increase trust in certain experts while limiting others' ability to question underlying assumptions [15]. Similarly, policy documents can act as intermediaries that structure authority; highly detailed language may restrict the role of some agencies, as seen in the UK case [17].

Overall, sustainability in building projects emerges not from technical tools alone but from ongoing interactions between actors, artifacts, and practices. The gap between policy goals and implementation reflects social and organizational dynamics as much as technical ones. ANT helps explain why sustainable building initiatives succeed or struggle by showing how networks of human and non-human elements shape outcomes and power relations. The literature indicates that these efforts work best when technologies fit local practices and when actors engage with one another around shared goals.

Abstract. This study employs a cradle-to-grave (A–D) life-cycle assessment over a 120-year reference period, utilizing a 1 m^2 deck functional unit, span-normalized for equivalent comparison, to evaluate the total greenhouse gas emissions throughout the life cycle of two railway bridge types: a historic wrought-iron viaduct and a reinforced-concrete underbridge. Two case-specific Life Cycle Assessment models are developed for the experiment, utilizing consistent UK factors, product-level data for materials, quantified transport and site plant metrics, activity-based operations and maintenance (coatings, membranes/joints, bearings, local strengthening), and explicit Module D credits from end-of-life recovery. The wrought-iron viaduct has a carbon footprint of 2.20 tCO_2e/m^2 (A–D), while the concrete bridge has a carbon footprint of 5.8 tCO_2e/m^2. The numerical findings are supported by module analyses and sensitivity assessments, which demonstrate that A1–A3 and end-of-life are the primary determinants. The principal conclusion is that, when feasible, the retention of wrought iron and focused renovation surpasses new short-span concrete in terms of whole-life carbon; for concrete, performance is contingent upon binder selection and B-stage strategy when membranes, joints, and bearing policy are comprehensively modelled. Low-clinker binders, integral/semi-integral abutments, waterproofing/joints with a lifespan of at least 40 years, EAF-route steel for reinforcement, and inspection-driven deconstruction exemplify effective practice levers that enhance engineering decisions, reduce total lifecycle costs and disruptions, and advance societal net-zero objectives.

Keywords: Circular Economy · Lifecycle Analysis · Systems Thinking · Carbon Inventory · Energy Inventory · Net Zero

1 Introduction

Bridges and viaducts are vital transportation infrastructure that cross urban and natural boundaries. They are critical infrastructures underpinning the growth of built environment. Strategically important designs often require over 100 years of longevity. Their

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 945–953, 2026.
https://doi.org/10.1007/978-3-032-34930-9_110

lifespan comes with a high environmental cost: their material-intensive nature increases embodied carbon. Embodied carbon can make up over 60% of railway infrastructure's carbon footprint, according to [1]. Cement accounts for 8% of global CO2 emissions, and steel for 7% [2]. Development of sustainable building design and construction methods is crucial to decarbonizing rail transportation. The UK's net-zero transition needs the railway sector to address its infrastructure's high embodied carbon [1], which includes rethinking bridge design and material use.

The circular economy (CE) replaces the linear model of 'take-make-dispose' with the 10R principles of discard, rethink, recycle, and recover, as described by Koohmishi et al. [3], including R0 Refuse, R1 Redesign or Rethink, R2 Reduce, R3 Reuse, R4 Repair, R5 Refurbish, R6 Remanufacture, R7 Repurpose, R8 Recycle and R9 Recover. Material substitution, design for disassembly, modularity, adaptive reuse of substructures, and end-of-life material recovery can be applied to railway bridges. CE methods must not compromise structural performance; railway bridges must meet strict safety, serviceability, fatigue, and durability standards under operation. This study examines reinforced-concrete underpass bridges and wrought-iron viaducts in the UK rail network. They were chosen because they reflect diverse building eras and maintenance demands with variable whole-life carbon consequences.

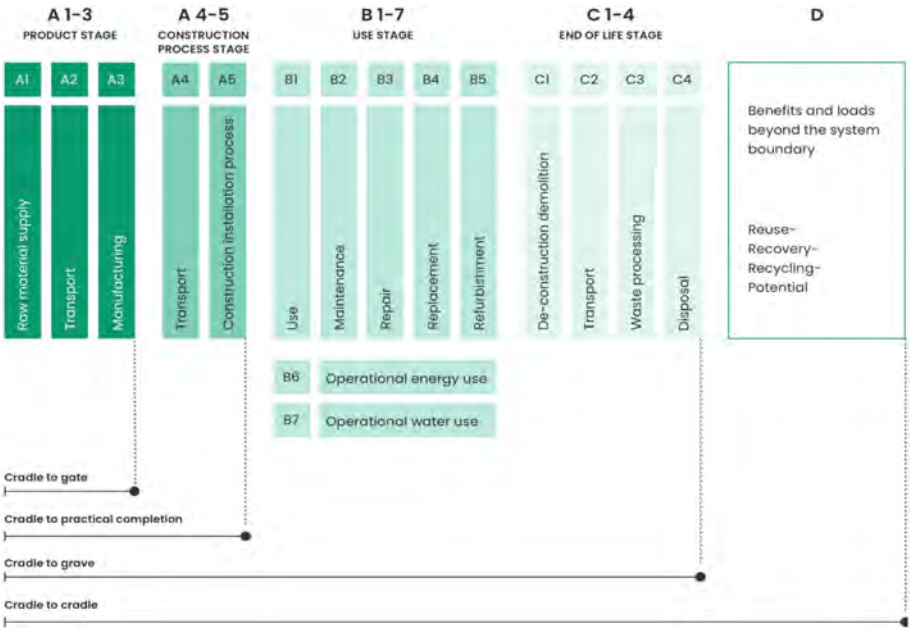

Fig. 1. Lifecycle stages and systems boundary of engineering assets.

Railway networks adopt many wrought iron and concrete structures, but their complete lifespan environmental performance has not been thoroughly assessed. This study tackles this gap by performing Life Cycle Assessment (LCA) of these two structures, focusing on their carbon emissions throughout the lifecycle, as shown in Fig. 1. This study

offers new findings by comparing each system's circular economy concepts, e.g. material recovery potential and design for adaptation, to decide which is more sustainable. The goal is to quantify and compare whole-life (A–D) greenhouse-gas emissions per 1 m^2 of deck for a historic wrought-iron railway viaduct and a reinforced-concrete under bridge over a 120-year period and to identify circular-economy interventions that reduce carbon without compromising Eurocode-compliant safety, serviceability, fatigue and durability. Comparing concrete and wrought iron bridge structures under the same functional unit will provide new discoveries and insights. Rail engineers will significantly benefit from co-design, planning, building, operation, maintenance, and end-of-life management of bridge infrastructures.

2 State of the Art Literature Review

Many wrought-iron railway viaducts in the UK are over 100 years old (e.g. in Sherrington). Ancient wrought iron viaducts follow circular economy (CE) principles of structural longevity, adaptive reuse, and material recovery. For transport network conservation, wrought iron is more ductile and fatigue-resistant than modern materials [4]. Wrought iron constructions can endure a century if maintained, demonstrating CE "design for longevity". Archives suggest that disassembled wrought iron components were reused in the 19th and early 20th centuries, starting the current cycle [4]. Medieval wrought iron production processes, material defects, and lack of standardization made large-scale reuse and recycling difficult. Retrofitting historic structures to current load and safety regulations may require steel strengthening or composite solutions, limiting cyclical advantages. Although difficult, wrought iron viaducts are noteworthy circular infrastructure examples of CE-aligned preservation, adaptive reuse, and modular disassembly.

Concrete bridges generally cause considerable initial embodied carbon; however, their extended service lives and little maintenance reduce their environmental impact, as indicated by lifecycle assessments. The incorporation of fly ash or GGBS decreases embodied emissions and enhances structural integrity [5]. Embodied carbon, along with energy associated with building operation, demolition, and recycling, is being incorporated into LCA frameworks. Recyclable concrete aggregates contribute positively to environmental sustainability. Numerous studies [5] indicate that concrete has a longer lifespan than steel; nevertheless, the studies primarily focus on A1–A3 phases, maintenance schedules, or specific mixtures. This reallocates responsibilities and enhances the advantages of "minimal intervention" at only design stage. However, local variables, environmental product disclosures, and durability-oriented B-stage modelling are not currently utilised to create bridge-specific, audit-ready A–D life cycle assessments per square meter. In order to promote circular economy initiatives (e.g., low-clinker mixtures, membranes/joints with a 40-year lifespan, design for deconstruction), LCA evaluations should consider both with and without Module D.

Most previous research on wrought-iron viaducts targeted B-stage repainting/strengthening using mild-steel proxies for A1–A3, partial boundaries (typically A1–A3), without considering Phase D. They adopted generic intervals instead of ISO 12944

or product/condition data. Often, there is no per-m^2 functional unit, span normalization, or consistent factor sets across A-D stages. Circular solutions like SCMs, high-grade recycled aggregate, and modular precast are generally considered separately from a whole-life system boundary. These limitations make it difficult to compare smaller A1–A3 combinations to larger B-stage treatments or concrete D credits to metal D credits. They also make it difficult to renovate, replace, buy, and report under PAS 2080. Thus, this study fills the gap by comparing lifecycle outputs per square meter between a wrought-iron viaduct and a reinforced-concrete underbridge. UK-relevant parameters (DEFRA/DESNZ for transport, fuels, and waste; ICE/EPDs for A1–A3), durability-based B-stage modelling, and with- and without-D reporting are fully considered. This allows quantitative evaluation of circular-economy solutions. Engineers in practice can utilise our outcomes to achieve net-zero targets.

3 Research Methodologies

This study applies a cradle-to-grave LCA structured to ISO 14040/14044 and EN 15978 [6, 7], with the functional unit (e.g. unit capacity), system boundary (e.g. right of way), and reporting (per-m^2 FU, span normalisation, and A–C/A–D disclosure) aligned with other studies [2]. This study follows ISO/EN 15978 and 14040/14044 [6, 7]. A1–A3 (product stage), A4 (transport to site), A5 (construction/site energy), B2/B4/B5 (maintenance, replacement, strengthening), C1–C4 (deconstruction, transport, processing, disposal), and D (circular practices) are modules covered. Inactive bridge decks have no operating energy or water consumption, hence track/rolling-stock operation is excluded from B6/B7. The study spans 120 years. Data is supplied in tCO_2e using GWP-100 factors and presented in both A-C and A-D formats for clarity. The single-track bridge's functional unit (FU) is 1 m^2 of deck plan area (length $\times$ clear deck width), following best practices for FU discipline and boundary clarity [2]. Multiplexing by the clear deck width yields per-metre data in this FU, which avoids width/span bias and follows whole-life reporting norms. DEFRA/DESNZ (transport, fuels, waste), ICE, and product EPDs for A1–A3 together with peer-reviewed infrastructure LCA studies and the project BoQ are primary data sources.

3.1 Recycling and Decommissioning

Inspection and condition monitoring guide selective deconstruction at end-of-life comprises cover/chloride profiling, half-cell/corrosion-rate assessments, ultrasonic/GPR rebar and thickness measurement, and fatigue hotspot identification with SHM. This helps us plan for design-for-deconstruction (DfD) and determine which parts may be reused, refurbished, or recycled well using circular economy principles. The wrought-iron viaduct recycles 95–100% of ferrous mass for secondary steel, resulting in a 0.1–0.2 tCO_2e/t recycling burden. Masonry components are increased for secondary usage. Deconstructing a concrete bridge generates 15–25 $kgCO_2e$ per ton of concrete. Between 50–70% is converted into RA1/RA2, yielding 20–40 $kgCO_2e$ per ton in substitution credits. The rebar should be fully recycled. About 20% of building energy comes from demolition fuel. According to EN 15978 [6], Module D provides beyond-boundary benefits.

Each stage of the 10R hierarchy is supported by inspection data and deconstruction plan: Reject (avoid too much detail); Reevaluate (integral/semi-integral abutments to remove bearings); Minimize (low-clinker compositions, streamlined sections); Repurpose (removable parapets, plates, and masonry blocks); Restore (targeted coating/patching to prolong life); Revamp (grit-blast and recoat ironwork and add a new coating to RC decks); Remanufacturing recycles iron and steel into new parts. Utilize unused parts. Recycling (high-yield metals, quality-assured RA1/RA2) and energy recovery from non-recyclable waste are two ways. Implementing 10R in this way maximizes retained value and clarifies Module D's high metal recovery and reliable concrete replacement.

3.2 Case Study I: Wrought Iron Structure

Sherrington Viaduct, an 1887 five-span, two-track underbridge, with three wrought-iron longitudinal main girders each span with cross-bracing. Spans 1 and some of 2 and 5 have filler-beam decks, whereas 3 and 4 have steel transverse troughing, as shown in Fig. 2. Later Victorian buildings followed Board of Trade railway company rules and used allowable-stress procedures. British standards did not apply in 1907 since BS 153 Steel Girder Bridges was not created until the early 1920s. The current design for upgrade follows Eurocode 3, incorporating Eurocode 2 and fatigue requirements for wrought iron material qualities determined by testing and conservative characteristic values, and maintenance scenario (re: NR/L2/CIV/032).

Fig. 2. Sherrington Viaduct

3.3 Case Study II: Concrete Structure

The structure located between Brixton Junction and Denmark Hill Station. It elevates railway traffic above a pedestrian street, as shown in Fig. 3. The initial design process was unspecified. A precast concrete ballasted deck and edge panels have been added to ATL and UP Cat lines. Slab track decks make up the UP Cat. Unaltered CAT lines have concrete infill panels supported by wrought iron girders. The design and assessments are based on Eurocode 2 with actions from Eurocode 1 considering standardized execution,

durability requirement and maintenance scenario (re: NR/L2/CIV/032). Where fitted, components, bearings, and deck waterproofing/joints comply with rail specifications. Maintenance assumptions reflect standard practice that involve re-waterproofing, joint renewal, bearing replacement and predictive inspections to manage deterioration and defer heavy interventions. These parameters are Eurocode-consistent and form the basis of the LCA modelling in this study.

Fig. 3. Cambria Rd. Under Bridge. Note: both case studies adopt identical FU and boundaries.

4 Results and Discussions

The total lifecycle GHG emissions are assessed for both structures, shown in Table 1. Cambria Rd exhibits A1–A3 emissions of 2.88 tCO_2e/m^2, whereas Sherrington demonstrates A1–A3 emissions of 2.81 tCO_2e/m^2. Sherrington possesses a little advantage since, although ferrous materials have a higher factor per tonne, the metal mass per square meter is less than the concrete volume per square meter in Cambria's slab method, and the preserved historic fabric does not contribute additional A1–A3 emissions. The clinker content and slab quantity regulate Cambria's Material production and manufacturing phase (MRMP) in practice. The tonnage of newly introduced steel such as strengthening or secondary steel and the designated steel production method (EAF versus BOF) are the primary considerations for Sherrington's MRMP. As shown in Fig. 4, if A1–A3 are allocated to the heritage fabric instead, Sherrington's MRMP would increase by that amount. This is why the boundary assumption (e.g. right of way and sub-systems layers of bridge structures) must be clearly defined.

Cambria Rd. has much greater C&T impacts compared to Sherrington A4–A5 0.377 tCO_2e/m^2, approximately 6.5% of its A–D. The disparity arises from the greater transported tonnage and site plant energy associated with reinforced concrete compared to the wrought-iron example, which involves far less new work. A4 freight scales proportionally with haul distance, therefore, longer supply chains would exacerbate the disparity. Nonetheless, the A5 plant remains unaffected by distance and continues to be the most significant C&T component for RC. The most effective method to diminish emissions is through local sourcing, rail-barge freight, and electrified or HVO facilities, with a primary emphasis on material decarbonization. Further analysis indicates that the

Table 1. Life cycle assessments of Sherrington Viaduct and Cambria Rd. Under Bridges

Lifecycle stage	Sherrington Viaduct (tCO_2e/m^2)	Cambria Rd UB (tCO_2e/m^2)
Material production and manufacturing	2.806	2.880
Construction and Transport (C&T)	0.031	0.377
Operation and maintenance (O&M)	0.172	0.017
Recycling and Decommissioning (R&D)	−0.809	2.493
Total	2.200	5.767

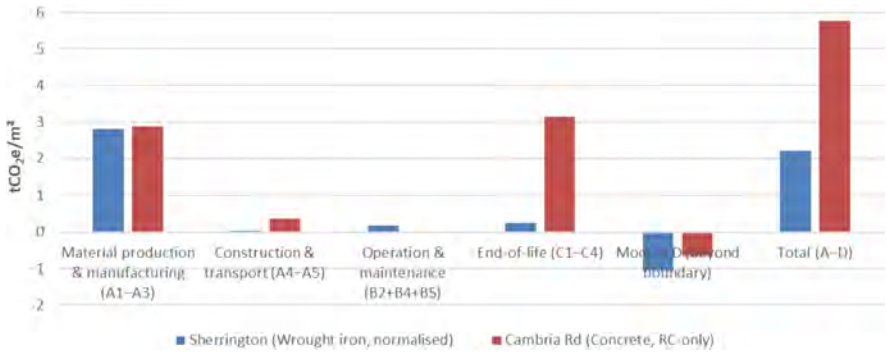

Fig. 4. Comparison of whole-life carbon emissions between wrought-iron and concrete bridges

Sherrington wrought iron viaduct possesses a greater operating and maintenance (O&M) carbon footprint of around 0.172 tCO_2e/m^2. This is primarily due to coating renewals and restricted structural repairs. Conversely, the concrete bridge (Cambria) exhibits a significantly lower value of approximately 0.017 tCO_2e/m^2. This is since it merely entails substituting the bearings, rather than requiring significant ongoing maintenance such as refilling the membrane and joints.

Sherrington viaduct demonstrates RDP − 0.809 tCO_2e/m^2. In contrast, Cambria Rd RDP at 2.493 tCO_2e/m^2. The difference stems from Sherrington's substantial metal recovery compared to little concrete credits, where even quality-assured RA1/RA2 substitution only partially mitigates the costs of demolition and processing. To secure the wrought-iron credit and improve the concrete outcome, the deconstruction must be directed by inspections. Mid-life structural health monitoring, NDT, and condition assessment (GPR for rebar configuration, cover/chloride profiling, half-cell/corrosion-rate analysis, thickness/rivet evaluations, ultrasonic pulse velocity) ascertain components amenable to reuse or remanufacturing, segregate uncontaminated concrete for premium

recycled aggregate, and formulate selective extraction methodologies to avert contamination and downcycling. Integrating materials/product passports (steel grades, coating specifications, mix/EPD identifiers), DfD details and a C-stage process statement boosts recovery rates and diminishes demolition fuel use, hence swiftly increasing C and D results. The instruction is to Reduce, Repair, Refurbish, and Reuse before Recycling or Recovering, in accordance with circular economy (10R) principles. For Sherrington, this maintains substantial metal credit, but for Cambria, it improves quality of aggregate and amplifies the minimal concrete substitute benefit.

5 Conclusions

This study offers a comparable, per-square-meter and span-normalized whole life cycle assessment of two prevalent railway bridge typologies in the UK. Throughout a 120-year span, the wrought-iron viaduct exhibits around 2.20 tCO_2e/m^2 (A–D), whereas the reinforced-concrete underbridge demonstrates approximately 5.77–5.81 tCO_2e/m^2 (A–D), thereby strongly advocating for the preservation and selective refurbishment of wrought-iron where structurally viable. The results yield specific actions: for low-clinker concrete mixes, (i) implement waterproofing/joints with a lifespan of >40 years, (ii) ensure effective drainage, and (iii) utilize integral/semi-integral abutments to mitigate both A1–A3 and B; for wrought iron, (i) reduce new metal tonnage, (ii) employ EAF-route steel for reinforcement, and (iii) plan inspection-driven deconstruction (materials passports, DfD) to maintain the D-credit. These strategic actions reduce carbon emissions and costs while maintaining safety performance, enabling net zero with minimal inconvenience to passengers and the public.

Identifying Accurate Growth Models for Biogenic Carbon Uptake of Wood in Dynamic LCA

David von Dufving[1,2(✉)], Marijke Steeman[1], and Liselotte De Ligne[2]

[1] Department of Architecture and Urban Planning, Ghent University, Ghent, Belgium
david.vondufving@ugent.be
[2] Department of Environment, Ghent University, Ghent, Belgium

Abstract. Trees store biogenic carbon, which, when retained in wood products, can temporarily contribute to climate change mitigation. Dynamic Life Cycle Assessment increasingly accounts for this temporary storage by quantifying its "climate change–biogenic" impact using the Global Warming Potential (GWP) indicator. While current dLCA approaches model the timing of carbon storage and release, a standardized approach for representing tree growth, and thus carbon sequestration, remains lacking, causing significant variability in results. Existing practice typically applies either a growth approach, where sequestration is modelled as a negative pulse emission at harvest, or a regrowth approach, where sequestration occurs gradually as replacement trees grow. As various regrowth models are employed in contemporary dLCA studies, this study compares one growth model (G_G) and three regrowth models: (i) a Gaussian distribution (R_GD), (ii) the Chapman–Richards function (R_CR), both commonly used, and (iii) a newly proposed model based on Net Annual Increment data from national forest inventories (R_NAI). The four models are applied to calculate the GWP100 climate change–biogenic impact of stem wood for two hardwood and two softwood species used in timber construction in Germany. Results suggest that the NAI regrowth model captures growth dynamics most detailed, but its high data requirements and questions about its data validity raise questions about scalability and practical implementation. Regardless of model, the hardwoods offer a higher temporary carbon sink potential, thus offering a possible environmental incentive to promote the use of hardwoods in long-lived construction products.

Keywords: Biogenic Carbon · dynamic Life Cycle Assessment · Carbon Storage · Bio-based Building Materials

1 Introduction

To meet the EU target of climate neutrality by 2050, temporary carbon removals are increasingly seen as essential (European Commission, 2025). However, despite the growing interest in crediting the temporary storage of biogenic carbon, there is still no scientific consensus on how to incorporate this effect into dynamic Life Cycle Assessment (dLCA) (European Commission, 2024). This uncertainty has led to diverse modelling approaches, raising concerns about robustness, and practical usability of dLCA.

L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 954–961, 2026.
https://doi.org/10.1007/978-3-032-34930-9_111

The Horizon Europe *WoodStock Project* addresses these challenges by developing a robust and transparent LCA framework for (underutilised) wood products (WoodStock Project, 2024). In line with the WoodStock objective of incentivizing sustainable forest management and underutilised wood streams, including hardwood and post-consumer wood, the project adopts the dynLCA framework of Levasseur et al. (2010), regarded as one of the most detailed and reliable dLCA methods (Hoxha et al., 2020). Nonetheless, key uncertainties remain regarding the timing of biogenic carbon sequestration.

Several approaches for determining the timing of biogenic carbon sequestration have been proposed in literature. For example, Peñaloza et al. (2016) explored a "growth approach", where biogenic carbon sequestration is assumed to occur prior to harvest and is thus modelled as a negative pulse emission at harvest. In contrast, the "regrowth approach" assumes that harvest creates a carbon debt, which must be gradually re-sequestered through the growth of a replacement tree. Applying this second approach requires modelling how sequestration unfolds over time rather than treating it as an instantaneous event. Three different regrowth models are thus analyzed alongside the growth model (G_G). Two common regrowth models, namely the "Gaussian Distribution" (R_GD) and the "Chapman-Richards" (R_CR) function, as well as a newly proposed model based on the Net Annual Increment (R_NAI) growth derived from national forest inventories. This study aims to compare both approaches to determine which is best suited for use in the context of underutilised wood. The comparison between the different regrowth models furthermore aims to offer insights into the robustness of the R_NAI model, which could offer species-specific growth curves.

2 Methodology

2.1 Research Steps

To exemplify the effect of the different models, a product life-span of 100 years was assumed for stem wood of four common European tree species (*Picea abies* (PA), *Pinus sylvestris* (PS), *Quercus robur* (QR), and *Fagus sylvatica* (FS)) were chosen as example cases. In a first step species-specific biogenic carbon contents were derived based on von Dufving et al. (2026a) (711.3 $kgCO_2/m^3$ for PA, 826.1 $kgCO_2/m^3$ for PS, 1056.19 $kgCO_2/m^3$ for FS, and 1140.5 $kgCO_2/m^3$ for QR). For the growth model the negative biogenic carbon content was then inventoried for the year of harvest (year 1). This simplification is needed to assess the impact of the growth and the regrowth models over the same Time Horizon. For the regrowth models, the biogenic carbon content was allocated over defined regrowth time frames, representing the time it takes to re-sequester the biogenic carbon. The regrowth time frame of each species (39 years for PA, 37 years for PS, 52 years for FS, and 65 years for QR) was calculated based on NAI data, expressing biomass accumulation until the functional unit of $1m^3$ stem wood is regrown (von Dufving et al. 2026b). Afterwards, annual dynamic characterization factors for a 100-year Time Horizon, based on Resch et al. (2021), were applied to calculate GWP-biogenic.

2.2 Growth and Regrowth Models

The G_G model allocates the carbon uptake as a pulse emission in year 1, equal to the negative biogenic carbon content. The growth curve of the R_GD model is calculated according to Eq. (1) and normalized so that the total carbon sequestration equals the carbon content (Cherubini et al. 2011).

$$f(x) = \frac{A}{\sqrt{2\pi\sigma 2}} e^{-\frac{(x-\mu)2}{2\sigma 2}} \tag{1}$$

μ = mean = regrowth time frame/2
σ = standard deviation = mean/2
A = biogenic carbon content

The R_CR model is also commonly employed using its first derivative and is stipulated in Eq. (2) and normalized in Eq. (3) For the shape parameters k (0.023) and p (Levasseur et al., 2010), fixed values based on Resch et al. (2021) were employed.

$$f_{CR}(y) = kpe^{-ky}\left(1 - e^{-ky}\right)^{p-1} \tag{2}$$

k = variable growth rate parameter
p = variable catabolism parameter

$$f_{bio,i\ (y)} = m_{CO_2,i} \cdot f_{CR}(y) / \sum_{y=0}^{RP} f_{CR}(y) \tag{3}$$

$m_{CO2,i}$ = biogenic carbon content of inventory product

The R_NAI model uses Net annual increment data (in in m^3 ha^{-1} $yr.^{-1}$) to model growth curves. This study draws on the publicly available "Volume_increment_database" by (Pilli et al., 2024) which reports species-specific NAI data at a regional level, based on harmonized data reported by the latest available National Forest Inventories of each country. For this study averaged data from Germany were chosen, as extensive data entries are available for all four relevant tree species. Utilizing the same formula which was employed to calculate the regrowth time frames based on von Dufving et al. (2026b) (Eq. 4), annual growth values, which are then multiplied with the negative carbon content, can be computed.

$$\sum_{i=1}^{t} \left(\frac{A}{f}\right) * NAI_i = 1 \tag{4}$$

A = the production area in ha, e.g. 15 $m^2 f$ = the fraction of the area used for the biomass, e.g. 0.75 for stem of softwood, 0.7 for stem of hardwoodNAI_i = Net Annual Increment of the biomass in m^3/ha/y for year i. (To normalize the total growth to 1, the growth value of the last year was manually constrained.)

3 Results

3.1 Annual Biogenic Carbon Sequestration

This results section compares the annual biogenic carbon sequestration values as inventoried during the Life Cycle Inventory phase. When comparing the different growth models with each other it becomes apparent that annual biogenic carbon sequestration varies significantly across the four modelling approaches (Fig. 1).

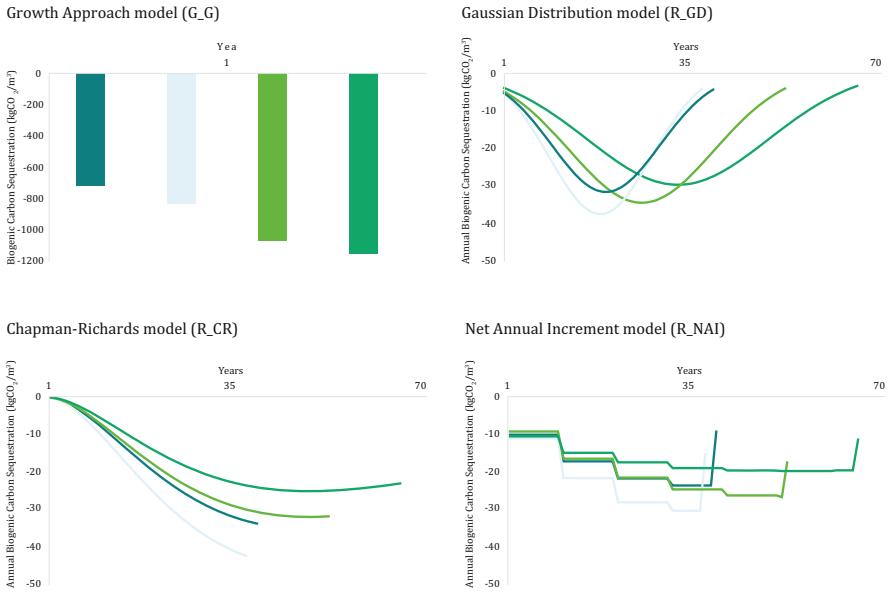

Fig. 1. Line Diagram showcasing the annual biogenic carbon sequestration value in kgCO2/m^3 for 1m^3 for selected European tree species (PS: light blue, PA: dark blue, FS: light green, QR: dark green) and growth models.

The G_G model assumes that the total carbon sequestration occurs in the first year. In contrast, all regrowth models gradually distribute sequestration over the defined regrowth time frames. The R_GD model assumes a symmetrical distribution of sequestration, peaking precisely at the midpoint and tapering off evenly on both sides. When employing this model, all species thus follow the same pattern, only more stretched or condensed depending on the species. The R_CR model portrays sequestration as a continuous curve that typically peaks in the early stages of the rotation, depending on the specific values of its shape parameters k and p (48 years for the parameters chosen in this study). The R_NAI model, by contrast, estimates sequestration based on biomass growth dictated by age classes (e.g., in 10-year intervals), resulting in a stepped profile. This approach generally shows a flatter peak in sequestration before the midpoint of the rotation period and then slowly tapers off. Furthermore, all species exhibit a lower annual biogenic carbon sequestration value for their last year, due to the requirement of total biogenic carbon sequestration equaling the biogenic carbon content.

3.2 GWP-Biogenic

This section compares the effects of the diverging growth curves and biogenic carbon sequestration values on GWP-biogenic. When comparing the GWP-biogenic score of the same species across models, species-specific differences become apparent (Table 1). For PA, biogenic carbon sequestration averages $-621.85 \pm$ a standard deviation of 62.06 $kgCO_2/m^3$, exhibiting an on average 30% lower GWPbio score than QR. For PS, biogenic carbon sequestration averages -727.11 ± 68.72 $kgCO_2/m^3$, exhibiting an on average 18% lower GWPbio score than QR. For FS, biogenic carbon sequestration averages -873.74 ± 125.35 $kgCO_2/m^3$, exhibiting an on average 2% lower GWPbio score than QR. For QR, biogenic carbon sequestration averages -895.2 ± 167.35 $kgCO_2/m^3$. In summary, the order of GWP-biogenic scores between species within the same model is generally constant, irrespective of which model was chosen. Across the models QR showcases the highest average temporary carbon sink potential followed by FS, PS, and PA.

When comparing the GWP-biogenic score of the same model across species, model-specific differences become apparent. When employing the G_G model, biogenic carbon sequestration averages -933.53 ± 199.02 $kgCO_2/m^3$ and GWPbio values on average are 27% higher than those for the R_NAI model. When employing the R_GD model, biogenic carbon sequestration averages -758.7 ± 116.85 $kgCO_2/m^3$ and GWPbio values on average are 4% higher than those for the R_NAI model. When employing the R_CR model, biogenic carbon sequestration averages -696.41 ± 97.16 $kgCO_2/m^3$ and GWPbio values on average are 4% lower than those for the R_NAI model. When employing the R_NAI model, biogenic carbon sequestration averages -729.24 ± 106.27 $kgCO_2/m^3$. In summary, the order of GWP-biogenic scores between models within the same species are generally constant, irrespective of which species was chosen. Across the species the G_G model showcases the highest temporary carbon sink potential followed by the R_NAI model, the R_GD model, and the R_CR model.

Table 1. GWP-biogenic in $kgCO_2/m^3$

Species	G_G	R_GD	R_CR	R_NAI
PA	−711.3	−611.92	−569.99	−594.2
PS	−826.1	−717.35	−611.92	−694.57
FS	−1056.19	−851.41	−777.44	−809.91
QR	−1140.54	−854.14	−767.82	−818.32

4 Sensitivity Analysis

A sensitivity analysis was conducted to assess the robustness of the R_NAI's NAI data and its effect on the resulting GWP-biogenic values. For this purpose, NAI data for the same previously selected species were retrieved for France and compared with the

corresponding results from Germany. The objective was to determine whether country-specific differences change the results significantly. To ensure comparability between countries, the same species-specific biogenic carbon contents used for Germany were applied to the French dataset. However, because the NAI values differ between the two countries, new regrowth time frames had to be calculated for each species based on the same methodological approach described earlier. The resulting regrowth periods for France were 40 years for *Picea abies* (PA), 98 years for *Pinus sylvestris* (PS), 83 years for *Fagus sylvatica* (FS), and 106 years for *Quercus robur* (QR). Compared with the German NAI data, the French regrowth time frames are generally longer, though the magnitude of this difference varies considerably across species (see Fig. 2). The shape of the growth curves over time also diverges. For multiple species the German data indicate a continuously increasing growth rate, in contrast to the more linear and overall decreasing trend observed for France. These differences also have significant implications for GWP-biogenic. While the average GWP-biogenic score across the selected species for the German dataset is -729.3 kg CO_2/m^3, the French dataset exhibits an average of -615.57 kg CO_2/m^3 for the same species, representing a reduction of approximately 16%. However, this effect is not consistent across species, with results ranging from an increase of $+17\%$ for PA to a reduction of -38% for PS.

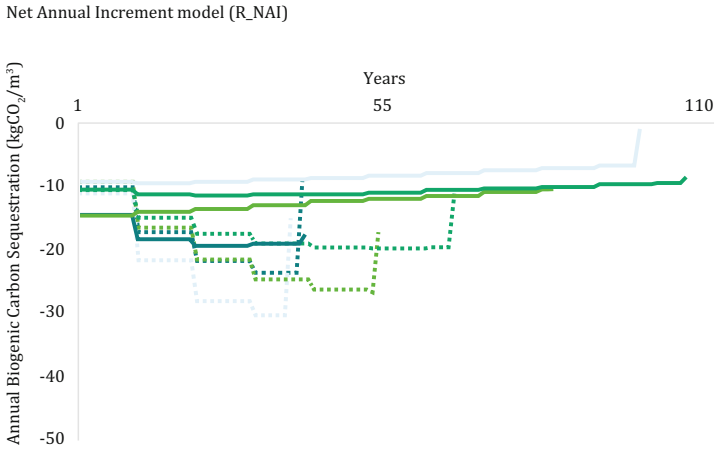

Fig. 2. Line Diagram showcasing the annual biogenic carbon sequestration value in kgCO2/m^3 for selected European tree species based on NAI FR (solid line) and NAI DE data (dotted line) (PS: light blue, PA: dark blue, FS: light green, QR: dark green)

5 Conclusion

This study compared four growth models for dynamic LCA with the aim of identifying a suitable approach to calculate GWP-biogenic of long-lived timber products. Given WoodStock's objectives and consistent with findings from literature, post-harvest regrowth models appear preferable to the growth model because they provide more conservative estimates and support incentives for continued forest regeneration. Among the

evaluated regrowth approaches, the R_NAI model offers the highest level of detail and transparency due to its direct reliance on national forest inventory data. Assuming these data are robust, both the R_CR and R_GD models provide reasonable approximations when NAI data is unavailable or deemed overly complex. R_CR may be preferable when a more conservative estimate or species-specific parameterization is required, whereas R_GD offers the most accessible implementation. Across the models, QR exhibited the highest average temporary carbon sink potential, followed by FS, PS, and PA. This suggests a potential environmental incentive to expand the use of selected hardwoods in long-lived construction products to increase the construction industry's climate change mitigation potential.

The study also highlighted several limitations with the sensitivity analysis. While it was not within the scope of this research, to validate the underlying NAI data, the high deviation in growth curves and subsequent GWP-biogenic results within the same species between Germany and France seem significant. Therefore, future research should focus on simplifying the NAI regrowth model, to minimize the risk of unreliable data.

Abstract. Wood-based panels (WBPs) are increasingly important in sustainable and circular construction due to their renewable origin, efficient use of wood residues, and recycling potential. With global WBP production reaching approximately 366 million m^3 annually, evaluating the environmental impacts associated with their production has become increasingly important. This study presents a systematic literature review of life cycle assessment research on particleboard, medium-density fiberboard (MDF), oriented strand board (OSB), and plywood using a PRISMA-based methodology and the Web of Science database. A total of 22 peer-reviewed studies published between 2015 and 2025 were comparatively analyzed in terms of system boundaries, environmental indicators, recycling approaches, and production hotspots.

The reviewed studies showed that MDF generally exhibits the highest environmental impacts, with reported carbon footprint values of approximately 500–600 kg CO_2e/m^3 due to energy-intensive fiber refining and drying processes. In contrast, OSB and plywood demonstrated comparatively lower carbon footprints ranging between 190–220 kg CO_2e/m^3 and 100–150 kg CO_2e/m^3, respectively, while particleboard typically ranged between 300–400 kg CO_2e/m^3 owing to more efficient raw material utilization and lower processing energy requirements. Adhesive production and thermal drying were consistently identified as the dominant environmental hotspots across panel types. These variations are also influenced by regional energy mixes, resin systems, and methodological assumptions.

Overall, the review highlights the importance of recycling pathways, cascading utilization, and methodological consistency in supporting circular wood-based panel production systems with lower environmental impacts.

Keywords: Wood-Based Panels · Life Cycle Assessment (LCA) · Recycling · Circular Design · Sustainable Construction

1 Introduction

The construction sector is one of the largest consumers of natural resources and contributes significantly to global greenhouse gas emissions. Current estimates indicate that, considering both operational and embodied carbon emissions, the built environment accounts for approximately 37% of global energy-related carbon emissions. While

https://doi.org/10.1007/978-3-032-34930-9_112

energy-efficient building technologies have achieved notable progress in reducing operational energy consumption, the embodied carbon associated with building materials remains a critical challenge in transitioning to sustainable construction systems [1]. Wood-based panels are increasingly recognized as environmentally advantageous alternatives to traditional construction materials such as concrete and steel. In addition to being renewable, wood products can store biogenic carbon throughout their service life, contributing to climate change mitigation strategies. The Intergovernmental Panel on Climate Change has highlighted that the use of long-lived wood products in buildings can play a significant role in reducing the carbon footprint of the built environment [2].

WBPs are engineered materials produced by combining wood particles, fibers, or veneers under heat and pressure using adhesives (Table 1). Among wood products, engineered panels-including particleboard, fiberboard (FB), oriented strand board (OSB), and plywood (PW)-are widely used in both structural and non-structural applications, such as interior components, furniture systems, flooring, roofing, and wall cladding [3].

Table 1. Classification of Wood-Based Panels [4]

Panel Type	Typical Density (kg/m^3)	Production Highlights	Typical Application
Particleboard	400–800	Pressed at moderate temperatures; adhesive dominates environmental footprint	Interior wall panels, subfloor layers, partition elements, interior finishing components
Fiberboard	400–1000	High energy use for fiber refining and drying; adhesive is a key impact contributor	Interior wall cladding, door panels, mouldings, decorative interior building components
Oriented Strand Board	600–1200	Directional pressing; resin production and drying emissions are dominant	Structural sheathing, wall and roof panels, subflooring systems
Plywood	400–800	Drying veneers, adhesive bonding; energy intensive for hot pressing	Structural panels, roof and wall sheathing, formwork panels

The global WBP industry has experienced significant growth in recent years in response to increasing demand from the construction and furniture sectors. According to Food and Agriculture Organization (FAO) data, global WBP production reached approximately 366 million m^3 per year. Table 2 presents production volumes of WBPs in the World, Europe and Türkiye between 2022–2024 [5].

Life Cycle Assessment defined by ISO 14040 and 14044, provides a standardized framework to evaluate environmental impacts of wood-based panels (WBPs) across their life cycle [6]. Circular construction principles-emphasizing resource efficiency, modular

Table 2. Global Wood-Based Panel Production

Region	Wood based panel	Unit	2022	2023	2024

design, and material reuse-enhance WBPs' potential for recycling and cascading use. Environmental performance is influenced by raw material supply, adhesives, production energy, and end-of-life management, with adhesive production and thermal drying identified as major hotspots [7]. Despite growing LCA literature, studies vary in system boundaries, functional units, and regional energy contexts, often focusing on cradle-to-gate assessments of single panel types. Integration of recycling scenarios and circular strategies remains limited.

This study systematically reviews recent LCA research on particleboard, medium-density fiberboard, oriented strand board, and plywood, providing a comparative overview of environmental impacts, identifying key production hotspots, and highlighting methodological gaps.

2 Review of LCA Studies on Wood-Based Panel

A systematic literature review was conducted to evaluate recent life cycle assessment (LCA) studies on wood-based panels (WBPs). The review followed the PRISMA framework to ensure transparency and consistency in the study selection process [8]. Web of Science was selected because it provides high-quality peer-reviewed indexing and reduces duplicate records commonly encountered across multiple databases. The literature search was performed using the query:

Topic Search = ("wood-based panel*" AND "life cycle assessment")

The search was limited to English-language publications published between 2015 and 2025. Only peer-reviewed journal articles and review articles were considered. The initial search identified 38 records. After title and abstract screening, studies unrelated to

LCA methodology, non-WBP materials, and studies lacking quantitative environmental assessment were excluded. Full-text evaluation resulted in 22 studies being included in the final comparative analysis. The selected studies were analyzed in terms of system boundaries, functional units, environmental impact indicators, recycling approaches, and major environmental hotspots. Studies were included only if they reported quantitative LCA indicators and clearly defined functional units and system boundaries. Methodological differences among studies, including regional energy mixes and recycled wood utilization rates, were also comparatively evaluated. Figure 1 illustrates the PRISMA-based literature screening and study selection process applied in this review, including identification, screening, eligibility assessment, and final inclusion stages.

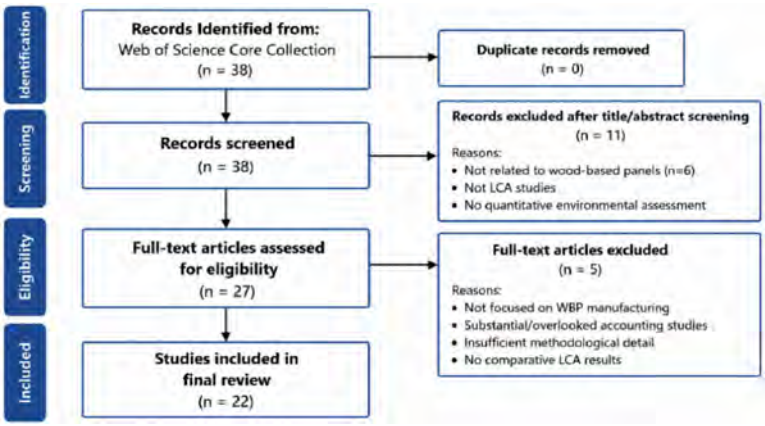

Fig. 1. PRISMA flow diagram of the literature selection process.

Figure 2 presents the comparative carbon footprint of WBPs based on literature averages, visualizing the complete life cycle: raw material extraction, panel production (resin production, drying), distribution, use phase, and end-of-life (landfill, energy recovery, recycling). Key environmental hotspots such as energy use, CO_2 emissions, and waste generation are highlighted, providing a clear view of life cycle stages for circular construction assessments [9].

LCA studies demonstrate that environmental performance varies with production technologies, energy sources, and raw materials (Table 3). PB production environmental impacts are dominated by adhesive manufacturing and drying energy. MDF production requires mechanical defibration, resin bonding, and hot pressing, with fiber refining and thermal drying as major energy inputs. The broad variation in carbon footprint values reported across studies is mainly associated with differences in regional electricity mixes, resin formulations, recycled wood content, and cradle-to-gate versus cradle-to-grave system boundaries [10, 11].

Overall, the reviewed studies consistently identify resin production and thermal drying as the dominant contributors to global warming potential across all panel types. OSB shows relatively balanced performance due to efficient strand utilization and moderate energy profiles, emerging as a promising candidate for circular applications. Plywood

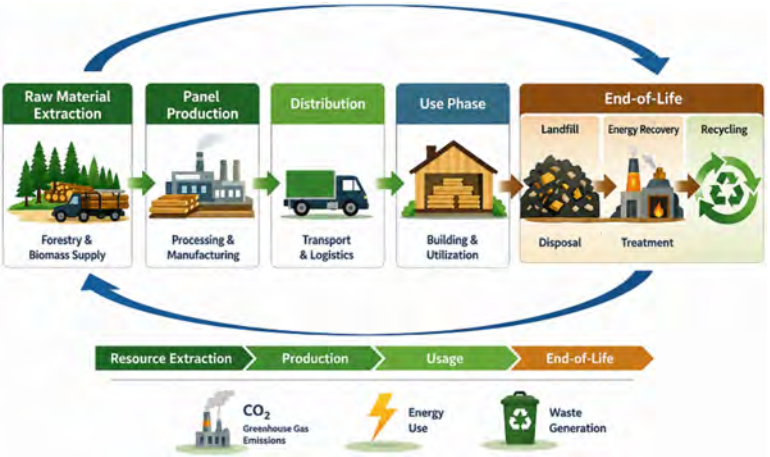

Fig. 2. Life cycle stages and major environmental hotspots of wood-based panels within circular construction systems.

Table 3. Comparative Environmental Performance of WBPs.

Panel	Energy Use (MJ/m^3)	Carbon Footprint (kg CO_2e/m^3)	Key Hotspots
PB	3.200–5.000	300–400	UF resin, pressing energy
MDF	4.000–6.500	500–600	Refining, adhesive, drying
OSB	3.500–5.500	190–220	Strand orientation, PF resin
PW	3.000–6.000	100–150	Veneer drying, adhesive

performance varies with veneer thickness, wood species, and adhesive systems, with recycling requiring mechanical separation techniques [12].

Across the reviewed studies, adhesive production and thermal drying consistently emerged as the major environmental hotspots in wood-based panel manufacturing. Environmental performance was found to vary considerably depending on resin systems, production technologies, regional energy mixes, and recycled wood utilization rates. Several studies also highlight the importance of raw material sourcing. The use of recycled wood and industrial residues can substantially reduce environmental burdens by decreasing the demand for virgin timber resources. However, the quality variability of recycled wood and the presence of contaminants such as adhesives and coatings may limit recycling rates in certain panel products.

Despite the environmental advantages of recycled wood utilization, several technical and industrial challenges remain for circular wood-based panel production. The quality variability of recycled wood, together with adhesive contamination and coating residues in post-consumer wood, may limit recycling efficiency and affect panel performance. Recycled wood is currently used more successfully in particleboard production because particle-based systems can better tolerate raw material heterogeneity

and contaminants, whereas MDF manufacturing requires higher fiber quality and more homogeneous material properties [3, 14].

3 Recycling and End-of-Life Scenarios of Wood-Based Panels

End-of-life management significantly affects the overall environmental performance of wood-based panels. Typical disposal routes include landfill, energy recovery, and mechanical recycling into secondary panel products. Mechanical recycling allows recovered wood particles or fibers to be reintroduced into new panel production, reducing the demand for virgin raw materials [13, 14].

Circular construction strategies emphasize the reuse and recovery of building materials. Modular panel systems and demountable building components allow materials to be recovered and reused at the end of a building's service life. Moreover, digital material passports can facilitate better tracking of materials and improve recycling efficiency [15]. Recent studies indicate that recycled wood recovered from demolition and renovation activities is predominantly utilized in particleboard production, where heterogeneous raw materials and residual contaminants can be more effectively tolerated compared with fiber-based panels such as MDF. Several LCA studies reviewed in this work reported that increasing recycled wood content in particleboard manufacturing can significantly reduce virgin wood demand and lower fossil-based emissions associated with raw material extraction and transportation. In contrast, MDF recycling remains more technically constrained because repeated fiber processing and adhesive contamination negatively affect fiber quality, board density uniformity, and mechanical performance. Therefore, the environmental benefits of cascading utilization in wood-based panel systems depend not only on recycling rates but also on maintaining material quality through efficient sorting, contaminant removal, and optimized secondary material flows within circular construction systems [16]. Table 4 summarizes recent LCA studies on wood-based panels and identifies the dominant environmental hotspots and system boundary approaches reported in the literature.

Comparative analysis clearly delineates environmental performance profiles for different panel types. MDF exhibits the highest carbon and energy demands due to fiber refining and high drying energy requirements. Particleboard generally performs better than MDF but has a slightly higher carbon footprint than OSB, which benefits from efficient strand use and moderate energy consumption, making it a promising candidate in the context of circular economy. Plywood's environmental performance varies depending on veneer thickness, wood types used, and adhesive systems; recycling processes require mechanical separation techniques.

Table 4. Summary of Selected LCA Studies and Reported Environmental Hotspots

Panel Type	System Boundary	Key Findings	References
WBPs	Various	Systematic review of LCA studies; most focus on cradle-to-gate	[16]
PB	Cradle-to-gate	Adhesive production and energy use account for a major part of total environmental impact	[17]
MDF & PB		PB production generally exhibits lower global warming potential than MDF due to lower energy demand and reduced fiber processing requirements.	[18]
MDF		Resin production accounts for a significant portion of total GWP	[19]
OSB & PW		OSB generally has a lower carbon footprint compared to plywood	[20]
PW		Adhesive and energy	[21]

4 Conclusions and Recommendations

The reviewed literature shows that wood-based panels (WBPs) can significantly reduce environmental impacts in construction due to their renewable origin, carbon storage potential, and compatibility with industrial production. Particleboard and OSB generally perform better environmentally than MDF and plywood because of more efficient residue use and lower energy demand.

Using recycled wood, improving production energy efficiency, and adopting renewable energy sources can further reduce carbon footprints. Circular construction strategies—such as modular panel systems enabling component reuse—extend material lifespans and reduce waste. The long-term environmental benefits of wood-based panels in circular construction systems depend not only on renewable raw material use but also on the effective integration of recycling, cascading utilization, and material recovery strategies throughout the product life cycle. Key insights include:

- **Hotspots:** Resin production and thermal drying dominate environmental impacts across panel types.
- **Panel Variability:** MDF has higher embodied carbon; OSB generally lower than MDF and plywood.
- **Recycling & Circularity:** Mechanical recycling and modular design improve lifecycle performance, though adhesive contamination remains a challenge.
- **Methodological Variation:** Differences in system boundaries, functional units, and energy mixes highlight the need for harmonized LCA frameworks.

Future research should focus on bio-based adhesives, advanced recycling, and integrated LCA approaches including cascading material use. Standardized datasets and digital material passports could enhance traceability and circularity of WBPs in sustainable construction.

Parametric Life Cycle Cost Assessment of Timber Slabs Incorporating Circularity Strategies

Vanessa Tavares(✉), Daniel Silva, and Rita Mendonça

BUILT CoLAB, Rua do Campo Alegre 760, 4150-171 Porto, Portugal
vanessa.tavares@builtcolab.pt

Abstract. Implementing sustainability and circularity in the built environment requires design strategies that consider not only environmental but also economic performance across the entire life cycle. However, Life Cycle Cost (LCC) assessment is rarely applied as a decision-support tool, especially when externalities are included in the evaluation of timber construction. This study presents a parametric LCC assessment approach for an innovative timber-based structural system within the Universal Timber Slab (UTS) project. The methodology integrates conventional LCC—covering production, installation, and end-of-life—with a circular-economy LCC that accounts for the potential value of some circular strategies, such as reuse and recycle, as well as relevant externalities, including internalisation of environmental impacts, green labelling and green financing, faster construction times, and worker health and safety. The parametric LCC model enables streamlined evaluation of multiple design configurations, material choices, and end-of-life scenarios. It is applied to a set of UTS variations to assess the economic performance of the UTS solution. Results show that although some UTS configurations may present higher initial costs compared to conventional alternatives, circular strategies such as component reuse and material recovery can substantially reduce total life-cycle costs. The study highlights the economic viability of circular timber structural systems and provides a streamlined decision-support tool for designers, engineers, and promoters. By integrating LCC with circular-economy principles, the research supports a transition toward more resource-efficient, low-impact, and economically viable construction practices.

Keywords: Circularity · Life Cycle Costing (LCC) · Sustainability · Timber buildings · Wood construction

1 Introduction

The global construction sector faces an unprecedented challenge in reducing its environmental footprint without a substantial increase in costs, requiring a shift toward circular, sustainable, and low-carbon approaches with moderate cost solutions. A significant part of a building's life-cycle environmental burdens (impacts and costs) is due to material production and construction; therefore, material choice is central to carbon reduction

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 971–979, 2026.
https://doi.org/10.1007/978-3-032-34930-9_113

and cost control [1]. Complementary to Life Cycle Assessment (LCA), which focuses on the environmental impacts, Life Cycle Costing (LCC) is a methodological approach that assesses the total costs incurred throughout the entire life cycle of an asset, including investment (e.g., acquisition of materials, machinery, and land), construction, operation, maintenance, replacement, and end-of-life. Unlike upfront cost comparisons, LCC captures shifts between life-cycle phases, supporting more informed long-term decisions [2]. Alternatively, low-impact materials should be analysed not only in terms of emissions but also in terms of costs.

Timber, as a renewable bio-based resource, has lower embodied impacts than steel and concrete [3]. Mass timber systems, including cross-laminated timber (CLT) and glued laminated timber (glulam), have been widely evaluated for their environmental performance in construction, but their economic performance remains less clearly defined. Available studies suggest that wood-based solutions generally involve higher initial material and construction costs than conventional reinforced concrete or steel systems [3]. For instance, combined costs of raw material extraction, transport, and construction for mass timber can reach 8.39 €/m^2, compared to 5.39 €/m^2 for reinforced concrete [4]. In a 12-storey mixed-use building in North America, mass timber had 26% higher initial construction costs when compared to concrete; and 10% higher total LC cost [3]. At the material level, when comparing six structural systems for a three-storey townhouse, CLT was found to have the highest cost (~385 €/m^2), exceeding lightweight timber, steel, aircrete, brick, and reinforced concrete [5]. Furthermore, operational and maintenance costs may also be higher for mass timber buildings, with increases of 13%–16% relative to reinforced concrete attributed to more frequent interior finish replacement and termite protection requirements [6].

Despite these higher costs, potential economic trade-offs have been identified. Offsite prefabrication enables accelerated construction schedules and reduces on-site labour, equipment use, and overhead requirements, which can partially offset higher material costs [7]. In this context, cost estimates indicate that CLT buildings may achieve approximately 18% savings in costs related to labour, transport, machinery, and overhead when compared to reinforced concrete buildings [6], contributing to lower the overall costs, with 0.9–1.3% lower costs compared with reinforced concrete. Some LCC studies indicate that mass timber buildings often remain more costly than conventional alternatives [3, 4], whereas others report lower construction-related costs for CLT [6]. Such variation in findings can be partly explained by the sensitivity of LCC outcomes to contextual factors, including regional timber availability, transport distances, and the maturity of local supply chains [8].

Most LCC studies on mass timber follow conventional approaches with two limitations: a narrow boundary that excludes environmental and social externalities, and a linear cradle-to-grave life cycle that overlooks the economic value of circular strategies such as reuse, recycling, and life extension, especially relevant for timber systems with high residual value [9]. To date, existing LCC studies have not adopted a fully integrated framework encompassing environmental, social, and economic dimensions. In particular, no studies have applied a circular and environmental Life Cycle Cost Assessment (eLCC) approach while explicitly accounting for externalities. This constitutes a

significant research gap, as eLCC better captures long-term economic performance and supports sustainability-oriented decision-making.

To address this gap, the present study focuses on glulam-based slab and aims to develop an eLCC methodology that integrates environmental, social, and economic dimensions, providing a more holistic assessment of long-term performance and sustainability-oriented decision-making.

2 Methodology

2.1 Goal and Scope

This study developed a cradle-to-cradle LCC tool to assess the costs of an innovative slab developed within the UTS project [10], with the patent WO2025082958A1 [11]. The analysis focuses on the bay as the basic element that is repeated to build up the slab. The conventional LCC approach was extended to include environmental externalities and additional circular strategies, forming an expanded eLCC framework. The functional unit is defined as the production of 1 m^2 of a slab bay used as a floor element in a multi-story timber building, with a reference service life (RSL) of 60 years.

This preliminary slab adopts a timber–concrete hybrid system, where timber resists tensile stresses at the bottom and concrete carries compressive stresses at the top. It consists of 18 triangular bays, with 21.9 m^2, arranged in pairs over a 5.4 × 8.1 m span (Fig. 1). Each bay is divided into three segments, with additional cantilevered segments connecting the bays to the slab perimeter. In terms of fabrication, this study considers the mill-nailing per group approach, where milling and nailing occur during group assembly, followed by pressing for consolidation. The results presented are work in progress from the ongoing study [12].

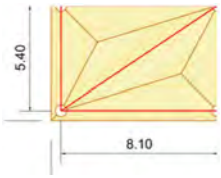

Fig. 1: UTS Building System: one bay.

2.2 Parametric LCC System and eLCC System Definition

The LCC process includes the foreground that covers the production stage, focusing on bay manufacturing costs and the background comprises processes outside the manufacturer's control, beyond the gate. The LCC represents the UTS production system, where circular strategies are applied conventionally, limited to recycling and energy recovery of timber (R8 and R9 in the circularity hierarchy). Four end-of-life (EoL) scenarios are considered: waste management (waste delivered to a facility, Sc0), 100% recycling of

timber into pellets (Sc1), 100% incineration with energy recovery (Sc2), and a 30% recycling / 70% incineration with energy recovery scenario (Sc3).

The eLCC approach used in this study incorporates externalities that are typically not captured, distinguishing it from whole LCC. These were first identified by the project consortium across the three pillars of sustainability and then selected based on their relevance, added value and data availability. System boundaries are also expanded beyond direct financial costs to capture impacts linked to circular strategies across the life cycle. Figure 2 presents the UTS eLCC process flowchart, which includes a redesign phase (R1 – rethink, R2 – reduce) embedded in the UTS project. At the EoL, the timber from the bay can be reused (R3), recycled (R8) within a closed-loop system to produce recycled timber, or sent to energy recovery (R9) if reuse or recycling is not feasible. By incorporating these alternatives, the system boundaries are expanded to support a more circular model across the product life cycle.

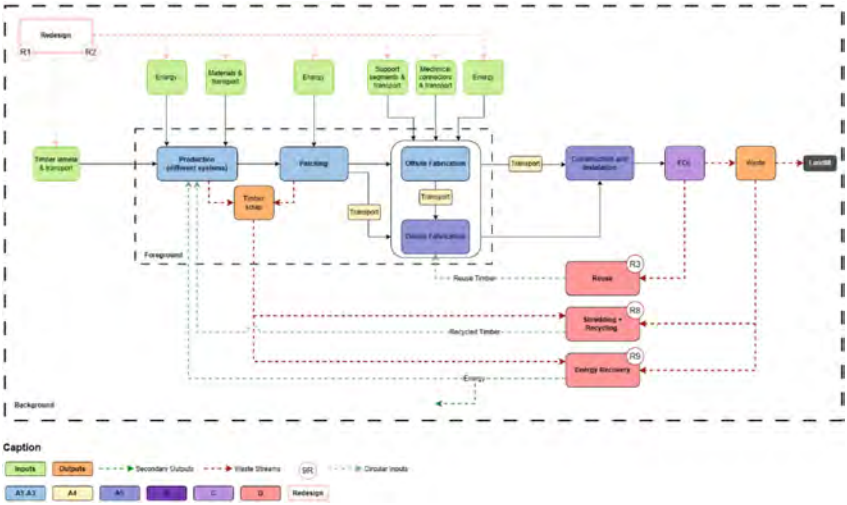

Fig. 2: UTS flowchart: the eLCC of the bay.

Table 1 outlines the various circularity scenarios evaluated within the eLCC framework, detailing the sensitivity analysis of the different percentages of reused, recycled and new timber (at production stage) and reusable, recyclable and landfilled (at EoL). The baseline scenario is based on the EU Annex guidelines for the EoL treatment of timber, assuming a 30% recycling rate and a 70% incineration rate [13].

Environmental, economic, and social externalities were assessed for the eLCC model. Five strategies were selected: i) circular strategies, ii) internalization of environmental impacts, iii) green labels and financing, iv) faster construction times, and v) workers' health and safety. Circular strategies capture the economic implications of life-cycle actions such as reuse and recycling with baseline scenario representing current feasibility and future scenarios to explore future technical limits. Internalisation of environmental impacts reflects the monetised cost of greenhouse gas emissions (GHG), calculated by multiplying LCA-derived global warming potentials (from the UTS LCA team) by

Table 1. Circularity alternatives considered for the eLCC.

Circularity Alternatives	New Timber	Recycled Timber	Reused Timber	Recyclable Timber	Reusable Timber	Incineration
Baseline (A0)	**100%**	**0%**	**0%**	**30%**	**0%**	**70%**
Max. Recycled (A1)	**70%**	30%	0%	Same as baseline		
Max. Reused (A2)	10%	0%	**90%**			
Reused (A3)	**50%**	0%	**50%**			
Max. Recyclable (A4)	Same as baseline			**70%**	0%	30%
Max. Reusable (A5)				30%	**90%**	10%
Recyclable / Reusable (A6)				**40%**	**40%**	20%

the European Union Emissions Trading System (EU ETS) carbon permit price. Green label and green financing capture the financial advantages associated with achieving green building certification, including access to lower interest rates. The values for the green label costs were retrieved from the BREEAM website, and financing assumptions were based on European Central Bank data and Leutner et al. (2024) [14]. Faster construction accounts for labour and time savings enabled by modular prefabricated timber systems, assuming traditional construction requires 40% more time [15]. Worker health and safety reflect economic benefits from reduced accident risks and improved working conditions in controlled modular environments. These benefits are quantified by aggregating direct healthcare, indirect productivity and intangible health-related quality of life costs, weighted against the annual frequency of accidents [16].

2.3 Life Cycle Inventory (LCI)

The LCI analysis involves the collection and calculation of inventory data to quantify the input and output flows of the assessed systems. Inventory data for materials and the production stage were obtained directly from the UTS project team at the University of Stuttgart, while data for the remaining life cycle phases were supplemented using literature sources and established databases. Production consists largely of concrete (49%), timber (30%), hardwood nails (11%), and the floor buildup (10%), along with minor inputs and energy/labour. Transport includes 300 km to site (A4) and 50–100 km to end-of-life destinations (C stages), with waste mainly composed of concrete (49%) and

timber (41%). Cost data were compiled from market analyses and construction-specific sources, including Gerador de Preços, Eurostat, CNR, and online retail suppliers.

3 Results and Discussion

The A1–A3 production stages dominate the costs with 524 €/m^2 followed by EoL phase, especially in the Sc0 scenario, where it accounts for 162 €/m^2. The LCC results show differences across the four analysed scenarios (Fig. 3). The Sc0 scenario has the highest total cost at 721 €/m^2, while Sc1 is the lowest at 555 €/m^2. Intermediate costs are 583 €/m^2 for Sc2 and 574 €/m^2 for the Sc3 scenario. These variations are mainly due to economic offsets at (stage C) or beyond EoL (stage D): Sc1 reduces about 92 €/m^2 of cost from material recycling. Sc2 reduces costs from energy recovery through incineration (46 €/m^2), whereas Sc3 relates to a combination of recycling and energy recovery through incineration (59 €/m^2). Within the production stage (A1-A3), timber has the highest cost, accounting for over 48% of costs, followed by the floor buildup with 32%.

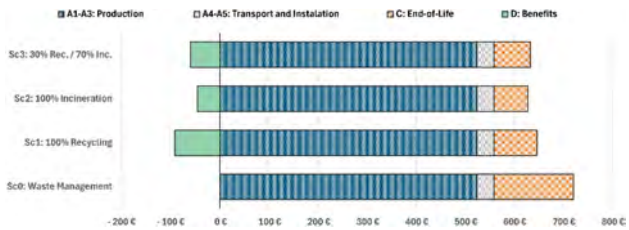

Fig. 3: LCC results (€/m^2) for bay production.

Within the eLCC analysis, the effect of varying the share of reused/recycled timber at the product stage and reusable/recyclable timber at EoL was assessed (Table 1). As shown in Fig. 4, the "Max. Reused" scenario achieves the lowest eLCC (352 €/m^2), representing a 39% reduction compared to the baseline. The "Reuse" scenario (50% reused bays) also shows a significant 24% decrease, while the "Max. Recycled" scenario achieves a 15% reduction.

EoL circular scenarios provide more moderate improvements: "Max. Reusable" reduces costs by 10%, "Recyclable/Reusable" by 9%, and "Max. Recyclable" by 8%. Overall, reuse strategies deliver the greatest economic advantage, with recycling and mixed EoL options offering smaller but still relevant savings. These results demonstrate that reuse strategies generally provide the greatest eco-nomic advantage, while recycling and mixed EoL strategies offer moderate, yet relevant, cost savings.

Figure 5 shows the contribution of each externality considered in this study. Results indicate that, excluding circular strategies, remaining externalities largely offset each other. Internalising environmental impacts increases costs by 4%, while the green label and reduced construction time decrease costs by 3% and 0.3%, respectively. The effect of worker health and safety is negligible at this scale.

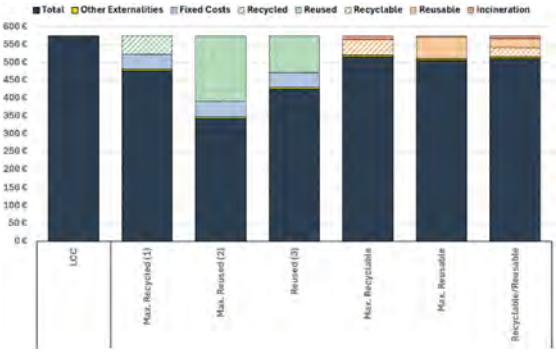

Fig. 4. eLCC results for the different circular scenarios.

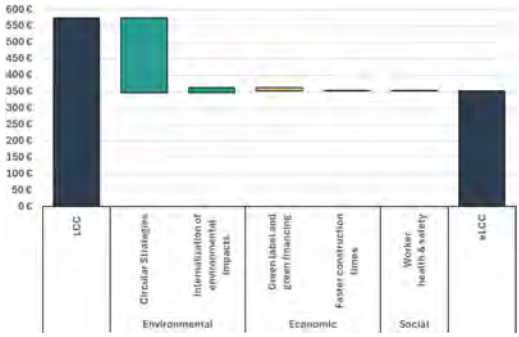

Fig. 5: Breakdown of the eLCC externality costs for the 'Max. Reused' scenario.

4 Conclusion

This study evaluated the life cycle costs (LCC) and environmental and circular life cycle costs (eLCC) of a timber bay under different circular scenarios. Results show that production stages (A1–A3), particularly timber, dominate total life cycle costs. The most favourable outcome was Sc1 (100% Recycling), while Sc0 (Waste Management) was the least favourable, mainly due to differences in end-of-life resource recovery.

The eLCC results highlight the economic benefits of circular strategies, especially reuse, which can reduce total costs by up to 47%. Recycling and other end-of-life options provide more moderate savings, while environmental, economic, and social externalities have a limited overall effect.

Overall, the results demonstrate that applying circular strategies to timber, particularly reuse, can reduce life cycle costs and help offset upfront costs. Extending these strategies to other construction materials and systems could further enhance the economic performance of the UTS solution and increase its market acceptability.

BIM-Based Tool for Carbon Emission Calculation in Construction Design Workflow

Leonardo da Silveira Pirillo Inojosa(✉) and Thiago Torres Ribeiro

Universidade de Brasília, Brasília, DF 70910-900, Brazil
leinojosa@unb.br

Abstract. The escalating global concern for environmental sustainability has placed significant pressure on the construction industry, a major contributor to carbon emissions, to adopt more effective methodologies for assessing and mitigating its ecological footprint. This issue has led to the development of advanced digital tools, particularly those integrated with Building Information Modeling. BIM-based methodologies offer a framework for integrating sustainable practices throughout the project lifecycle, from initial design to facility management. This study presents a method for calculating carbon emissions from BIM models and develops a tool to estimate emissions during the project design phase. This methodology utilizes a comprehensive database that details the environmental performance of key construction materials, derived from life cycle assessment (LCA) principles. The tool leverages Dynamo to extract model information from Revit and export it to an Excel spreadsheet for detailed carbon emissions calculations, enabling precise, integrated environmental analysis and decision-making. Additionally, this study highlights the necessity of enhancing designers' awareness concerning the environmental impacts of construction materials and structural configurations. The integration of such tools directly into the design workflow facilitates proactive environmental optimization, allowing for informed material selection and design modifications to reduce embodied carbon before construction.

Keywords: BIM · Carbon emissions · Design Workflow · Sustainability · Life cycle assessment

1 Introduction

The civil construction industry constitutes one of the main drivers of carbon dioxide emissions globally [1]. In light of the climate urgency, it becomes imperative for the sector to adopt effective methodologies to assess and mitigate its ecological footprint. The development of advanced digital tools, particularly those integrated with Building Information Modeling, emerges as a technological response to this demand [2], enabling the automation of material inventories and the dynamic calculation of embodied emissions during the initial design stages [3, 4].

BIM-based methodologies provide a robust framework for integrating sustainable practices throughout the life cycle of the built object. In the project context, the ability

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 980–988, 2026.
https://doi.org/10.1007/978-3-032-34930-9_114

to anticipate the environmental performance of materials and structural configurations is fundamental for reducing embodied carbon [5]. This study presents a method for calculating emissions from BIM models and details the development of a tool to estimate emissions in the design phase.

2 Theoretical Framework

2.1 BIM and Sustainability in the Construction Industry

The application of BIM transcends geometric representation, establishing itself as a holistic process of information management. In the context of sustainability, the focus lies on minimizing resource consumption. The integration of Life Cycle Assessment into the BIM workflow enables integrated environmental analysis, facilitating data-driven decision-making based on precise environmental performance data, allowing designers to compare material alternatives and quickly identify carbon impacts before the execution phase [1]. This digital interoperability minimizes the need for manual data entry, mitigating errors and optimizing the efficiency of the environmental assessment process [6].

2.2 Life Cycle Assessment and Embodied Carbon

LCA is a technique that allows measuring the potential impacts of a system throughout its existence [1]. According to ISO 14040, LCA is structured into four phases: goal and scope definition, inventory analysis, impact assessment, and interpretation [7]. In construction, this methodology enables focusing on embodied carbon, which refers to greenhouse gas emissions from extraction to assembly [1].

This research focuses on stages A1 to A3 (cradle-to-gate), comprising raw material extraction, transportation, and manufacturing, aligning with the "cradle-to-gate" life cycle [8]. The choice is justified by the reliability of data in Life Cycle Inventories and the direct influence of the designer on these phases. Focusing on these stages is essential as they represent the bulk of the embodied carbon of construction materials, where the designer has the most significant influence.

2.3 BIM-LCA Integration in the Project Workflow

The integration addresses the challenge of data fragmentation. According to Xue et al. [9], the main advantage is to perform iterative analyses. Automated extraction through parametric models mitigates the uncertainties of manual surveys, ensuring that the Global Warming Potential (GWP) calculation aligns with real-time decisions. The use of Dynamo fills the interoperability gap between modeling software and environmental databases [1].

Thus, the parameterization of BIM objects enables life cycle inventories to be updated dynamically, enhancing the selection of materials with a reduced carbon footprint from the early conceptual phases. This approach promotes circularity by allowing the quantitative evaluation of modular construction solutions and the precise analysis of materials'

environmental impacts, consolidating decision-making based on performance indicators throughout the entire building life cycle [10].

While established commercial tools such as Tally and One Click LCA offer robust Life Cycle Assessment (LCA) plugins within the BIM environment, their deployment faces technical and economic barriers in developing economies. Commercial plugins often rely on international databases (such as Ecoinvent or GaBi) that do not faithfully represent the Brazilian industrial matrix or local electricity grid emissions. Furthermore, high licensing costs limit their widespread adoption in public projects.

The development of a custom Dynamo-Excel workflow addresses this gap by directly mapping native Revit parameters to national cost and environmental indices like SINAPI. This open-access framework democratizes carbon accounting in the design workflow, providing a scientifically justified alternative tailored to local regulatory contexts without financial overhead.

2.4 Structural Protagonism in Construction

The evolution of construction over time is intrinsically linked to the materials and technologies adopted for structural systems. The protagonism of the structure in defining architecture reflects an integration in which the structural system defines the architectural form itself. However, aesthetics based on large spans or bold plastic forms entail a significant environmental impact due to high material consumption, such as cement and steel [11].

Given that the structure is often the subsystem with the largest material volume, optimizing it offers the greatest leverage for decarbonization. Analysis of structures reveals that technological control and precision in specification, now enhanced by BIM, allow for accurate quantification of embodied carbon impact. Consequently, parametric optimization of these structural elements becomes vital for reducing embodied energy, enabling designers to evaluate trade-offs between spatial efficiency and the environmental load of components [12].

3 Methodology

The research followed a methodological design divided into four main stages: literature review; collection of carbon emission coefficients; tool development; and validation through a case study.

For data collection, the Inventory of Carbon and Energy (Inventário de Carbono e Energia - ICE) and the National System for Research on Construction Costs and Indices (Sistema Nacional de Pesquisa de Custos e Índices da Construção Civil - SINAPI) were used as a basis, focusing on embodied carbon (“cradle-to-gate”).

3.1 Workflow and BIM-Dynamo Integration

The tool was designed to operate integrally within the design workflow, using Autodesk Revit as the parametric modeling software and Dynamo as the automation engine (Fig. 1).

The process begins with the correct categorization of elements in the BIM model, ensuring that the volume and material parameters are correctly completed.

The script developed in Dynamo operates on three fronts:

- Category Selection: Filters the construction elements that compose the structure and enclosure.
- Parameter Extraction: Collects volume (m^3) and area (m^2) data directly from Revit families.
- Interoperability: Exports this data to an external Excel spreadsheet, where carbon emission coefficients are applied automatically.

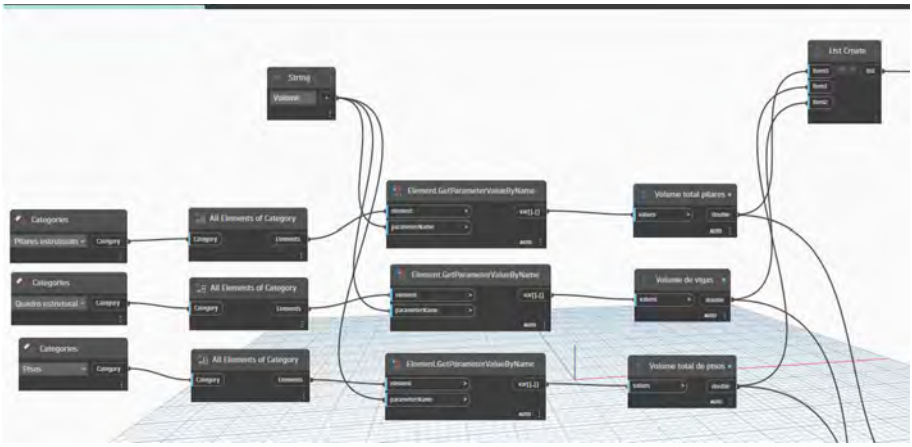

Fig. 1. Visual programming routine in Dynamo environment for extracting quantities from Revit categories. Source: Adapted from Ribeiro, 2024 [1].

3.2 Carbon Calculation Criteria

The calculation is based on the quantification of embodied carbon, specifically in the "Cradle-to-Gate" stage, which comprises raw material extraction, transportation, and manufacturing [13]. The base formula applied in the tool is (1):

$$E_{total} = \sum (V_i \times \rho_i \times FE_i) \tag{1}$$

Where:

- V_i is the volume of material extracted from the BIM model.
- ρ_i is the density of the material.
- FE_i is the emission factor (CO_2 eq/kg) obtained from inventories such as ICE and adapted to the Brazilian context via SINAPI.

3.3 Case Study

As a methodological validation tool, the study utilized the standard project of the FNDE Creche Pré-Escola Tipo 1. This project holds special importance due to its widespread replication across the national territory [1], conferring high potential social and environmental impact to the study. The BIM model of the daycare (Fig. 2) enabled testing the tool on a complex geometry integrating various constructive subsystems.

In this application, different material scenarios were compared to assess the variation in total carbon dioxide equivalent ($CO_2\ eq$) emissions.

Fig. 2. Three-dimensional representation of the BIM model used for testing the tool. Source: Authors.

4 Results and Discussions

4.1 Analysis of Emissions in Creche Type 1

The 3D visualization facilitated the identification of oversized elements that impacted the carbon footprint. The application of the tool to the FNDE Creche model revealed that reinforced concrete structural systems are the main contributors to the building's carbon footprint. This diagnosis underscores the need to explore material alternatives with lower emission factors, as suggested by frameworks that automate the comparison of alternatives based on inventory data.

- **Critical Points Identification.** Automated extraction enabled the identification that in standardized projects, careful material specification can significantly reduce the

global impact without altering the building's functionality. Additionally, the interoperability between the modeling environment and calculation spreadsheets allowed variations in emission coefficients to be reflected in real time, validating the effectiveness of automation in mitigating human errors and ensuring inventory precision.

- **Subsystems Comparison.** The comparison of various subsystems simultaneously identified the structure as the largest share of embodied carbon in the project, reinforcing the need for structural optimization in large-scale public sector projects. Parallel to the data demonstrate that the strategic replacement of high-impact components with circular alternatives or lower footprint options can substantially reduce total emissions, corroborating the technical feasibility of integrating sustainability metrics from the initial modeling phases.

4.2 Proactive Decision Making

The tool enabled the simulation of different material scenarios for the daycare building. By altering the concrete class or enclosure type in the BIM model, the impact on total CO_2 *eq* emissions was recalculated instantly (Fig. 2). This demonstrates that transparency of environmental data in the design workflow increases the designer's awareness and facilitates the selection of lower-impact materials (Fig. 3).

Fig. 3. Graph of emission distribution by material in the Structural Model for FNDE Daycare Building. Source: Ribeiro, 2024 [1]

4.3 Quantitative Baseline Results

The automated extraction of the FNDE Creche Tipo 1 BIM model yielded a total material volume that translated into an overall embodied carbon footprint of approximately 342.5 tCO2eq for the structure and envelope components (Stages A1–A3). The reinforced concrete structural system (beams, columns, and slabs) alone accounted for 68.2% of the total emissions, confirming the structural protagonism discussed by Inojosa (2019).

4.4 Material Scenario Comparison

To validate the tool's utility in proactive decision-making, two structural scenarios were simulated:

- **Scenario A (Baseline):** Standard structural concrete (CP II concrete blend) resulted in 233.5 tCO2eq for the structural frame.
- **Scenario B (Eco-optimized):** Replacing standard concrete with a pozzolanic ash-blend concrete (CP IV) reduced the structural embodied carbon to 191.4 tCO2eq, representing an instantaneous 18% reduction in the structural footprint.

This real-time feedback loop inside the Excel sheet allows designers to quantify environmental optimizations before any material procurement begins.

4.5 Data and Interoperability Challenges

The effectiveness of the tool is linked to the maturity of the information in the model, facing the following technical challenges:

- **Level of Development:** The accuracy of calculations depends on an adequate LOD (ideally >300), as simplified models omit essential components, resulting in underestimates of embodied carbon.
- **Parametric Integrity:** Failures in filling "Material" and "Volume" parameters in Revit make automation via Dynamo unfeasible, requiring rigor in modeling [14].
- **Inventories and Local Reality:** Dependence on external databases imposes the challenge of constant updating and adaptation of international coefficients to the Brazilian energy and industrial matrix [1].
- **Interoperability:** Barriers persist in data transition between BIM and calculation environments, especially for non-standardized systems.

Overcoming such limitations is fundamental so that automated analysis is not restricted to post-design stages, allowing sustainability metrics to guide design from its conceptual phases.

5 Conclusion

The present study demonstrated the technical feasibility of integrating visual programming tools into the BIM workflow for carbon emissions management. The developed tool proved effective in automating quantity takeoffs, mitigating errors inherent to manual processes, and allowing sustainability to consolidate as an iterative design parameter essential for managing the carbon footprint of the AEC industry in a technically rigorous manner.

The FNDE Creche Pré-Escola Tipo 1 case study validated the tool in a replicable and socially relevant context, highlighting the significant environmental impact of structural systems. The use of BIM-LCA to optimize material consumption is crucial for decarbonizing the sector. However, the study's focus on stages A1–A3 (Cradle-to-Gate) limits

the application of circular economy principles. Future iterations must incorporate structural disassembly, materials reuse, and end-of-life processes (C1–C4) to fully capture material value retention in a circular built environment.

The precision of environmental analysis relies on the model's Level of Development and the integrity of parametric data. Successful implementation requires both technological mastery and clear guidelines in BIM Execution Plans. Future work should expand the database to include maintenance and end-of-life phases and integrate with cost databases for a balance between ecological efficiency and financial viability. Ultimately, democratizing environmental analysis tools in project workflows can transform the construction industry into a more advanced and environmentally responsible sector.

From Operational to Embodied Emissions: Insights into the LCA of Key Building Systems

Anna Dalla Valle(✉), Fabrizio Leonforte, Andrea Campioli, Monica Lavagna, Claudio Del Pero, and Niccolò Aste

Department of Architecture, Built Environment and Construction Engineering (DABC), Politecnico di Milano, Milan, Italy
anna.dalla@polimi.it

Abstract. After years in which operational emissions dominated the international debate on building sector, embodied emissions are now receiving increasing attention, proved by policy requirements that extend the assessment to construction materials and technical building systems. Nevertheless, building systems are often overlooked or modelled using database values that do not accurately reflect their real physical composition. Focusing on key systems relevant to building decarbonization, the paper aims to evaluate the material intensity and associated environmental impacts, pointing out the complexities underlying the LCA modelling of three technical systems – Heat Pump, Water Loop Fan Coil, and Multi Converter – developed in RE-SKIN Horizon project. The intensity of the embedded materials/components has been defined through close collaboration with manufacturers to obtain primary inventory data, collected by a process that balances simplification with an adequate level of detail. Environmental impacts have been assessed in compliance with EN 15804 + A2, focusing on GWP as key indicator. The results provide a highly granular understanding of the resources invested into building systems and, especially if they emerge as hotspots, to be handled over the entire life cycle. This is crucial for improving product-level environmental performance and, when scaled up, for supporting building-level characterization.

Keywords: Life Cycle Assessment · Building System · Inventory · Impacts

1 Technical Building Systems at the Spotlights

The shift from operational to embodied emissions in the building sector is now imperative, consolidated by recent policy developments, notably the recast of the Energy Performance of Buildings Directive [1], which extends the scope of assessment to the whole life cycle greenhouse gas emissions. If operational emissions have dominated for a long time, in recent years embodied emissions have been increasingly deemed 'critical', particularly in highly efficient or nearly zero-emission buildings, in which operational impacts are progressively reduced. In this respect, several Life Cycle Assessment (LCA) studies conducted at building level highlight the significant contribution of embodied impacts to total life cycle impacts, specifically underlining the importance of technical

https://doi.org/10.1007/978-3-032-34930-9_115

and electrical equipment [2–4]. Beside construction products, the inclusion of these systems in building assessment is essential, even if they are still often omitted in practice or covered superficially for a variety of reasons (mainly lack of environmental data). Neglecting building systems, or modelling them only partially, means to overemphasize the saving in term of operational emissions, ignoring the material intensity and upstream impacts associated with the technologies used to achieve such savings [5, 6]. The omission or partial accounting of the embodied emissions from building systems may lead to incomplete and potentially misleading LCA evaluation.

In this context, the present paper provides insights into material intensity and environmental impacts of key building systems currently used for building decarbonization: Heat Pump, Water Loop Fan Coil, and Multi Converter (details in paragraphs below). The study has been developed within the project RE-SKIN "Renewable and Environmental-Sustainable Kit for building Integration" [7], funded in the framework of the Horizon programme, aimed at assessing the related life cycle impacts. Moving beyond a preliminary assessment largely based on assumptions, the work relies on detailed primary data inventories, subjected to process of simplification to achieve a high level of modelling granularity while preserving feasibility. The resulting analysis contributes to more accurate measurement of product-level environmental performance within the RE-SKIN toolkit, subsequently implemented and validated in real case-study buildings.

2 RE-SKIN Toolkit

RE-SKIN is an integrated multifunctional system for the energy retrofit of existing buildings, addressing both the envelope (roof and façade) and HVAC system [8], the latter being the focus of this study. The roof is renovated through a building-integrated hybrid photovoltaic-thermal (BIPVT) system that generates electricity and heat while providing thermal and acoustic insulation. The air heated by the hybrid roof supports heating and domestic hot water via a solar-assisted air-to-water Heat Pump able to provide 18kWp. Furthermore, as the system operates in direct current (DC), the electricity produced by BIPVT directly supplies the Heat Pump without AC conversion, thereby improving overall system efficiency. The DC Heat Pump is also connected to decentralized DC water loop heat pumps installed in each room, enabling both heating and cooling via the building hydronic network. Such components integrate a DC compressor to increase the thermal power (about 1.5 kW each) coming from the centralized DC heat pump, according to the energy demand of each room. This allows to minimize heat losses on the existing distributions pipes and to avoid condensation in cooling mode.

In addition, an energy storage system composed by repurposed electric vehicles batteries is also included, to store PV electricity. All AC/DC power fluxes, including grid interfacing, are managed by a Multi Converter that allows the interconnection of multiple DC generators, DC loads and energy storages. It avoids the DC/AC conversion from the PV modules and thus the presence of a plant-sized PV inverter, regulating the voltage and/or current, without other power modulation equipment. Moreover, it allows a bi-directional power flow with the AC grid whenever the generated/stored DC energy is insufficient, or when excess PV electricity cannot be stored locally.

3 Ways to Approach Detailed System-Specific Inventories

Developing a detailed life cycle inventory for technical building systems is particularly demanding, calling for iterative collection process as experienced with RE-SKIN partners. Many sub-components could be not standard products, with limited pre-existing information. Furthermore, given the high number of sub-components and the supply chain articulation, information is always fragmented, non-digitized and dispersed across suppliers, making data collection complex and time-consuming. From the manufacturer point of view, compiling a detailed inventory typically entails a manual breakdown of the system, that requires a considerable internal coordination across technical, procurement and assembly areas. From the LCA analyst point of view, an additional effort is demanded to keep operators informed about the needed information and clarify their relevance for the environmental modelling, translating LCA requirements into practical instructions for manufacturers and establishing priorities for the data collection. This mutual learning process is fundamental for achieving appropriate balance between simplification and modelling granularity.

Depending on the technological and component complexity of the systems under investigation as well as the state of awareness and resources monitoring within the company, in terms of inflows and outflows, two methodological pathways can be identified. They derive from industrial collaboration, and they are replicable to approach a detailed inventory for building systems.

The first way – here applied to Heat Pump and Water Loop Fan Coil – consists of the single-item breakdown of the system. This method requires the identification of each individual sub-component constituting the product and its systematic characterization in terms of material type, quantity, unit weight and total mass. Additional process-related elements, such as auxiliary materials, refrigerant and manufacturing energy consumption, are integrated. In this way, although some simplification in relation to material composition, a high level of granularity is ensured, allowing a detailed identification of hotspots, nonetheless substantiated by considerable effort in terms of data collection. Following this approach, the collected data are related to: 63 items for the main unit and 65 items for the evaporator, complemented by refrigerant and manufacturing energy consumption, for the Heat Pump; 31 items, complemented by refrigerant, for the Water Loop Fan Coil.

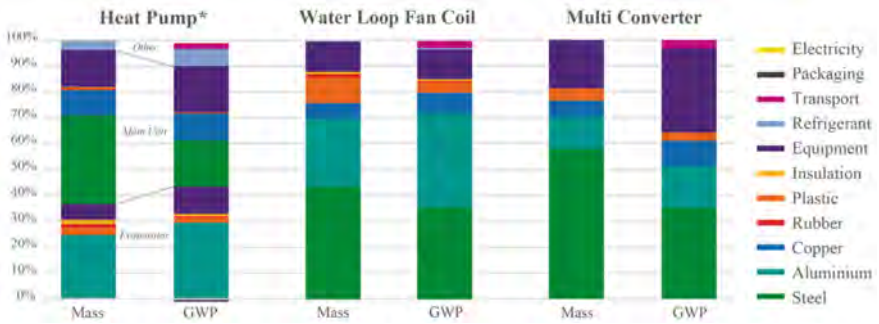
The second way – here adopted for Multi Converter – is based on the aggregated-item strategy, needed to face highly complex electronic systems tailor-made as in this case for RE-SKIN toolkit. Instead of characterizing each item individually, sub-components are grouped into functional clusters. These clusters are then associated with representative material categories, quantified based on their overall weight and, whenever possible, to the technical arrangement (e.g. number of units per module and number of modules per system). Further refinements of the inventory are encouraged for the most material-intensity clusters. In this way, feasibility and representativeness are in a sense 'offset', remaining balanced to enable complex multi-component systems to be modelled without excessive simplification and by avoiding disproportionate analytical efforts. In particular, the inventory has been structured considering, for the Multi Converter, around 4500 items aggregated into a matrix of 7 aggregated-item groups and 6 main material categories.

Both methodological pathways aim to achieve enough level of detail to capture the material intensity and environmental hotspots of the system, ensuring practical applicability in relation to the manufacturer maturity.

4 LCA Modelling of Building Systems

In the present study, the LCA of key building systems – namely Heat Pump, Water Loop Fan Coil and Multi Converter – specifically designed within the Horizon project RE-SKIN, has been carried out in compliance with EN 15804 + A2 [9], consistently with Level(s) framework [10] requirements. The LCA modelling considers one complete system (1 p) and focuses primarily on Global Warming Potential (GWP), following a cradle-to-gate boundary (A1-A3 modules), and it has been performed using SimaPro 9.6 software, with background data sourced from Ecoinvent 3.10 database.

Depending on the inventory details available from the manufacturers, the following approaches have been implemented during the systems modelling:



- for mono-material items (e.g. support plate), the environmental profile was directly linked to a specific representative material dataset (e.g. *'Aluminium alloy, AlMg3'*);
- for double/triple-material items (e.g. pipe insulation), the modelling focused on the most relevant constituent (e.g. '*Polyurethane, flexible foam'*), because the missing data about materials share made the allocation to individual materials not feasible, forcing the cut-off of minor constituents (e.g. acrylate adhesive);
- for multi-material items (e.g. inverter and control units), the modelling was preferred where available at product-level (not material), by selecting representative background dataset for functionally equivalent products (e.g. *'Inverter'* and *'Electronics, for control units'*). This approach allows to depict highly complex assemblies, composed of several sub-components and materials, avoiding impractical level of disaggregation.

With regard to transport, the absence of information on the upstream supply chain required the adoption of assumptions. For both material-level and product-level, *'market for'* datasets have been selected in order to account, although in a simplified manner, the geographical fragmentation and foreign sourcing of sub-components, often produced outside the European Union. For the final stage of the supply chain, namely from the sub-component supplier (e.g. valve producer) to the building system assembler (e.g. Heat Pump manufacturer), a standard transport distance of 1000 km by lorry has been taken. Packaging materials, both for incoming items and outgoing products, and manufacturing waste were excluded from the system boundary due to lack of data.

5 Combined Results of Material Intensity and GWP Impacts

The LCA results are presented by explicitly linking material intensity (expressed in kg of materials per complete system) with the associated A1-A3 environmental impacts, taking GWP as key indicator (expressed in $kgCO_2e$ per complete system). Note that despite the effort in data collection to ensure granularity, the detailed inventories developed for each system and the resulting impacts were re-aggregated into main material areas to

return results as percentage (Fig. 1). This clustering step was necessary to improve visual clarity and consistency graphics, especially in systems modelled through fully disaggregated single-item breakdown, in which the large number of individual sub-components would otherwise hinder readability. The matching between material mass distribution and GWP contribution allows a direct understanding of how material intensity translates into embodied emissions.

* Heat Pump materials are aggregated but reported separately for main unit and evaporator.

Fig. 1. Percentage distribution of material intensity and GWP impacts for the 3 building systems.

5.1 Heat Pump

The total GWP (A1-A3) of the Heat Pump, referred to one complete system, amounts to 3.36E+03 kgCO_2e. The cumulated mass of the system is 366 kg, composed of 218 kg for the main unit, 135 kg for the evaporator and 13 kg of refrigerant (excluding the wooden pallet used for packaging). The GWP hotspot analysis confirms that the main unit is the largest contributor to total embodied emissions (47%), closely followed by the evaporator (45%), while the remaining elements – refrigerant, packaging, transport, energy, grouped under *'Other'* – account for a minor share (8%).

Within a more detailed breakdown of the main unit, complex equipment represents the primary hotspot (52.6 kg generate 39% GWP impacts of main unit only), reflecting the incidence of the technological and electrical sub-systems (e.g. inverter, compressor, control units). Metals parts turn out secondary hotspots. In particular, steel makes up the largest mass share of the main unit but plays a less impact role (124.8 kg = 38% GWP), compared to copper and brass, distinguished by high emissions relative to their mass (36.5 kg = 22%GWP). By contrast, for the evaporator, aluminium dominates both in terms of material quantity and environmental impacts (90.2 kg = 67%GWP of evaporator only), due to its extensive use in structural parts. It is followed by fan and wiring (22.5 kg = 24%GWP). In both main units and evaporator, minor contributions arise from plastics, rubber and insulation, consistent with their limited mass shares. In either case, however, it is worth pointing out that all metals are modelled as fully virgin materials, due to lack of data about any recycled content, but including metal working. Moreover, further refinement could be achieved by modelling in detail the R410a refrigerant here used in

the heat pump (13 kg = 7%GWP total impacts), currently approximated using the most representative available dataset (*'Refrigerant R134a'*).

5.2 Water Loop fan Coil

The total GWP (A1-A3) of the Water Loop Fan Coil, referred to one complete unit with an overall mass of 34.7 kg, is estimated at 2.53E+02 kgCO_2e. From the hotspot analysis, the environmental profile is evidently dominated by metallic materials. Steel (15.2 kg = 36%GWP) and aluminium (9 kg = 36%GWP) represent the two main contributors to total impacts, modelled by comprising in both virgin material production and metal working, showing their significant mass and energy-intensive production. Secondary contributors rely on the complex equipment (4.1 kg = 11%GWP), including the compressor, copper and brass (2.1 kg = 8%GWP), mainly used for valves and hydraulic connections. Plastics, transport, insulation and refrigerant show minor contributions, even if – as happens for the Heat Pump – refined results could be achieved by modelling the R290 refrigerant used in the Water Loop Fan Coil (0.88 kg = 0.6%GWP), now approximated using the only available dataset (*'Refrigerant R134a'*).

5.3 Multi Converter

The total GWP (A1-A3) of the Multi Converter, referred to one complete system having a total mass of 254.6 kg, stands at 1.59E+03 kgCO_2e. The GWP hotspot analysis shows that the major contribution is allocated to steel (147 kg = 35%GWP), mainly used for the mechanical and structural elements and modelled by assuming 80% recycled content, as declared by the manufacturer, including the associated metal working process. Complex equipment, despite the smaller mass consisting essentially of electronics, represent similarly relevant share (47.6 kg = 33%GWP), highlighting the high material and processing intensity embedded in electronic assemblies, including sensing cards, digital cards, power boards and control boards. In third place, there is aluminium (32 kg = 16%GWP), also used for the mechanical parts but modelled with 40% recycled content, as declared by the manufacturer. It is followed by copper (16 kg = 10%GWP), considering virgin material production and reflecting its use in electrical connection and cabling. Plastic (12 kg = 3%GWP) and transport account for minor shares of total impacts.

6 Ongoing Effort to Advance Embodied Emission Reliability

Among the results, metals clearly emerge as major contributors to embodied emissions, due to their extensive use and energy-intensive production. Rather to simply suggest cutting down metals use or to find alternative materials (where structurally feasible), the findings emphasize the need to improve data quality, through more transparent information on material composition, recycled content and processing routes, supported by increased supply-chain traceability. In addition, to advance the reliability of embodied emissions modelling, electronics also deserves particular attention, given their disproportionately high impacts compared to their weight, due to the presence of precious metals, system complexity and energy-intensive manufacturing processes. In these instances, even small miscalculations in the inventory data or modelling inaccuracies may significantly influence the environmental results.

However, the study acknowledges several limitations. As first, the modelling primarily accounts for material flows, capturing only partially the working processes and excluding production waste and packaging, because of the lack of primary data. While some assembly phases may involve relatively minor impacts, there are greater uncertainty for complex sub-components, for which upstream production processes are often difficult to trace and quantify. The second constraint is that, where necessary, proxy datasets (e.g. refrigerants) and simplified assumptions (e.g. transport) were adopted, becoming areas for future refinement [11–13] as data quality improves and additional primary information becomes available. The challenge is in the intrinsic complexity of technical building systems, often comprising hundreds of sub-components. Manufacturers typically act mainly as assemblers, sourcing components from fragmented and geographically dispersed supply chains [14], with limited knowledge of upstream processes and little influence beyond supplier selection. This results in often unavailable key information for sub-components, making the collection of primary data particularly demanding and inevitably leading to simplification in LCA modelling. Furthermore, the cradle-to-gate boundary excludes downstream phases, including transport to site, installation, use, maintenance and end-of-life processes [15], which will be addressed in future analyses to provide a more comprehensive life cycle perspective.

In this context, improved supply chain mapping and traceability are essential for advancing the robustness of LCA results. Greater transparency at supplier level would reduce uncertainty and enhance reliability of embodied carbon assessments, supporting more informed low-impact decision-making across the building sector value chain.

Shifting from product-level to building-level assessment, the LCA of building systems appear increasingly critical. Indeed, many studies rely in practice on generic, not product-specific datasets, which often do not properly reflect the actual physical composition, technological specificity and technical performance of the systems under analysis. This restriction is mainly due to the limited availability of reference datasets, both in widely used databases, where many technologies remain insufficiently covered, and in Environmental Product Declarations (EPDs), which – although increasingly available – refer to specific products that may not match the system under analysis. Bypassing EPDs and looking to source the RE-SKIN building systems from databases, poor results are generated by both Ecoinvent and Ökobaudat. Fan Coil and Multi Converter are not directly represented: for the Fan Coil, the closest proxy is *'Decentralized ventilation units'*; for the Multi Converter, the only potentially comparable datasets are *'Inverter'* available in Ecoinvent with three different power (*0.5 kW, 2.5 kW, 500 kW*). They are yet all substantially different from the systems analysed. Conversely, Heat Pump case is more documented, but the comparison of the available datasets highlights significant variability in the estimated embodied impacts (Fig. 2), even when expressed for comparable nominal power. The RE-SKIN Heat Pump reflects a detailed air-water system-specific inventory, resulting in higher material intensity compared to generic datasets. Ecoinvent datasets rely only on brine-water systems, clearly scaling impacts with system capacity, but showing close order of GWP magnitude with RE-SKIN. Instead, Ökobaudat datasets, despite referring to same air-water technologies, display substantially lower impacts, due to different assumptions and system boundaries.

Overall, in building-level characterization the choice of datasets for technical systems can strongly influence the resulting LCA impacts, potentially affecting not only the magnitude of the results but also the identification of environmental hotspots and the derived decarbonization strategies. Accordingly, the importance of continuously improving the reliability of embodied emission for building systems, in order to capture the actual technological configuration and material intensity with sufficient granularity to avoid misrepresentation of environmental hotspots.

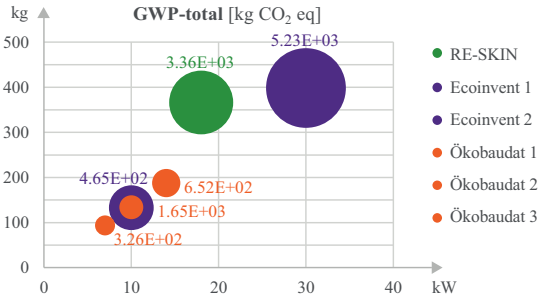


Fig. 2. Comparison of Heat Pump LCA datasets: nominal power (kW, x-axis) vs. system mass (kg, y-axis), with bubble size representing embodied emissions (GWP, A1-A3).

Abstract. This paper presents a methodological and conceptual framework for the development of an integrated AI model aimed at predicting the life-cycle performance and circularity of construction products in accordance with the new EU Construction Products Regulation (CPR 2024/3110). The proposed approach integrates artificial neural networks (ANN), life-cycle assessment (LCA), life-cycle costing (LCC), and material circularity indicators (MCI) to support automated prediction of environmental, technical, and circularity-related parameters required for Digital Product Passports (DPP).

The methodology focuses on defining relevant datasets, engineering ANN architectures, selecting LCA/LCC indicators aligned with CPR 2024 requirements, and establishing validation procedures based on regression-performance indicators such as RMSE and MAE. ANN models are intended to process datasets describing material composition, environmental profiles, production technologies, transport parameters, and durability characteristics in order to generate predictive outputs including global warming potential (GWP), recyclability rates, expected service life, and end-of-life scenarios.

The proposed framework demonstrates how AI-based tools may support manufacturers, designers, certification bodies, and regulatory institutions in addressing CPR 2024 requirements related to sustainability assessment, circularity performance, and digitalization of product information. The paper outlines the methodological basis for future development, validation, and implementation of integrated AI-driven sustainability assessment systems for construction products.

Keywords: Artificial Intelligence · CPR 2024 · Digital Product Passport · Life Cycle Assessment · Circularity

1 Introduction

The construction sector represents one of the largest consumers of natural resources and one of the major generators of waste, which is why the transition toward a circular economy has become an important priority of the European Green Deal and the

Circular Economy Action Plan [1, 8, 9]. In this context, the new EU Construction Products Regulation, CPR 2024/3110, introduces new requirements related to sustainability assessment, transparency, circularity, and digital product information [2].

A particularly important role is assigned to the concept of the Digital Product Passport (DPP), which enables structured monitoring and traceability of technical, environmental, and circularity-related product characteristics throughout the entire life cycle [3]. At the same time, the growing complexity of data concerning material composition, production processes, durability, and end-of-life scenarios creates the need for advanced analytical tools capable of processing complex environmental and lifecycle datasets.

In this regard, artificial intelligence, especially models based on artificial neural networks (ANN), can provide significant support in modelling complex non-linear relationships between parameters that define the performance of construction products. By combining AI approaches with life-cycle assessment methods (LCA), life-cycle costing (LCC), and material circularity indicators (MCI), it becomes possible to develop an integrated predictive model based on AI methods for estimating key environmental and circularity indicators [11, 12].

Existing studies have mainly focused either on standalone life-cycle assessment approaches or on isolated applications of artificial intelligence in construction materials research. However, limited research has addressed the integration of ANN-based predictive systems with LCA, LCC, material circularity indicators, and Digital Product Passport requirements within the regulatory framework of CPR 2024.

The aim of this paper is to develop a methodological framework for predicting life-cycle performance and circularity of construction products in accordance with CPR 2024. The research question of the paper is how AI models can support automated prediction of life-cycle indicators and circularity metrics required within the new CPR 2024 regulatory framework. The paper focuses on defining relevant datasets, representative input and output parameters, ANN architecture principles, and validation procedures for future model implementation. Unlike previous studies that primarily address LCA methods or AI applications independently, this research proposes an integrated AI-driven framework that links predictive ANN models with life-cycle and circularity indicators within the regulatory context of CPR 2024 and Digital Product Passport implementation.

Since the objective of this study is to establish a methodological framework for future AI-assisted sustainability assessment of construction products, the implementation, training, and validation of the proposed model using real datasets are considered future research activities and are therefore outside the scope of the present paper. The focus of this research is on defining the architecture, data structure, predictive variables, and validation methodology required for subsequent model development and testing.

2 Regulatory Framework: CPR 2024 and Digitalization of Information on Construction Products

The new European Union Construction Products Regulation, CPR 2024/3110, represents a significant step toward greater sustainability, transparency, circularity, and digitalization of data related to construction products [2]. Compared to the previous CPR 305/2011 regulation, the new framework substantially expands the requirements

concerning environmental performance assessment, material circularity, lifecycle transparency, and the availability of digital information throughout the entire life cycle of construction products.

One of the central elements of CPR 2024 is the Digital Product Passport (DPP), defined as a structured digital repository of information related to product composition, environmental characteristics, technical performance during use, potential for reuse and recycling, and end-of-life management scenarios. The DPP concept is intended to improve transparency, traceability, and accessibility of product-related information across the entire construction value chain [3].

CPR 2024 also places stronger emphasis on life-cycle assessment methodologies and relies on instruments such as Environmental Product Declarations (EPD) and LCA indicators, including global warming potential, resource consumption, embodied energy, and waste generation [4–6]. The increasing quantity and complexity of sustainability-related data create the need for advanced digital and AI-based analytical tools capable of supporting automated processing and interpretation of environmental and circularity indicators required by CPR 2024.

3 Life-Cycle and Circularity Indicators of Construction Products

Assessment of construction product sustainability is commonly based on Life Cycle Assessment (LCA), Life Cycle Costing (LCC), and Material Circularity Indicators (MCI). LCA quantifies environmental impacts throughout the product life cycle, including production, transport, use, and end-of-life stages, while LCC evaluates the associated economic costs. MCI complements these approaches by assessing the circularity potential of products through indicators such as recycled content, durability, reuse potential, and recovery efficiency [4–7].

Within the proposed framework, key performance indicators include Global Warming Potential (GWP), life-cycle energy consumption, service life, recyclability rate, and Material Circularity Indicator (MCI). These indicators represent the target variables predicted by the ANN model and are aligned with sustainability and circularity requirements introduced by CPR 2024.

4 Conceptual Model of the Integrated AI System

The proposed integrated AI model combines artificial neural networks (ANN), life-cycle assessment (LCA), life-cycle costing (LCC), and material circularity indicators (MCI) to predict sustainability and circularity performance of construction products based on material composition, manufacturing processes, environmental profiles, transport characteristics, and durability parameters. The overall structure and data flow of the proposed framework are presented in Fig. 1.

As illustrated in Fig. 1, the proposed framework integrates material composition, manufacturing processes, LCA datasets, and durability-related information as input variables for ANN-based predictive modelling. The system combines ANN, LCA, LCC, and MCI to generate sustainability and circularity indicators that can be incorporated into Digital Product Passport systems in support of CPR 2024 implementation

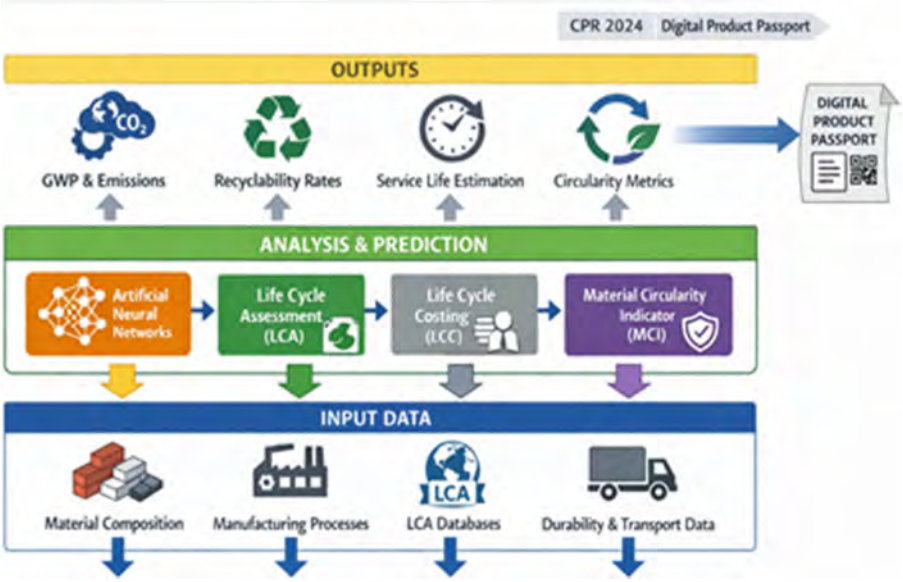

Fig. 1. Conceptual framework of the integrated AI–LCA–DPP model for predicting life-cycle performance and circularity of construction products in support of CPR 2024 requirements.

5 Methodology for the Development of the AI Model

The development of the proposed integrated AI model is based on a multi-phase methodological approach that includes identification of relevant datasets, definition of representative input and output parameters, development of artificial neural network architecture, and establishment of procedures for validation and evaluation of model performance. The proposed methodology is intended to provide a technically feasible framework for future implementation of AI-assisted sustainability assessment systems within the CPR 2024 regulatory context.

5.1 Structure and Data Sources

The first phase of the model development process refers to the identification, collection, and structuring of datasets capable of describing the environmental, technical, and circularity-related characteristics of construction products throughout their life cycle. The methodology foresees the use of data derived from Environmental Product Declarations (EPDs), LCA databases, technical product specifications, and datasets related to construction materials and manufacturing processes.

Potential data sources may include databases such as Ecoinvent, One Click LCA, EC3, and publicly available EPD repositories. The expected output parameters include global warming potential (GWP), energy consumption over the life cycle, estimated service life of the product, recycling and reuse rates, material circularity indicators, and end-of-life management scenarios [4–6].

For illustrative purposes, the proposed framework assumes datasets derived from Environmental Product Declarations (EPDs) and LCA repositories containing several hundred Environmental Product Declaration records representing concrete, steel, timber, insulation materials, and other major construction product categories. Such datasets are expected to provide sufficient variability for training and evaluating ANN-based prediction models within the proposed framework.

Based on these datasets, the key input parameters of the model are defined, including material composition (share of different components), type of production technology, energy requirements of manufacturing processes, transport distances and transport modes, physical and mechanical material properties, durability parameters, resistance to degradation, and recycled material content.

Table 1 presents the proposed structure of ANN input and output variables used within the predictive framework.

Table 1. Proposed structure of ANN input and output variables

Category	Variable	Description
Input	Material composition	Share of virgin and recycled materials (%)
Input	Manufacturing energy	Energy consumption during production (MJ/kg)
Input	Transport distance	Transport distance from production to site (km)
Input	Transport mode	Road, rail, sea, or combined transport
Input	Density	Material density (kg/m^3)
Input	Mechanical properties	Strength and durability characteristics
Input	Service-life parameters	Expected durability and degradation resistance
Input	Recycled content	Percentage of recycled material (%)
Output	Global Warming Potential (GWP)	kg CO_2 eq
Output	Life-cycle energy consumption	MJ
Output	Service life prediction	Years
Output	Recyclability rate	%
Output	Material Circularity Indicator (MCI)	Dimensionless index

The proposed dataset structure provides a preliminary basis for ANN training and enables prediction of key environmental and circularity indicators required for CPR 2024 compliance and Digital Product Passport implementation.

The preliminary structure of the ANN training dataset is expected to contain approximately 10–15 representative input parameters describing material composition, manufacturing processes, transport characteristics, and durability properties of construction

products. The proposed dataset structure represents a simplified but technically feasible basis for future ANN model training and sustainability prediction tasks.

5.2 Architecture of Artificial Neural Networks

For the development of the predictive model, a Multilayer Perceptron (MLP) artificial neural network architecture is proposed due to its ability to model complex non-linear relationships between multiple input and output variables. The preliminary ANN architecture consists of an input layer containing approximately 10–15 neurons corresponding to product-related parameters, two hidden layers with 24 and 16 neurons respectively, and an output layer generating predictions of key sustainability and circularity indicators, including Global Warming Potential (GWP), life-cycle energy consumption, service life, recyclability rate, and Material Circularity Indicator (MCI).

The proposed network is intended to be trained using the backpropagation algorithm and the Adam optimization method. ReLU activation functions are proposed for the hidden layers, while linear activation functions are applied in the output layer to support regression-based prediction tasks. The proposed ANN configuration represents a preliminary methodological framework intended for future implementation, calibration, and validation using real-world datasets derived from Environmental Product Declarations (EPDs), LCA databases, and technical product specifications.

5.3 Validation and Evaluation of Model Performance

In order to ensure reliability and scientific validity of the proposed model, the application of different methods for evaluation of model performance is foreseen.

The validation methodology may include:

- splitting datasets into training and testing subsets,
- application of k-fold cross-validation methods,
- evaluation of prediction errors using statistical indicators such as RMSE, MAE, and coefficient of determination (R^2).

Additionally, the methodology foresees implementation of regularization and overfitting-prevention techniques, including early stopping procedures and dropout regularization methods during ANN training. Such an approach enables assessment of the model's capability to generate reliable predictions and to generalize prediction results on datasets not previously used during the training process.

A proof-of-concept implementation using datasets derived from EPD repositories and LCA databases is planned as the next phase of the research in order to evaluate model feasibility, prediction accuracy, and practical applicability.

6 Discussion: Potential Application of AI Models within the CPR 2024 Framework

The application of integrated AI models may provide significant benefits for stakeholders involved in the development, assessment, and regulation of construction products [12]. For manufacturers, AI-assisted analytical tools can support faster evaluation of environmental and circularity performance during product development, enabling optimization

of material composition, production technologies, embodied carbon, recyclability, and resource efficiency [8]. At the same time, certification bodies and regulatory institutions may benefit from automated analysis and interpretation of sustainability-related data, improving transparency, consistency, and efficiency of construction product assessment within the CPR 2024 framework.

Despite these advantages, several limitations should be considered. The reliability of AI predictions depends on the quality, consistency, and availability of training datasets, while significant variations among Environmental Product Declarations (EPDs), life-cycle datasets, product categories, and geographical regions may affect model performance. In addition, the lack of standardized datasets for certain construction products remains a challenge for achieving high prediction accuracy and generalization capability. Nevertheless, the proposed framework demonstrates considerable potential for supporting sustainability assessment and circularity evaluation of construction products in accordance with CPR 2024 requirements.

7 Conclusion

The transition of the construction sector toward a circular economy requires the development of advanced methodological and digital tools capable of supporting assessment of environmental and circular performance of construction products. The new EU Construction Products Regulation (CPR 2024/3110) introduces significantly expanded requirements regarding transparency of information, lifecycle impact assessment, sustainability reporting, and digitalization of product data through the concept of Digital Product Passports [1, 8].

This paper presents a methodological framework for the development of an integrated AI model that combines artificial neural networks with life-cycle assessment methods (LCA), life-cycle costing analysis (LCC), and material circularity indicators (MCI). The proposed framework is intended to support development of predictive systems capable of estimating key environmental and circularity-related performance indicators of construction products based on data associated with material composition, manufacturing processes, transport characteristics, and durability parameters.

The proposed methodological framework demonstrates the potential applicability of AI technologies in supporting implementation of CPR 2024 requirements and future Digital Product Passport systems. Integration of AI-assisted analytical tools could contribute to more efficient development of sustainable construction products, optimization of material flows, improved certification procedures, and increased transparency and traceability of sustainability-related product information within the construction sector.

The research additionally contributes to the emerging field of AI-supported sustainability assessment of construction products within the regulatory context of CPR 2024 by proposing an integrated framework that links ANN predictive modelling with lifecycle and circularity indicators.

Although experimental validation is outside the scope of the present study, the proposed framework provides a technically feasible and structured basis for future implementation and testing of AI-assisted sustainability assessment systems using real-world construction product datasets.

Abstract. The construction sector has a major environmental impact due to high resource consumption, energy use, and carbon emissions. Among construction materials, concrete is a major contributor to GHG emissions. Optimizing logistics—such as increasing recycling and reuse or sourcing local materials—can significantly reduce concrete's environmental footprint and improve construction sustainability. Furthermore, transport-related emissions stem from raw material extraction and delivery, concrete mixing and distribution, and construction and demolition waste management. Life Cycle Assessment (LCA) is a key method for evaluating these impacts. This paper presents the application and results of a new calculation tool within two selected case studies that highlights the role of transport within a full LCA and includes the benefits of reusing building materials in a circular approach by reducing reliance on virgin resources and securing more circular supply chains. Using the tool, we examine the environmental and economic impacts of these different scenarios, focusing on recycled concrete versus landfill disposal. A structured calculation matrix incorporates key factors such as concrete composition, transport distances, and CO_2 emissions. By applying relevant national standards, the divergent results will be analyzed and discussed. The systematic assessment of these parameters will identify opportunities to improve environmental performance.

Keywords: Circular Economy · Recycled Concrete · Circular Indicator · Parameters for Circular Assessment · Standards

1 Introduction

The global construction sector is responsible for a substantial share of energy consumption and greenhouse gas (GHG) emissions, largely due to the extensive use of resource-intensive materials such as concrete [1].Cement production alone accounts for approximately 7–8% of global CO_2 emissions, making concrete a critical target for sustainability improvements. While significant research has focused on reducing emissions through material innovation, such as alternative binders and low-carbon cement,

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 1006–1014, 2026.
https://doi.org/10.1007/978-3-032-34930-9_117

transport-related impacts remain under-examined. These impacts arise throughout the life cycle of concrete, including raw material extraction, production, distribution, and end-of-life waste management [2]. The transition toward a circular economy in construction—emphasizing reuse, recycling, and reduced reliance on virgin materials—offers considerable opportunities to mitigate environmental impacts [3]. However, the benefits of circular strategies depend heavily on logistical factors such as transport distances and infrastructure availability [4].This study aims to evaluate the environmental and economic implications of transport within a full LCA framework according to CEN Standard EN 15978 [5]. A dedicated calculation tool has been developed within the framework of the COST Action CA21103CircularBand applied to two case studies to assess different scenarios, with a particular focus on recycled concrete versus landfill disposal.

2 Methodology

2.1 Calculation Tool

A calculation tool was developed to evaluate environmental impacts across different scenarios. Transport is explicitly modeled across all stages using distance-based emission factors. The tool incorporates a structured matrix including:

- Material composition (cement, aggregates, recycled content)
- Transport distances and logistics chains
- CO_2 emission factors (kg CO_2 per ton-kilometer)
- Energy consumption
- Cost parameters (transport, processing, disposal fees)

The tool enables scenario comparison and sensitivity analysis.

2.2 System Description

The analysis encompasses all relevant life cycle stages, namely: (i) the product stage, (ii) the use stage, and (iii) the end-of-life stage. In addition, potential benefits and loads beyond the system boundary are considered within the framework (Fig. 1)

The product stage includes material production processes, comprising raw material extraction (A1), transport to manufacturing facilities (A2), and the production of construction products (A3). The construction process stage accounts for the transportation of materials to the construction site (A4) and the environmental impacts associated with installation activities (A5), including energy use and emissions.

As this study focuses on specific building components—particularly concrete—rather than a complete building system, a simplified approach is adopted that considers only embodied emissions and energy. Operational energy and water use (B6 and B7) are excluded. Furthermore, differences in material service life relative to the overall building lifespan are not explicitly modeled; therefore, replacement and refurbishment processes (B4 and B5) are not included.

The end-of-life stage comprises deconstruction processes (C1), transport of materials to waste processing facilities (C2), waste treatment operations (C3), and final disposal

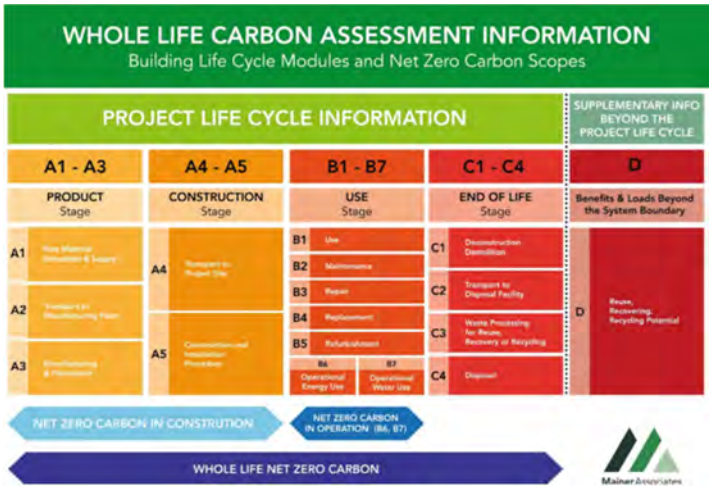

Fig. 1. Model of the life cycle of buildings and components based on EN 15978-1

(C4). Beyond the system boundary, Module D accounts for potential net environmental benefits associated with reuse and recycling.

Given that the primary objective of this study is to evaluate the influence of transportation distances on the environmental performance of conventional and recycled concrete, the analysis focuses on modules with variable parameters. Modules A3 to C1 are treated as constant baseline values across the compared scenarios. The assessment therefore emphasizes processes related to concrete production, transport from varying source locations, recycling operations, and associated logistics. Additionally, the reduction in demand for virgin concrete is incorporated into the calculation model as an environmental credit.

2.3 Case Studies

To demonstrate the application of this life cycle assessment approach, two representative case studies are analyzed (Fig. 2). These compare a conventional linear concrete production model (Scenario A) with a circular alternative incorporating recycled aggregates (Scenario B).

Case Study A (Linear Scenario): Conventional concrete production with landfill disposal of construction and demolition waste (CDW). Scenario A represents the life cycle assessment (LCA) of conventional concrete, reflecting current standard practice. It assumes the production of concrete exclusively from virgin materials and its disposal in a landfill at the end of its service life. This scenario follows a linear life cycle model, without the incorporation of circularity principles such as reuse or recycling.

Case Study B (Circular Scenario): Use of recycled aggregates and closed material loops.

Scenario B represents an alternative LCA approach incorporating circular economy principles. In this scenario, concrete contains a defined proportion of recycled aggregates and is further processed at the end of its life cycle to produce new recycled concrete.

Compared to Scenario A, Scenario B includes additional transportation processes (A2), specifically for the delivery of recycled materials from recycling facilities to concrete production plants, alongside the transport of primary raw materials.

The end-of-life stage also differs substantially. Instead of landfill disposal, this scenario includes transport to recycling facilities, material recovery processes, and subsequent reuse. These processes correspond to modules C2 and C3, as well as Module D, which accounts for benefits beyond the system boundary through avoided impacts associated with the substitution of virgin materials.

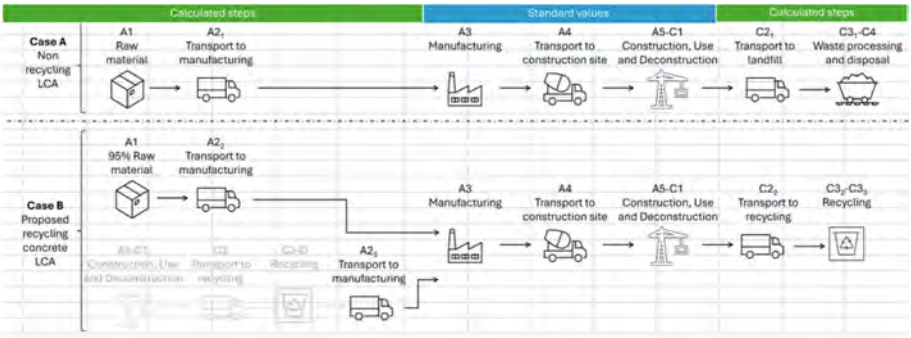

Fig. 2. Manufacturing process for two scenarios based on LCA modules: (A) traditional concrete production and (B) concrete production with recycled aggregate

In a realistic case study, transportation distances were implemented into the matrix according to the following table (Table 1):

Table 1: Actual distance used in the calculation.

Distances	Km	Relation to case
Raw material -cement- to concrete production site	11	A2–1 (case A) and A2–2 (case B)
Raw material -gravel- to concrete production site	24.5	A2–1 (case A) and A2–2 (case B)
Raw material -sand- to concrete production site	24.5	A2–1 (case A) and A2–2 (case B)
Recycling center to concrete production	5	A2–3 (case B)
Concrete production to construction site	11.2	A4 (both cases)
Construction site to landfill	35.4	C2–1 (case A)
Construction site to recycling center	11	C2–2 (case B)

The ratio used in the example is cases study A (100% virgin concrete) versus cases study B (95% virgin concrete and 5% recycled concrete aggregates)

2.4 Assumptions and Parameters

Key variables include:

- Transport distances
- Mixture of the concrete
- Transport mode (primarily truck-based)
- National standards governing recycled material use

These parameters were selected to reflect realistic construction practices and regulatory frameworks.

The life cycle inventory is based on datasets from the Ecoinvent v3.7. Impact categories are defined in accordance with the EN 15804.A functional unit of 1 m^3 of concrete with a compressive strength of 25 MPa is adopted. The concrete mix design follows standard industry practice and consists of: 1 part cement (Portland cement CEM II/A-S 32.5), 2 parts sand (30.77%), 3 parts gravel (46.15%), and 0.5 parts water (7.69%).

Taking into consideration recent research findings [6], the amount of additional cement for recycled concrete is feed into the calculation with the factor of 8% of additional cement in the mixture (Table 2).

Table 2. Composition of concrete (prime) and with the use of recycled aggregates.

Composition of concrete	Prime	Recycled aggregates
Overall	2350 kg/1 m^3	2350 kg/1 m^3
Prime raw material	2065 kg/1 m^3	1440 kg/1 m^3
Secondary raw material	– kg/1 m^3	600 kg/1 m^3
Cement	285 kg/1 m^3	310 kg/1 m^3

Energy consumption associated with the recycling of aggregates is incorporated using datasets for waste concrete treatment and sorting processes available in the Ecoinvent database. For the transportation analysis, freight transport is modeled using a 16–32 metric ton lorry (EURO 4 standard), as specified in the database. A CO_2 neutral transport mode would neutralize the negative effect of transport distance.

2.5 Methodology Used for Calculation

To quantitatively evaluate the environmental impacts of both scenarios, Global Warming Potential (GWP) is calculated for each life cycle stage. The assessment distinguishes between the linear system (Scenario A) and the circular system (Scenario B), capturing

the contributions of production, transportation, end-of-life processing, and potential benefits beyond the system boundary.

$$GWP_{case\ A} = A1 + A2_1 + C2_1 + C3_1 + C4 \tag{1}$$

$$GWP_{case\ B} = A1 * P_{recycled} + A2_2 + A2_3 + C2_2 + C3_2 + C3_3 \tag{2}$$

$$A1 = \sum_{1}^{M} M_{material} * GWP_{material} \tag{3}$$

$$M_{material} = \frac{P_{material}}{100} * 1000 * M_{concrete} \tag{4}$$

$$A2_1 = \sum_{1}^{M} \frac{M_{material}}{1000} * GWP_{transport} * D_{material} \tag{5}$$

Recycled Con.	5							

3.2 Environmental Performance

The analysis shows that transport contributes significantly to total lifecycle emissions. Key findings include:

- Transport distance is an influential factor influencing environmental impact
- Local sourcing and recycling significantly lower emissions
- Recycling efficiency and material quality influence environmental outcomes
- The vehicle-type related impact is relevant for the calculation

3.3 Waste Deposit and Distance as a Factor for Reuse, Including a Calculation

The use of non-recycled concrete, following the specified proportions and based on data from the Ecoinvent database, results in a GWP of 161.97 kgCO_2 eq per tonne of concrete, excluding the transportation phase. The use of 90% of non-recycled concrete and 10% of recycled concrete results in a GWP of 161.79 kgCO_2 eq per tonne of concrete, excluding the transportation phase. So initially, the gain without considering the distance is in fact 0.18 kg CO_2 eq per tonne of concrete.

When considering total GHG emissions, emissions increase by 0.001% or 0.01 kg CO_2 eq. for each additional kilometer across all categories (A2 and C2). An increase of 10 km leads to a 0.01% rise in GHG emissions from the concrete. If the additional distance to the recycling center reaches **11.30 km**, emissions increase, reaching 0.18 kg CO_2 eq per tonne of concrete, and the gain from using recycled concrete becomes neutralized. This means that this is the tipping point, when gains turn into losses. Regarding recycled concrete, when distance is not considered, the incorporation of 1% recycled material into the mix results in a reduction of GHG emissions by 0.011%, avoiding the release of 0.018 kg CO_2 eq per tonne of concrete. Consequently, with standard values accepted under European regulations ranging between 5% and 10% recycled content, savings of between 0.05% and 0.11% can be achieved, representing significant reductions in the environmental impact of concrete.

When transportation distances are considered, assuming equal distances, emission reductions remain largely unaffected. However, distance becomes a critical factor if the recycling facility is far enough away to negate the emission savings achieved.

If the calculation reduces the amount of additional cement for recycled concrete with the factor of 0% instead of 8% of additional cement in the mixture, then the tipping point would be at **77.18 km** of additional distance to the recycling center.

4 Discussion

The results emphasize the critical role of transport in the sustainability of concrete production and also the importance of improved concrete mixtures when using recycled aggregates [7]. While material innovations remain important, optimizing logistics can also provide substantial additional reductions in emissions.

Circular economy strategies, particularly the reuse of concrete materials, demonstrate clear environmental and economic benefits. However, these benefits are highly context-dependent and rely on local infrastructure and regulatory conditions.

The study also highlights the importance of national standards, which can either enable or constrain the use of recycled materials. Greater harmonization of standards could facilitate broader adoption of circular practices.

Limitations of this study include the use of generalized emission factors. The strength of the calculation matrix is that it uses case-sensitive data to get a quantitative answer on the exact savings or evenlosses overall in respect to its global warming potential.

The newly developed tool enables a precise assessment of the transportation stage by accounting for both associated gains and losses. In contrast to existing calculation methods, which typically estimate CO_2 emissions solely on the basis of transport distances, this tool facilitates a comprehensive evaluation aligned with the environmental performance assessment framework for buildings as defined in the EN 15978. Consequently, it supports the quantification of environmental impacts and benefits beyond the system boundary. This tool is in fact able to calculate potential net benefits from reuse or recycling in module D of the framework. (D).

This capability represents a significant advancement, effectively transforming the traditionally linear Life Cycle Assessment (LCA) encompassing pre-construction, construction, use, and end-of-life stages into a genuinely circular assessment process. Moreover, this tool is using real-world logistics data to replace assumed transport distances to get an exact assessment on a case-by-case approach.

5 Conclusion

This study demonstrates that transport is a key factor in the environmental and economic performance of concrete within a life cycle framework together with the concrete mixtures when using recycled aggregates. The application of a dedicated calculation tool reveals that the transport distance of all involved sites (not only the building site) strongly influences emissions, and circular supply chains and local sourcing are essential for reducing environmental impact.

Integrating transport considerations into LCA tools can support more informed decision-making and promote sustainable construction practices.

LCA and LCEA of an Industrial Building: A Volvo Case Study

Giovanna Ferreira Alves(✉), Milena Franco Fagundes, and Sergio Fernando Tavares

Civil Engineering Post-Graduate Program (PPGEC), Federal University of Parana, Centro Politécnico, Curitiba 81531-980, PR, Brazil
giovannaferreira@ufpr.br

Abstract. The pursuit of more sustainable buildings has gained prominence in the industrial sector, where energy demand tends to be high from the early stages of the project through the operational phase. Thus, reduction of embodied energy represents a strategic drive for reducing environmental impacts and optimizing the use of natural resources. In this study, Life Cycle Assessment (LCA) and Life Cycle Energy Analysis (LCEA) are applied to an industrial building of Volvo in Brazil to (i) assess embodied energy demand at the first life-cycle stage, (ii) identify impact hotspots at this stage, and (iii) propose reduction strategies based on the results. The methodology adopted in this study follows the guidelines established by the international standards ISO 14040 and ISO 14044, which address LCA, as well as the European standards EN 15804 and EN 15978, which are specific to the environmental assessment of buildings. A BIM model was used to extract materials inventory and EPDs were used in analysis for reduction strategies. The results show that steel and concrete are the most impactful materials, and there are few reduction strategies available, since Brazil is a country where only a small number of companies evaluate the environmental impact of their products compared with other countries. However, the interpretation of these impacts, in turn, can support indicators such as carbon footprints, which are required for the issuance of carbon credits.

Keywords: Life Cycle Assessment · Life Cycle Energy Analysis · BIM · EPD

1 Introduction

The search for more sustainable buildings has gained prominence in the industrial sector, where energy demand tends to be high from the initial phases of the project through to operation. In this context, reduction of embodied energy represents a strategic vector for reducing environmental impacts and optimizing the use of natural resources.

The Life Cycle Energy Analysis (LCEA) is a methodological approach that allows quantifying embodied energy demand throughout all phases of the building, from raw material extraction and input manufacturing to the usage phase and end of life (Cabeza, 2014). This approach allows for the identification of the main embodied impact hotspots

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 1015–1023, 2026.
https://doi.org/10.1007/978-3-032-34930-9_118

and supports the proposal of more efficient technical and operational solutions. An LCEA does not fully replace an LCA, but it is useful for more detailed analyses of the energy input variables throughout the lifecycle (Tavares et al., 2006). Thus, based on these analyses, significant environmental impacts such as CO_2 emissions, either full or equivalent, can be identified (Fay et al., 2000). The interpretation of these impacts, in turn, can underpin indices such as carbon footprints, which are requirements for issuing carbon credits.

Thus, in this study, LCEA is applied to the Warehouse P220 project, an industrial building of Volvo do Brasil Veículos S.A., located in the city of Curitiba, Paraná, Brazil. The objective is to assess embodied energy demand in the early stages of the life cycle, identify impact hotspots, and propose reduction strategies based on the results obtained. The scope of the analysis covers the pre-operational phase of the building's life cycle, stages A1 to A3, in accordance with the European Union standard EN15978: Environmental performance assessment of buildings. Operational energy use and operational energy efficiency were not assessed in this study. The functional units adopted are embodied energy demand, expressed in megajoules per square meter (MJ/m^2), and carbon dioxide emissions per square meter (kg CO_2/m^2).

2 Methodology

The methodology adopted in this study is divided into three stages. The first stage involves calculating the environmental impacts of the building analyzed using the calculation method proposed in Tavares's thesis (2006), complemented by the methodological update in the article by Tavares and Bragança (2016). Additionally, environmental inventory data from recognized sources were used, such as the Environmental Product Declarations (EPDs) from national and international suppliers, including Votorantim Cimentos, ArcelorMittal, Bauforumstahl, and ATIC (Technical Association of the Cement Industry) of Portugal. The calculations follow the guidelines established by the international standards ISO 14040 and ISO 14044, which address LCA, as well as the European standards EN 15804 and EN 15978, which are specific to the environmental assessment of buildings.

The LCEA structure presented here considers the initial stages of the building's life cycle: extraction and production of materials, including the embedded energy in raw material extraction, manufacturing, and industrial processing processes. These steps are described in the EN 15978 standard as A1, A2, and A3.

The evaluated metrics include embodied primary energy (MJ) and carbon dioxide emissions (kg CO_2). These indicators characterize the embodied environmental impacts associated with material production and processing in the early life-cycle stages.

The second stage of the methodology involves identifying impact hotspots, which are the processes and materials that concentrate the greatest impact throughout the building's lifecycle. Finally, the third and last stage of the methodology compared and analyzed the impact hotspots materials with market-available materials in search of better sustainability performance. The materials analysed in this section are concrete, steel, and cement. The cement was examined to determine if any type of cement offers better sustainability performance for use in concrete.

The building description is presented in Sect. 2.1. The impact calculation results are available in Sects. 3.1 and 3.2 of the Results section. The impact hotspots assessment is described in Sect. 3.3, and the comparative analyses are presented in Sect. 3.4. Sections 4 and 5 are Discussion and Conclusions, respectively.

2.1 Industrial Building Description

The building studied is the industrial warehouse named Warehouse P220, belonging to Volvo do Brasil Veículos S.A., located in Curitiba, Paraná, Brazil. The project has a constructed area of 4.431,46 m^2 and adopts a conventional construction system for industrial buildings. The foundation consists of a continuous flight auger pile, foundation blocks, and a concrete floor/slab. The vertical enclosures use concrete blocks with a metal-sheet finish, and the roof is formed by double-faced metal sheets with rock wool thermal insulation.

Figure 1 shows the 3D visualization of the building's BIM model. The project was provided by the company responsible for the project from design through renovation and construction.

Fig. 1. 3D visualization.

The inventory for this project was compiled by extracting quantities from the BIM model and gathering data from the structural projects in .dwg format. The BIM model provided architectural design information alongside quantity tables for all materials. For the structural projects (reinforced concrete and steel structures), the .dwg file was supplied. Consequently, it was necessary to review all drawings and conduct a quantitative survey of the materials related to this discipline.

3 Results

3.1 Embodied Energy

Table 1 presents the materials used in the construction, their respective total embodied energy (EE) values, and the specific value per square meter of built area. The estimated total embodied energy of the building is 11.879.886,19 MJ, corresponding to 2.680,80 MJ/m^2. A36 steel is the material with the highest embodied energy, totaling 4.993.292,27 MJ, followed by concrete with a compressive strength of 30 MPa, with 3.565.751,94 MJ.

Table 1. Embodied energy values of materials (MJ).

Material	EE Total (MJ/m^2)	Percentage (%)	Cumulative Percentage (%)
Concrete fck = 30Mpa	3565751,94	30.02	30.02
Concrete fck = 40Mpa	409283,88	3.45	33.47
CA-25 Steel	271547,64	2.29	35.76
CA-50 Steel	1520531,91	12.80	48.56
A36	4993292,27	42.03	90.59
Concrete block 19 cm × 19 cm × 39 cm	90750,31	0.76	91.35
Ceramic tile cladding	6112,14	0.05	91.40
Paints	42401,18	0.36	91.76
Wooden doors	624,32	0.01	91.77
Gypsum board 70 cm × 70 cm	24541,30	0.21	91.98
Steel sandwich panel. Galvalume RAL9003, sheet thickness 0.43 mm	436515,52	3.67	95.65
Steel roof sheet TP25, pre-painted on both sides, thickness 0.5 mm	261657,88	2.20	97.85
Rock wool 50 mm	99643,33	0.84	98.69
Guardrail and handrail	2009,44	0.02	98.71
Mortar	141171,13	1.19	99.90
Steel and iron	14052,00	0.12	100.00
Total	**11879886,19**		
Total per m^2	**2.680,8**		

Regarding the percentage distribution of embedded energy among the ten main materials, A36 steel accounts for 42.03%, followed by concrete with a compressive strength of 30.02 MPa at 30%, CA-50 steel at 12.80%, and steel sandwich roofing panels at 3.67%. These four materials together make up 88% of the building's total embedded energy.

Embodied energy, based on the materials' life-cycle stages, can be divided into production, transportation, and waste losses. It is observed that the production, exploration, and transportation of inputs (Stage 1) account for approximately 88% of the total embodied energy, underscoring their significance for the project's energy impact.

3.2 Embodied CO_2

Regarding greenhouse gas emissions, Table 2 presents the values of carbon dioxide (kg CO_2) embedded in each material. The results follow a similar trend to the embedded energy, with concrete and steel being the main emitters.

Table 2. Embodied CO_2 results for construction materials

Material	Totals (kg CO_2)	Percentage (%)	Cumulative Percentage (%)
Concrete fck = 30Mpa	328499,15	41.09	41.09
Concrete fck = 40Mpa	39234,49	4.91	46.00
CA-25 Steel	3611,79	0.45	46.45
CA-50 Steel	23780,68	2.97	49.42
A36	381017,90	47.66	97.08
Concrete block 19 cm × 19 cm × 39 cm	3639,99	0.46	97.54
Ceramic tile cladding	314,01	0.04	97.58
Paints	3122,00	0.39	97.97
Wooden doors	22,30	0.00	97.97
Gypsum board 70 cm × 70 cm	1374,55	0.17	98.14
Steel sandwich panel. Galvalume RAL9003, sheet thickness 0.43 mm	7900,93	0.99	99.13
Steel roof sheet TP25, pre-painted on both sides, thickness 0.5 mm	3884,49	0.49	99.62
Rock wool 50 mm	200,57	0.03	99.64
Guardrail and handrail	36,37	0.00	99.65
Mortar	2555,20	0.32	99.97
Steel and iron	254,34	0.03	100.00
Total	**799448,76**	**100.00**	
Total per m^2	**180,40**		

A36 steel appears as the main emitter (47.66%), followed by concrete with fck = 30 MPa (41.09%), concrete with fck = 40 MPa (4.91%), and CA-50 steel (2.97%). Together, these four materials account for more than 96% of the embedded CO_2.

3.3 Impact Hotspots

The analysis of embedded energy and CO_2 emissions data helps identify hotspots, which are the processes and materials with the greatest impacts throughout the building's life

cycle. The results show that the main critical points are related to the industrial production of concrete (fck = 30 MPa and fck = 40 MPa), A36 steel, and CA-50 steel, which together account for more than 88% of the total embedded energy and over 96% of CO_2 emissions.

These materials exhibit high energy intensity during their manufacturing stages, involving processes such as burning, thermal transformations, transportation of inputs, and fossil fuel use. Additionally, their high mass and volume within the structure's composition reinforce their weight in the overall life-cycle impact. The production stage—especially cement, aggregates, and rolled steel—is the largest contributor to the project's total energy load, accounting for approximately 88% of the embedded energy, as shown in Table 1.

3.4 Comparative Analysis of Kg CO_2 for Impact Hotspots

The kg CO_2 data for the most impactful materials were collected from their respective EPDs. For CA-50 steel, the EPD published by ArcelorMittal was used. For A36 steel, the EPD published by Bauforumstahl was used. For concrete, EPDs published by Votorantim Cimentos were used. And for cements, EPDs published by Votorantim Cimentos and ATIC were used.

The comparison between the materials was made using the inventory extracted from the project. Thus, the mass (for steels) and the volume (for concrete) remained constant across the comparison scenarios. The values obtained are in kg CO_2 equivalent.

A36 steel is the material with the greatest environmental impact in the project, responsible for more than 40% of the embedded CO_2 emissions. Therefore, it is recommended to reevaluate the use of this material as outlined in the project. As a more sustainable alternative, adopting ArcelorMittal's XCarb steel is recommended, as its production has significantly lower embedded CO_2 emissions. This is due to the use of recycled scraps and the process's exclusive use of renewable energy.

Replacing CA-50 steel with ArcelorMittal's XCarb steel lowers embedded CO_2 by about 25%. For the A36 steel used in the metal structure, the reduction is even greater, exceeding 85%, due to its larger mass in the building.

Among potential scenarios to enhance the environmental performance of concretes, the SPECTRA 40 concrete from Votorantim Cimentos in São Paulo stands out as a promising option. This concrete uses a single mix design throughout the structure, simplifying the pouring process and reducing on-site concrete and steel consumption (VOTORANTIM CIMENTOS, 2025).

The SPECTRA 40 concrete from São Paulo showed better sustainability results than the fck = 40 MPa concrete, reducing CO_2 emissions by more than 5,000 kg, equivalent to a 13% decrease.

Finally, a comparative analysis between cements CP II, CP III, and CP IV was conducted. The analysis evaluates the cement content in 1 m^3 of concrete with a compressive strength of 30 MPa. Thus, for concrete with fck = 30 MPa, 265 kg of CP II, 300 kg of CP III, and 300 kg of CP IV were used. The values for CP II and CP IV were provided, and the authors adopted the value for CP III.

To develop the cement analysis, the EPDs provided by Votorantim Cimentos and ATIC Portugal were used. The Portuguese EPD was used for CP IV because there is no published EPD with a Brazilian scope for this cement.

Among the evaluated cements, CP III shows the best sustainability performance, with values 40% lower than CP II and 49% lower than CP IV.

4 Discussion

The EPD used for the concrete is from Votorantim Cimentos, while the EPDs for steel are from ArcelorMittal and Bauforumstahl. Votorantim Cimentos is the only company to have published an EPD for this material with a scope in Brazil, just as ArcelorMittal is the only company to have an EPD for steel with a partial scope in Brazil. The Bauforumstahl EPD was used as a reference for A36 steel despite the European scope, because there is no published EPD for this material with a Brazilian scope. The ArcelorMittal EPD for XCarb steel was used as a reference, despite its scope being limited to Luxembourg and Spain. Additionally, the geographic scope of ArcelorMittal's steel EPD must be considered. This EPD presents the environmental impact of the material in the pre-operational phase (A1-A3) in Morocco, while the end-of-life phases (C-D) have a global scope. Therefore, the document is not fully applicable in Brazil.

The results show that, for steels, the best alternative is ArcelorMittal's XCarb product. This material has its entire production process carried out using renewable energy and uses recycled raw materials.

Regarding concrete with fck = 40 MPa, it is recommended to use SPECTRA 40 concrete from Votorantim Cimentos in São Paulo, as it offers better sustainability performance. Spectra is a type of concrete with a single mix design, developed to meet all stages of structural construction, thereby simplifying and making the pouring process more efficient. Its versatility contributes to the longevity of the concrete structure and allows for reduced use of materials such as concrete and steel. As an additional benefit, using Spectra can result in 3% to 4% savings on the total cost of the structure.

The assessment of the cements aimed to compare the sustainability performances per cubic meter of concrete with a compressive strength of 30 MPa. The results show that CP III performs best compared to CP II and CP IV. To achieve this result, a CP III content of 300 kg per cubic meter of concrete was established. This value was adopted by the authors. It is recommended to validate this number with a specialist to confirm the results.

Furthermore, the assessment of the presented cements is insufficient to draw a comprehensive conclusion about sustainability because the other materials that make up the concrete must also be evaluated, including aggregates and possible additives.

The results and suggested alternatives are related to the sustainability performance of the materials. However, substituting these materials involves other analyses from different specialities, as structural analysis. It is recommended to have a structural expert in reinforced concrete and metal structures evaluate the substitution of these materials. Additionally, if the substitution increases the quantities of these materials, a future sustainability analysis should be conducted.

5 Conclusions

In the developed study, the embodied primary energy demand (MJ) and embodied CO_2 emissions (kg CO_2) associated with building materials were evaluated.

The results show that the most impactful materials are A36 and CA-50 steels, and concretes with fck = 40 MPa and fck = 30 MPa, as they have the highest EE and the most embedded CO_2, due to their high-energy production processes and their significant contribution to the project in mass and volume.

The continuation of this study aims to develop an LCA for the building's use, operation, and end-of-life phases. The analyses of the use and operation phases involve energy-efficiency studies that evaluate energy generation and systems such as lighting, air conditioning, and machinery. The end-of-life phases involve circular-economy studies, including the optimisation of waste utilisation and opportunities for recycling and material recovery, using digital documentation such as Material Passports.

Abstract. Green roofs and green façades are widely recognized as effective Nature-based Solutions (NbS), offering opportunities to advance sustainable construction practices. However, these systems often involve technologically complex multilayer assemblies and require high maintenance. This study focuses on an innovative modular clay tile designed to accommodate a low-thickness substrate layer for plant growth, providing a lightweight and easily installable solution. Since this system represents a novel approach compared with conventional NbS technologies, its environmental implications remain unexplored. Therefore, a methodological life-cycle framework was developed to support the environmental evaluation of these hybrid systems that operate across regulatory and functional boundaries between clay construction products and vegetative components. The defined system boundaries include both tile manufacturing and use-stage processes associated with the vegetated system. The implementation of a pilot production line with detailed flow accounting allows the collection of foreground data on the tile manufacturing process. These data are integrated with laboratory experiments on the performance of substrate and vegetation layers to estimate, under controlled environmental conditions, CO_2 storage processes relevant to the overall life cycle environmental profile. The incorporation of these empirical datasets strengthens the evaluation of early-stage product innovation, including GHG sequestration capacity with each m^2 of surface capable to store between 5.5–8.6 kg of CO_2. In addition, the study highlights the importance of modelling irrigation and maintenance scenarios, which represent key drivers of environmental performance, and will be further investigated in future experimental monitoring. The findings offer insights into opportunities for integrating modular NbS into sustainable built environments.

1 Introduction

Environmental damage resulting from construction activities has historically not been fully considered in development decisions, influencing urban policies and planning practices [1]. The increasing and uncontrolled expansion of built and paved areas has globally led to the gradual loss of green spaces in cities [2].

Nowadays, due to risen environmental awareness, various incentive programmes promote Nature-based Solution (NbS) as an alternative solution to traditional grey infrastructures, aimed at regenerating the functionality of natural ecosystems [3]. In particular, NbS applied at the building scale, such as green roofs and green facades, offer multiple benefits, including their contribution to the regulation of rainwater runoff, mitigating the effect of UHI, improving biodiversity, air quality and city aesthetics [4–6]. In addition, they promote the sequestration of atmospheric CO_2 through plant photosynthesis, which captures carbon dioxide from the air and stores it as biomass [7, 8].

Despite many advantages, their adoption remains limited. This is largely due to complex maintenance requirements [9], and the technological complexity and material requirements associated with these systems [10]. To overcome these challenges, an innovative NbS named CAPT-TILE [11] has been developed as an alternative to conventional green roof and green façade systems. The CAPT-TILE system is a modular terracotta tile that enables vegetation growth on building surfaces, including horizontal, pitched, and vertical configurations. This paper proposes a methodological life-cycle framework to support the environmental evaluation of these hybrid systems that operate across regulatory and functional boundaries between clay construction products and vegetative components. Through the real case study application of CAPT-TILE production at the Industrie Cotto Possagno facility in Possagno (Italy), the framework focuses on the definition of system boundaries and life-cycle inventory development. In particular, the study quantifies the GHG sequestration potential associated with vegetation growth and highlights the importance of modelling irrigation and maintenance scenarios during the use stage. In doing so, the study establishes the methodological basis for a future full evaluation of the life-cycle environmental performance of the CAPT-TILE system.

2 The CAPT-TILE System

The CAPT-TILE system, shown in Fig. 1, consists of modular prefabricated terracotta tiles (463 mm × 293 mm) with a total depth of 40 mm, including a 30 mm zeolite-based substrate layer glued to the internal tile surface, and pre-cultivated vegetation on top. Vegetation grows on a thin soil layer with an approximal 10 mm thickness integrated with the zeolite substrate. Since CAPT-TILE green roof and façade systems are intended for commercialization in different climatic contexts across Europe, plant selection is limited to species capable of growing on shallow substrates and therefore varies according to climate conditions. For warmer climates, the CAPT-TILE configuration comprises drought-resistant succulent species (i.e., *Sedum*), whereas for colder climates leguminous species (i.e., *Trifolium repens*) is used. In addition, grasses belonging to the Poaceae family may also be adopted, both as macrothermal (i.e. *Cynodon dactylon L. Pers*) or microthermal (i.e., *Lolium perenne L., Poa Pratensis*) species.

Fig. 1. The single CAPT-TILE tile configuration

The resulting modular tile system can easily replace conventional roofing elements, while enabling vegetation growth on building surfaces.

3 Life Cycle of the CAPT-TILE

In accordance with EN 15804:2012 + A2:2019 [12], the assessment of the life cycle follows the principle of modularity. Under this principle, all processes that influence the environmental profile of the product throughout its life cycle can be assigned to the specific life-cycle module in which they occur. The entire life cycle of a CAPT-TILE is shown in Fig. 2, and it consists of product, construction, use, and end-of-life stages.

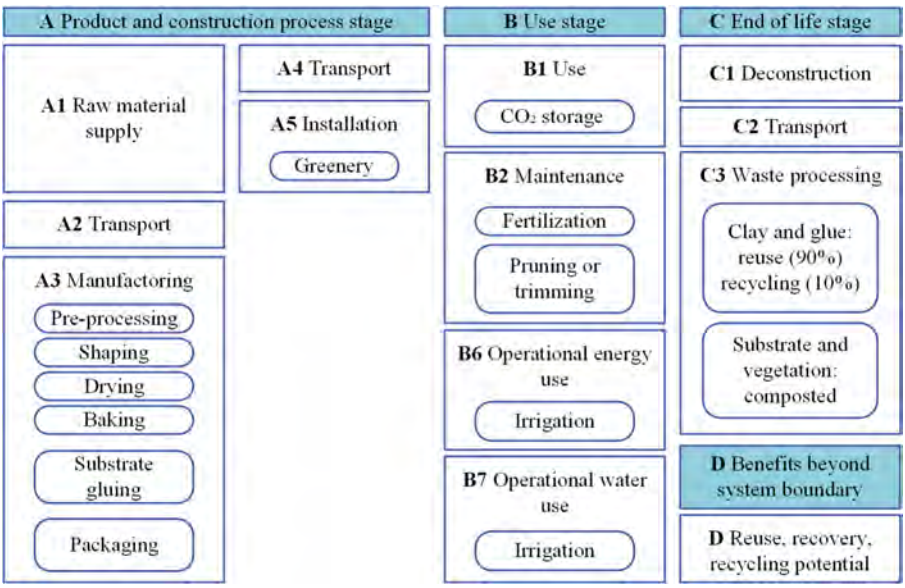

Fig. 2. Life-cycle of the CAPT-TILE

3.1 Product and Construction Process Stage

The product stage includes the processes related to the production of the CAPT-TILE system, from raw material extraction to the manufacturing of the clay tile with the glued zeolite substrate. Module A1 includes the extraction and processing of raw materials required for production. Raw materials used for the manufacture of the CAPT-TILE terracotta tile are clay, water, and mineral additives (i.e., basalt, porphyry limii, barium carbonate). In addition, hydrated lime is used as auxiliary material in the production process. The transport of raw materials and additives to the manufacturing plant (Module A2) is carried out by road using trucks, assuming empty return trips, while handling within the plant is primarily performed using a diesel-powered wheel loader according to the information provided by the manufacturer.

The CAPT-TILE production process can be divided into three stages: terracotta tile manufacturing (see Fig. 3a–d), bonding of the zeolite-based substrate to the tile (see Fig. 3e), and vegetation establishment on the substrate (see Fig. 3f).

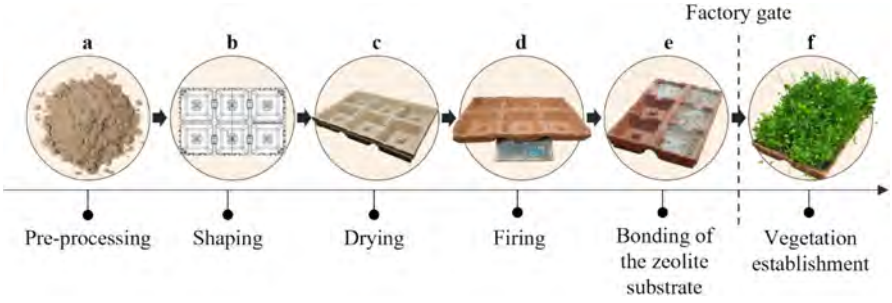

Fig. 3. The CAPT-TILE production process

Primary data concerning the manufacture of the terracotta tile (Module A3), have been directly collected from Industrie Cotto Possagno pilot plant, including the number of raw materials, the machineries, emissions, waste and packaging. The manufacturing plant is powered by electricity (35% from renewable energy sources) and methane supplied from the public energy grid.

The manufacturing process begins with the pre-processing of raw materials. Clay extracted from the quarry is first crushed and mixed with water and specific additives, such as barium carbonate and basalt, to obtain a homogeneous mixture suitable for shaping. In the shaping stage, the mixture of clay paste is pressed into the desired tile geometry. The shaped elements subsequently go through the drying stage, during which the water content is gradually reduced to avoid structural damage during the firing process. During these stages, internal material recovery is implemented: green and dry scraps, generated respectively during pre-processing and drying phase, are collected and reintroduced into the process. Then, the thermal treatment during the firing stage transforms the CAPT-TILE clay body into a durable terracotta product.

At the end of the pilot production line, there are additional machines dedicated to the application of glue (i.e., polyalphaolefin hot-melt adhesive) and zeolite-based substrate layer (i.e., micronized chabazite zeolite of Italian origin). The full formulation

data for these components are not accessible from the suppliers due to confidentiality, thus representative secondary data from recognized databases are used, ensuring technological and geographical representativeness. Instead, the installation of these dedicated machines inside the pilot plant enables detailed accounting of the associated energy consumption for the application and bonding of the zeolite-based substrate layer.

The final vegetative layer of the CAPT-TILE system is installed during the construction stage (Module A5). Vegetated turf rolls grown on commercial soil were supplied by specialized nurseries. During installation, the turf rolls are cut and shaped to match the dimensions of the CAPT-TILE modules and placed over the thin substrate layer integrated into the tile. This process is performed manually and does not require mechanical equipment or additional energy consumption. Data related to the cultivation and harvesting of vegetated turf rolls are obtained from databases, such as Agri-footprint and Ecoinvent, as these processes are considered background processes and do not constitute foreground data within the system boundary.

The CAPT-TILE elements with the glued zeolite-based substrate produced at the manufacturing plant, together with the vegetated turf supplied by the nursery, must be transported to the construction site. Consequently, a specific transport scenario is defined to support the calculation of impacts associated with Module A4. Thus, a reference transport distance of 100 km by road is assumed, using trucks with a payload capacity of 30 tons.

3.2 Use Stage

Conventional clay tiles do not require repair, replacement, refurbishment, or operational energy use during their service life, so Modules B1-B7 can be neglected. This assumption is aligned with the TBE PCR for clay construction products [13] and with common practice in LCA in the ceramic tile industry [14]. However, CAPT-TILEs differ from standard clay products because the system integrates a vegetative layer supported by a thin substrate. The biological components introduce additional processes that fall under specific EN 15804 use-stage modules. Since the use of CAPT-TILE installed on building surfaces is comparable to that of green roofs and green façades, the same processes are considered for the use stage assessment. According to previous LCA studies on these systems, the use phase may include pruning or trimming, irrigation and fertilization activities, and carbon sequestration through vegetation growth [15, 16]. Therefore, the boundaries of the CAPT-TILE system encompass the phases of use (Module B1), maintenance (Module B2), and operational energy and water use (Module B6–7), as reported in the following sections.

CO_2 Capture

The use stage of the CAPT-TILE (Module B1) includes the potential sequestration of atmospheric CO_2 associated with vegetation growth biological processes. To quantify this contribution, the organic carbon content of plant biomass from different CAPT-TILE configurations was experimentally determined under controlled laboratory conditions using the Modified Mebius method [17, 18]. The resulting organic carbon content was multiplied by the initial dry mass of each sample and converted to CO_2 equivalents. As reported in Table 1, the values were normalized to 1 m^2 to estimate the CO_2 storage

capacity [kg CO_2 m^{-2}] associated with the different vegetation–substrate configuration of the CAPT-TILE system.

Table 1. CO_2 storage capacity [kg CO_2 m^{-2}] after laboratory growth, for different CAPT-TILE vegetation configurations.

Vegetation–substrate configuration	CO_2 stored [kg CO_2 m^{-2}]
Mixture of C4 and C3 grass species (Cynodon dactylon, Poa pratensis, Lolium perenne) on commercial soil	5.9
Trifolium repens and Lolium perenne on peat	8.6
Lolium perenne on peat	7.0
Trifolium repens on hydromulch	5.8
Sedum mixture on commercial soil	5.5

Maintenance and Operational Energy and Water Use

Due to the presence of vegetation, the CAPT-TILE system requires periodic maintenance to ensure proper performance. Module B2 includes fertilization activities, based on typical horticultural practices for extensive green systems, while pruning or trimming are considered negligible since operations are manual. In addition, Module B7 includes the water consumption associated with irrigation of the vegetative layer. However, irrigation and fertilization processes are not always explicitly modelled in previous green roofs LCA studies [15]. Therefore, two alternative scenarios (i.e., no-irrigation and irrigation scenario) are considered for the CAPT-TILE system, reflecting the irrigation frequency and seasonal variability to be monitored during a four-year experimental campaign on mock-ups installed under two different climatic conditions foreseen by the project [11]. The irrigation scenario will be defined according to plant water demand through sensors installed for two vegetated applications characterized by different soil moisture requirements (warm-season 30% and cold-season grass species 70%, respectively). Water is supplied primarily from the mains water network through a buffer storage tank, while excess water is recovered and recirculated within the system. In the irrigation scenario, water consumption is accounted for in Module B7, while the associated electricity use for pumps and automated control systems is included in Module B6.

3.3 End of Life Stage

For conventional dry-mounted clay tiles, Module C1 can normally be considered negligible, since tiles can be manually removed without the need for additional energy use [13]. In addition, although CAPT-TILEs incorporate adhesive layers used to bond the substrate and the vegetative system to the clay tile, tests performed by Industrie Cotto Possagno demonstrated that the adhesive can be fragmented together with the tile during dismantling and treated together with the CAPT-TILE clay tile material in subsequent

recycling processes (Module C3). No additional demolition effort required due to bonded materials must be included in Module C1.

At end-of-life, the clay component is assumed to be largely recovered (90%) and reused or recycled, with the remaining 10% sent to recycling facilities, consistent with sector PCRs and typical EoL practice. The vegetative layer and the substrate, both biodegradable, are modelled as composted under Module C3. Finally, the benefits of reuse (90%) and recycling (10%) of clay roof tiles recovered from the demolition site at the end of their life in module C1, and the benefits of recycling and energy recovery of packaging are allocated to module D.

4 Conclusions

This study proposes a methodological framework for the environmental evaluation of innovative modular NbS, serving both as green roof and green façade systems, integrating clay materials and vegetative components. Using the CAPT-TILE system as a case study, the work defines the system boundaries, life-cycle stages, and data collection procedures necessary to assess both the environmental impacts associated with the manufacturing of components and the potential benefits related to vegetation growth on building surfaces, including experimental measurements of plant biomass CO_2 storage. To the best of our knowledge, these measurements represent one of the first attempts to quantify CO_2 exchange at a single green tile-scale. This approach provides novel information to conduct an estimation of the balance between the potential amount of CO_2 removed by the CAPT-TILEs in the operation phase and the amount released in its production and disposal. Considering that ceramic tile production may generate emissions of approximately 14.4 kg CO_2 eq m^{-2} according to literature data [19], the experimental results obtained for CAPT-TILE modules, showing CO_2 storage values of up to 8.6 kg CO_2 m^{-2}, suggest that innovative clay-based NbS may partially offset a significant share of life-cycle emissions. Overall, the proposed framework establishes the methodological basis for a future complete life-cycle environmental assessment of the CAPT-TILE system. In addition, the study highlights the importance of modelling the use stage, including irrigation and maintenance processes which are often simplified or neglected in conventional LCA studies of vegetated systems. Future research will focus on the full quantification of environmental impacts across all life-cycle stages, including the validation of vegetation performance and maintenance scenarios under real building operating conditions.

Abstract. This study assesses the climate impact of a multi-storey wood building in a life cycle perspective, using both static and dynamic life cycle assessment (LCA) approaches. It investigates how different circular economy scenarios encompassing recycling, reuse and cascading use affect the life cycle climate impact of the building. The results show notable differences in the calculated climate impact depending on the LCA approach, highlighting the importance of comprehensive accounting of biogenic carbon. The building's end-of-life stage gives a significant climate benefit when implementing circularity strategies for post-use wood materials. Among the assessed strategies, cascading provides the greatest climate benefit and results in the lowest life cycle climate impact for the building. Relative to the dynamic LCA (at year 100), the static LCA estimated a 138% higher climate impact for the baseline scenario involving energy recovery, and substantially underestimated the benefits of the circularity strategies. For recycling and reuse, the static LCA even showed 9–19% higher climate impacts than the baseline scenario. Overall, the findings demonstrate that both the choice of circularity strategy and the LCA approach substantially influence the calculated life cycle climate impacts of wood-based materials and buildings.

Keywords: Climate Impact · Circular Economy · Dynamic Life Cycle Assessment · Static Life Cycle Assessment · Wood Construction Materials

1 Introduction

The production and use of buildings account for about half of all extracted materials consumption and about one-third of waste generation within the European Union (EU) [1]. Improving material efficiency and promoting circularity across the design, construction, use and end-of-life (EoL) stages of buildings are vital steps toward a resource-efficient and low-carbon society. Alongside the ongoing efforts to improve energy efficiency and decarbonise the built environment, circular economy strategies are suggested as essential for achieving the 1.5 °C climate target of the Paris Agreement [2, 3]. According to

L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 1033–1041, 2026.
https://doi.org/10.1007/978-3-032-34930-9_120

the Circularity Gap Report [4], measures such as circular construction materials with recycled content and resource-efficient construction need to be implemented by 2050 to support achieving the Paris Agreement climate target. The EU Circular Economy Action Plan aims to advance circular economy in the built environment and among others identified the building and construction sector as a key area for advancing circularity practices [5].

Several Life Cycle Assessment (LCA) studies demonstrate the climate benefits of wood-based construction products and buildings compared with functionally equivalent non-wood alternatives [6–8]. However, most of these LCA studies focus primarily on the production stage of buildings. A comprehensive approach to sustainable construction needs to consider the entire material chains, from raw material extraction to EoL management [9]. Effective management of EoL building materials facilitates circular material flows in the built environment and thereby reduces environmental impacts. Munaro et al. [10] noted opportunities for circularity interventions at the EoL stage through strategies such as life extension, resource recovery, and recycling.

Previous studies (e.g. [11, 12]) explored the environmental implications of alternative pathways for post-use wood building materials, showing that efficient management of such materials can give significant net climate benefits. However, these studies are based on static LCA which does not address the timing of biogenic carbon flows. Dynamic approaches, on the other hand, are more suited for LCA of wood-based systems as such an approach comprehensively addresses the dynamics of biogenic carbon storage, delay and eventual release as emission [13].

This study compares the implications of using static and dynamic LCA approaches for analysis of the climate impact over the life cycle of a multi-storey wood building, focusing on the implications of circular economy practices for post-use wooden building materials, including recycling, reuse and cascading.

2 Methodology

Static and dynamic LCA methodologies are used to analyse the climate impact of a cross-laminated timber (CLT) building and to explore how different circularity strategies for the post-use wooden materials affect the building's life cycle climate impact.

2.1 Case Study

The CLT multi-storey building for the study was constructed in 2015 in Växjö, Sweden, and comprises 39 apartments with a total heated floor area of 2780 m^2. A photograph of the building is shown in Fig. 1. The mass of materials comprising the building is presented in Table 1. CLT is used for the building's exterior and interior walls, as well as for the intermediate floors. CLT, together with other wooden materials in the building, represents about one-fifth of the building material mass. Aggregates dominate the mass of materials and is used in the foundation and intermediate CLT floor slabs for stability. The other wooden materials (in Table 1) comprise plywood, glued laminated timber, chipboard, laminated wood flooring, wood decking, and wood used as laths and for doors. The other

Fig. 1. Photograph of the studied CLT building in Växjö, Sweden.

non-wood materials include asphalt, cellular plastic, cement, aluminium, polyethylene, and polypropylene.

Table 1. Material mass balance of the studied CLT building.

Material	Mass (tonne)	Material	Mass (tonne)
Aggregates	1091.8	Insulation (mineral wool)	53.7
Concrete	929.7	Coarse concrete	36.5
CLT	443.2	Rebars (recycled steel)	24.8
Gypsum board	225	Window	20.4
Other wooden materials	175.8	Facade stones	19.6
Steel (connections)	84.4	Glass	19.6
Plaster putty	79.6	Other non-wood materials	15.8

2.2 Scope of the Study

Functional Unit and System Boundary: The climate impact of the complete building is analysed over a 50-year reference service life, and normalised to 1 m^2 building floor area to compare the implications of the different circularity options and LCA approaches. The system boundary of the analysis follows EN 15978 [14] and EN 15804 [15], and is defined to include all activities connected to the product and construction (A1-A5), use (B1, B2 and B4) and EoL (C1-C4) stages and the potential benefits and burdens from post-use building material recovery and management (D).

2.3 Inventory Analysis

Product and Construction Stages: The inventory in the product stage (A1-A3) includes emissions of CO_2, CH_4, and N_2O from fossil fuels and cement production processes and biogenic carbon flows. These are calculated based on the mass of materials in

the building, using life cycle inventory datasets for material processing, energy supply, and transport from the Ecoinvent database (v3.8) [16]. The biogenic carbon flows associated with wood-based materials are accounted for using the −1/+1 approach. During the construction stage (A4-A5), emissions from transport are calculated using specific transportation emissions data from Ecoinvent (v3.8), while those for the construction and installation processes are calculated using standard data for the Swedish conditions [13]. Details of the modelling data are given in Dodoo et al. [13].

Use Stage: Carbon uptake associated with concrete carbonation (B1), maintenance (B2) and replacement (B4) are included in this stage. The carbon dynamics of carbonation are calculated using data provided by Dodoo et al. [17] while the emissions associated with B2 and B4 are calculated using data from Ecoinvent (v3.8) [16].

EoL and beyond Stage: The building is assumed to be deconstructed through selective dismantling after a 50-year reference service life. This is followed by the transport and reprocessing of EoL building materials, with a focus on wooden products, particularly the CLT panels as the main structural building material. The emissions accounted for at the EoL stage comprise those associated with the building's deconstruction (C1), the transport of post-use materials (C2), material processing (C3), and the potential environmental benefits (D) associated with the post-use material recovery and management. Following Dodoo et al. [17], 90% of the wood, concrete, steel, aluminium, and glass comprising the building are assumed to be recovered for further reprocessing. For concrete, steel, aluminium, and glass, recycling is assumed. The wooden materials are assumed to be recovered for energy in the baseline scenario, displacing fuels used for district heating, and are compared with circular economy strategies, including recycling, reuse, and cascading. Emissions from the EoL and beyond stages are calculated using data from Ecoinvent (v3.8) [16], supplemented with data from [18]. Transport-related emissions are calculated assuming the use of Euro 3 trucks and a distance of 100 km to waste processing sites.

Circularity Strategies: The circularity strategies explored (Table 2) mainly target the CLT as the structural building material, and aim to extend material use and delay biogenic carbon release. The recycling scenario assumes reprocessing of the CLT panels into wood chips for particleboard production. The reuse scenario assumes the use of the CLT panels in new applications while the cascading use follows a hierarchy where the CLT panels are first reused, then recycled into particleboard chips, and finally used for energy recovery. The substitution benefits from the post-use materials are allocated to the studied building after the end of its service life (year 50).

Table 2. Circularity scenarios and assumptions for CLT and other materials.

Scenario	Description
Recycling	90% of CLT/other wood recycled; 90% of other materials (see texts) recycled
Reuse	70% of CLT/other wood reused & 20% recycled; 90% of other materials recycled
Cascading	Reuse (as above) first, then recycling, and finally energy recovery of all wood.

2.4 Impact Assessment

Static and dynamic modelling approaches detailed by Dodoo et al. [13] are used for the impact assessment. The static approach uses Global Warming Potential (GWP-100) factors to convert the total emissions of each greenhouse gas (GHG) into CO_2-equivalent values using characterisation factors of 1, 29.8 and 273 for CO_2, CH_4, and N_2O, respectively, from the IPCC [19]. The dynamic approach accounts for the temporal distribution of GHG emissions and removals by tracking their annual flows and calculating climate effects over time using atmospheric response functions and radiative forcing models.

3 Results

Figure 2 presents the life cycle climate impact of the building for the recycling scenario, while Table 3 summarises the climate impacts for all the circularity scenarios and baseline of energy recovery, all calculated using the static LCA approach. In Table 3, the value for the production stage is negative because it includes the biogenic carbon storage (in Fig. 2), which is 1.3 times greater than the fossil carbon emissions. The impacts of the production stage and the use stage are the same for all scenarios and the baseline, as the differences between them arise from the EoL options, which vary across the cases. Overall, cascading provides the greatest benefit and results in the lowest climate impact. In contrast, reuse and recycling show 9% and 19% higher climate impacts than the baseline, respectively, according to the static LCA.

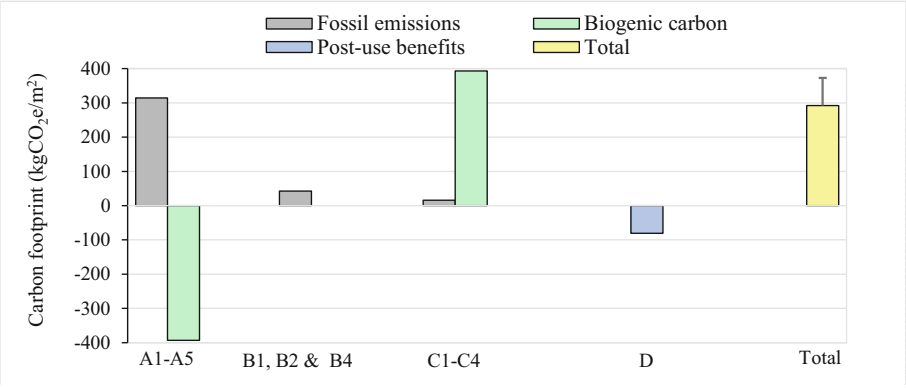

Fig. 2. Climate impact over the life cycle of the building. For the total, the main bar shows when including post-use benefits (D) and the error bar shows values excluding these benefits.

Table 3. Life cycle climate impact of the building under alternative EoL options (static LCA).

Life cycle stages	Climate impact (kg CO_2e/m^2) with alternative EoL options for CLT			
Production (A1-A5)	−99			
Use (B1, B2, & B4)	42			
EoL & beyond (C1-C4, D)	*Baseline*	*Recycling*	*Reuse*	*Cascading*
	302	348	324	266
Balance (net total)	**245**	**291**	**267**	**209**

Figure 3 shows the life cycle climate impacts of the building when the calculation is based on dynamic LCA. Essentially, the estimated climate impact varies with the time window over which the cumulative effects of GHG emissions and removals are assessed. Concrete carbonation during the building's service life (module B1) caused the gradual downward trend in the figure due to slow carbon uptake over time. Table 4 summarises the building's climate impacts for the dynamic LCA at year 100 and year 200 and also the life cycle climate impacts of the static LCA (based on Table 3). It shows differences in both the ranking and magnitude of the options between the dynamic and static LCA. The dynamic LCA shows that cascading gives the lowest climate impact, followed by reuse and recycling, with the baseline providing the least climate benefit and therefore the largest climate impact. This contrasts with the results of the static LCA, which ranks the baseline next after cascading. Furthermore, compared with the static LCA, the dynamic LCA shows significantly lower climate impacts and therefore greater benefits for the circularity strategies. This difference is due to how biogenic carbon is accounted and treated under the two assessment approaches. In contrast to the baseline, all the circular economy scenarios show negative climate impacts at year 100, indicating a cooling effect and thus substantial climate benefits. However, at year 200 only the cascading scenario shows a negative climate impact, although the climate impacts of recycling and reuse remain lower, between 31–42% lower than the baseline of energy recovery.

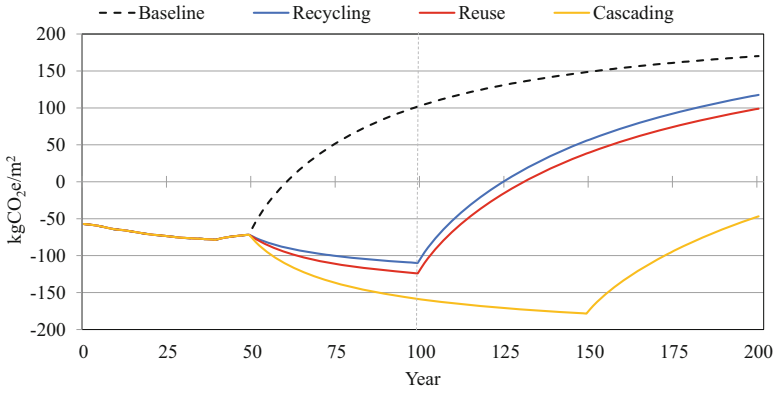

Fig. 3. Life cycle climate impact of the building under alternative EoL options (dynamic LCA).

Table 4. Climate impact of the building under alternative EoL options when using dynamic and static LCA approaches.

Description	Climate impact (kg CO_2e/m^2)		
	Dynamic LCA at year 100	Dynamic LCA at year 200	Static LCA (GWP-100)
Baseline	103	170	245
Recycling	−102	118	291
Reuse	−117	99	267
Cascading	−159	−47	209

4 Discussions and Conclusion

This study shows that the explored circularity strategies, encompassing reuse, recycling, and cascading, give significant climate benefits, and the choice of EoL strategy has a significant influence on the building's life cycle climate impact. It also demonstrates the relevance of the LCA approaches for analysing circularity strategies in wood-based systems. While several LCA studies have explored climate change implications of circularity strategies for the EoL of wood building materials, most are based on static LCA, and there is a paucity of studies using dynamic LCA approach. The present study therefore contributes to the literature by examining the implications of applying both static and dynamic LCA approaches in such a context.

The findings show significant differences in both the magnitude and ranking of climate impacts when using the static and dynamic LCA approaches. Cascading consistently provides the lowest climate impact across all approaches. The dynamic LCA showed much lower impacts, reflecting the benefits and effects of temporal carbon storage in wood-based materials. This also changed the relative performance of the EoL strategies explored compared with the static LCA. Reuse and recycling showed lower impacts than the baseline in the dynamic LCA, while in the static LCA both strategies resulted in 9–19% higher climate impacts than the baseline scenario.

These findings highlight the importance of accounting for the temporal dynamics of GHG flows in LCA of wood-based systems. They also add to growing evidence (e.g. [13, 20]) that dynamic LCA provides a more robust approach to treating biogenic carbon in wood-building LCAs. For example, Mghazli et al. [20] reported that static LCA yields 50% higher climate impacts for a wood building than dynamic LCA over a 50-year time horizon. Similarly, the present study showed that, compared with the dynamic LCA at year 100, static LCA gave a 138% higher climate impact for the baseline scenario. At year 100, the dynamic LCA showed reductions in climate impacts of 199%, 214%, and 254% for recycling, reuse, and cascading, respectively, compared with the baseline. In contrast, the static LCA indicated increases in climate impacts of 19% for recycling and 9% for reuse, and only a 15% reduction for cascading compared with the baseline, thereby substantially underestimating the climate benefits of circularity strategies.

Despite the potential benefits, several barriers limit the implementation of circularity strategies in the building sector. For example, buildings are often not designed to facilitate

post-use material recovery [21, 22]. To realise the climate benefits identified in this study, greater emphasis should be placed on design and construction practices that facilitate material recovery at the building's EoL. Overall, this study demonstrates the relevance of the choice of EoL strategy and the assessment approach, as both have a significant influence on the overall climate performance of a building.

Relative Indicators and Reference Benchmarks for Environmental Assessment of Buildings

Roman Rabenseifer(✉), Katarína Minarovičová, and Katarína Červeňová

Faculty of Civil Engineering, Slovak University of Technology in Bratislava, Bratislava, Slovakia
roman.rabenseifer@stuba.sk

Abstract. The increasingly urgent need to reduce greenhouse gas emissions and the ambition to achieve carbon neutrality by 2050 have intensified the necessity for EU member states to implement comprehensive evaluations of environmental impacts, including in the building construction sector. Today, we are approaching the limits of what can be achieved through further reductions in operational energy consumption of buildings. However, there is still significant potential for reducing building's primary embodied energy demand, which simultaneously offers opportunities for lowering greenhouse gas emissions expressed in terms of global warming potential (GWP). In this article, in addition to evaluating the current state of establishing GWP threshold values for building's embodied energy across EU countries, we also propose the development of reference benchmarks expressed per unit of heated floor area. In generating these benchmarks, we account for the building shape factor (the ratio of the heat exchange area of the building's envelope to the heated volume of the building), which is also used in the assessment of operational energy performance of buildings - and distinguish between two categories of envelope systems: heavy-mass and lightweight. We further present simplified examples demonstrating that relative indicators (e.g., GWP per m^2 of heated floor area) related to the shape factor provide a more accurate picture of actual environmental performance compared to values expressed only in relation to the unit of building's heated floor area.

Keywords: Embodied Energy · Global Warming Potential · Shape Factor · Benchmarking · Life Cycle Assessment · EPBD IV

1 Introduction

European climate policy as shaped by the Green Deal [1], the Climate Law [2], and successive revisions of the Energy Performance of Buildings Directive (EPBD) has driven new buildings toward ultra-low-energy or near-zero-energy performance. As operational energy demand approaches its practical minimum, attention is shifting toward embodied impacts arising before a building is commissioned.

Despite their importance, embodied impacts remain insufficiently regulated. Voluntary schemes such as BREEAM [3], LEED [4], and DGNB [5] include indicators

L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 1042–1049, 2026.
https://doi.org/10.1007/978-3-032-34930-9_121

for primary energy input (PEI) and global warming potential (GWP), but their benchmarks vary widely. EPBD IV [6] marks a turning point: from 2028, new buildings above 1000 m^2 must report their whole-life GWP, with the requirement extending to all new buildings from 2030.

Several EU Member States have already introduced embodied carbon limits (Fig. 1). However, the methodologies used to derive these limits differ significantly. A comparative review of available approaches showed that the reliability of benchmark values depends primarily on the representativeness of input data rather than on building typology or software.

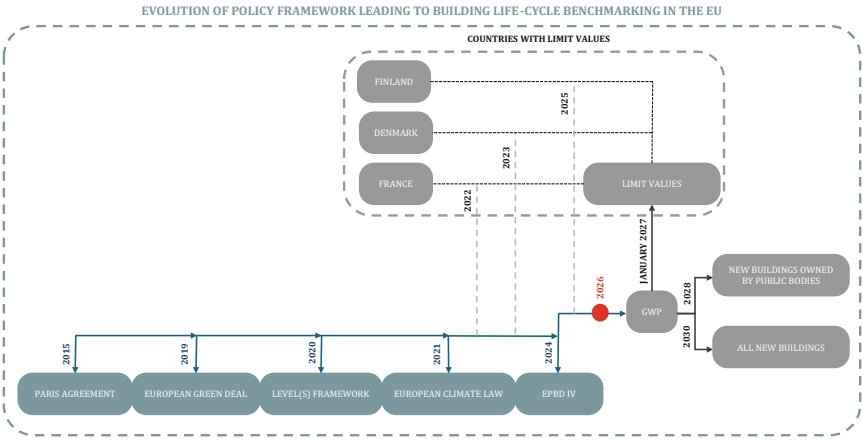

Fig. 1. Evolution of embodied carbon benchmarking in Europe (the list of countries with limit value is indicative only).

A more fundamental challenge concerns the indicators themselves. Absolute values favour small buildings; per-square-meter values ignore geometric efficiency. The authors' previous work [7, 8] suggests that the building shape factor (the ratio of the heat exchange area of the building's envelope to the heated volume of the building - *A/V* ratio), long used in operational energy assessment, provides a fairer basis for comparing embodied impacts.

This paper has three objectives:

- summarize recent European methodologies for establishing reference values;
- demonstrate why geometry-sensitive indicators are needed;
- propose a geometry-based benchmarking framework compatible with EPBD IV.

2 Current Approaches to Establishing Carbon Footprint Reference Values

The development of national benchmarks for embodied carbon has accelerated across Europe in response to the requirements of EPBD IV and the broader climate neutrality agenda. However, the methodological diversity among Member States remains substantial. Below are summarized four representative approaches. These approaches differ in data sources, system boundaries, statistical treatment, and intended regulatory application.

2.1 Parametric Modelling (Hungary) [9]

A parametric approach generates thousands of hypothetical residential buildings by varying key geometric parameters. Embodied carbon is calculated for modules A1–A3, B4, and C3–C4 of building's life cycle assessment. Reference values are expressed as median and percentile ranges (9.1–15.5 kg CO_2-eq/m^2/year). This method is useful where real LCA data are scarce, though it lacks real-world validation.

2.2 National Methodology Based on Real Projects (Czech Republic) [10]

The Czech INDICATE project assessed 50 most common types of real buildings (e.g., single-family houses, multi-residential buildings, office buildings, educational facilities, and logistic halls) using harmonized bills of quantities and BIM models. The full life cycle (A–C) was evaluated under three operational energy scenarios. The approach is accurate and representative but limited by sample size and incomplete national EPD coverage.

2.3 Pilot Study of Office Buildings (Poland) [11]

A preliminary benchmark of ~5000 kg CO_2-eq/m^2 over 60 years was derived from 11 office buildings. While useful as a first step, the dataset is too small and not fully harmonized with EN 15978 [12].

2.4 Analytical Basis for National Limit Values (Denmark) [13]

Denmark's methodology is the most comprehensive. From 163 representative buildings, a national limit value was defined as the 66^{th} percentile of area-weighted GWP results, yielding 9.9 kg CO_2-eq/m^2/year (A1–A4, B4, B6, C3–C4). Typology-specific limits were also introduced. Limitations include underrepresentation of some building types and mixed data sources.

2.5 Synthesis

Across all reviewed methodologies, a consistent pattern emerges: the reliability of benchmark values depends primarily on the representativeness and quality of input data, not on building typology or LCA software.

Countries with limited datasets may rely on parametric modelling, while those with established digital workflows can develop harmonized national databases. However, none of the reviewed methodologies explicitly address the influence of building geometry on embodied impacts - a gap that motivates the next section.

3 Limitations of Absolute and Per-Square-Meter Indicators

Absolute embodied energy or GWP values scale with building size and therefore favour small buildings. Normalizing by floor area improves comparability but still ignores geometric efficiency. Two buildings with identical floor areas may differ significantly in envelope area, proportions, or number of storeys, leading to large differences in embodied impacts.

The shape factor (*A/V* ratio) captures the relationship between envelope area and heated volume. It governs both heat transfer (operational energy) and material quantities (embodied impacts). Indicators that ignore this relationship risk unfairly penalizing certain typologies and distorting design incentives.

4 Geometry-Based Assessment of Embodied Impacts

4.1 Influence of Shape Factor

In the study published in Energies (2025) [7], a set of simplified geometric variants was generated by scaling a $3 \times 3 \times 3$ m cube in one or more dimensions. For each variant, the envelope area, heated volume, and shape factor were calculated, and embodied impacts were assessed for the product stage (A1–A3) using ÖKOBAUDAT data [14]. The results revealed two key relationships:

- Absolute embodied energy and GWP decrease with increasing shape factor (smaller buildings require fewer materials in total).
- Embodied energy and GWP per square meter increase with increasing shape factor (compact multi-storey buildings use materials more efficiently per unit of heated floor area).

These findings demonstrate that the shape factor governs the efficiency of material use in a similar way it governs heat transfer in operational energy assessments (Fig. 2)

4.2 High-Mass vs. Lightweight Systems

Using identical geometries, lightweight timber-based variants exhibited substantially lower embodied impacts than high-mass reinforced-concrete variants (Fig. 2). This supports the need for separate benchmark categories.

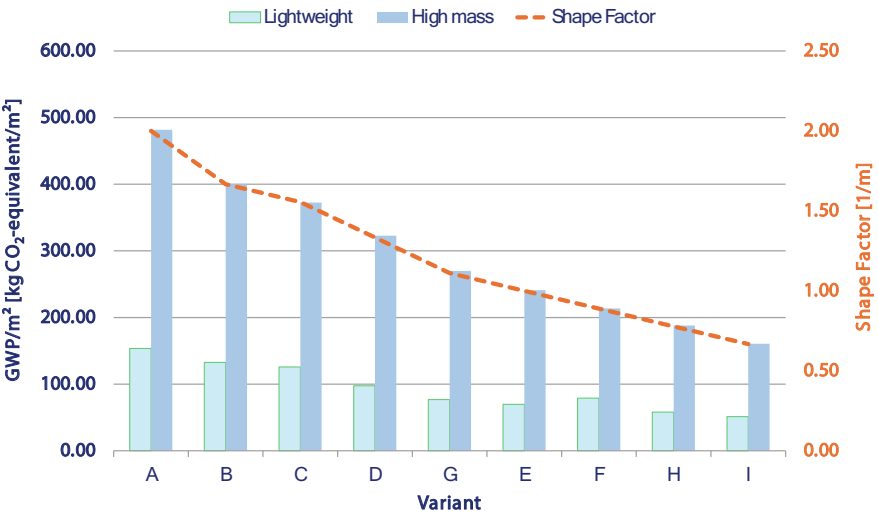

Fig. 2. Relationship between shape factor and GWP/m^2 - comparison of high-mass and lightweight variants. The shape factor (dashed line) is linked to the secondary y-axis and the GWP/m^2 value to the primary y-axis (adapted and redrawn from [7]). The letters A through I denote geometric variants ranging from 3 × 3 × 3 m to 9 × 9 × 9 m.

4.3 Influence of Floor Area, Proportions, and Roof Geometry

A later study (Energies, 2025 [8]) analyzed 40 realistic family house variants. Results showed that:

- multi-storey buildings have significantly lower embodied impacts per square meter;
- elongated floor plans increase the shape factor and embodied impacts;
- roof geometry has a secondary but noticeable effect.

4.4 Theoretical Basis

The Energies studies [7, 8] provided a theoretical justification for using the shape factor in embodied impact assessment. Since the same geometric parameters govern both operational and embodied performance, the shape factor offers a natural bridge between the two.

5 Proposal for a Geometry-Based Benchmarking Framework

The framework is based on fairness, representativeness, transparency, scalability, and compatibility with EN 15978 [12], EN 15804 [15] and EPBD IV [6].

5.1 Geometry-Adjusted Indicator

A geometry-adjusted benchmark metric, in this case for GWP_{adj}, is proposed:

$$GWP_{adj} = \frac{GWP_{A1-A3}}{A_{HF}} \times f(F_b) \tag{1}$$

where f_b = a/v ratio, i.e., the shape factor, $f(f_b)$ adjusts the benchmark to account for geometric effects, A_{HF} stands for heated floor area and $GWP_{A1\text{-}A3}$ for the embodied GWP of the product stage of the life cycle assessment. Compact buildings (low f_b) can meet stricter thresholds due to their efficient use of materials, while less compact buildings (high f_b) receive geometry-adjusted limits that ensure fair comparison.

5.2 Separate Categories

Given the large differences between high-mass and lightweight systems, two benchmark categories are proposed. Each category would have its own benchmark curve $f(f_b)$, reflecting typical material intensities for either system.

5.3 Data Collection Through Permitting and Certification

Embodied impact calculations can be integrated into building permitting and energy certification. This distributes data generation across the sector and avoids large-scale stock surveys. A transitional period can be used to collect data before applying thresholds.

The approach aligns with the gradual introduction of embodied carbon limits across Europe (Fig. 1) and offers a more nuanced alternative to fixed per-square-metre thresholds.

6 Conclusions

The move toward whole-life carbon assessment requires benchmarks that reflect real material efficiency rather than arbitrary typological differences. Existing European methodologies provide valuable insights but do not fully address the influence of geometry.

The authors' previous studies show that the shape factor (*A/V* ratio) is a strong predictor of embodied impacts and can serve as a fair basis for benchmarking when combined with heated floor area (A_{HF}) normalization. Distinguishing between high-mass and lightweight systems further improves accuracy.

Integrating embodied impact calculations into permitting and certification processes offers a practical way to collect representative datasets. Once sufficient data are available, geometry-adjusted benchmark curves can be calibrated and progressively tightened.

Refinement and practical implementation of this approach will benefit from ongoing research, real-world testing, and shared experience among different countries.

Ecosystem Services and Life Cycle Impact Assessment of Building Materials: A Scoping Review

Marina da Silva Seabra da Rocha(✉) and Eleonora de Sad de Assis

Architecture School, of Federal University of Minas Gerais, Paraíba Street, 697, 30130-141 Belo Horizonte, MG, Brazil
marinasseabra@gmail.com

Abstract. Life Cycle Assessment (LCA) is one of the most widely used methods for assessing construction sustainability. Despite its widespread adoption and well-established nature among assessors and certifiers, it faces some limitations. Therefore, the ecosystem services (ES) approach appears to be a promising alternative for overcoming these barriers. However, its theoretical basis remains underexplored as a complement to the LCA of building materials. Thus, this investigation, conducted through a scoping literature review, aims to identify the strengths and limitations of LCA-driven methods that incorporate ES principles for assessing the environmental impacts of building materials. We conclude that there are four types of LCA driving methods, with varying degrees of ES integration. However, ES integration into LCA for construction materials remains insufficient, as existing methods exhibit several limitations. This investigation contributes to identifying barriers and pathways for achieving true circularity in the built environment. It highlights the necessity of developing a new sustainability assessment tool that integrates ES on LCA, creating a unique assessment metric for the impacts of construction materials on ES, guiding built environment professionals in material selection, and potentially serving as a certification system.

Keywords: LCA · Building Materials · Construction Materials · Ecosystem Services · Scoping Review

1 Introduction

In the words of Vanderwilde and Newell [1] and Vieira, Calmon and Coelho [2] LCA is the main instrument for environmental management, as enshrined in the ISO 14.040 series of international [3] and ISO 14.044 [4] and the national technical standards. It is an "internationalised and standardised process for assessing the environmental impacts of products or processes throughout their life cycle" [1]. It is also one of the most explored in recent literature when compared to other assessment tools [2].

However, LCA is a very complex, expensive and subjective method [5], concerning the choice made by the assessor of boundaries of the product or process system being analysed, the objectives and even the scope of the assessment. In addition, it can be very

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 1050–1058, 2026.
https://doi.org/10.1007/978-3-032-34930-9_122

time-consuming, requiring a lot of experience of the person carrying it out and a large set of data that is often unavailable or non-existent [6]. And it also does not have indicators that are easily understood or aggregated into a single metric unit [7]. This method is not capable of fully accounting for impacts on the provision of ecosystem services – ES. LCA focuses above all on the interference of its object of study on regulation and maintenance services, especially carbon emissions. Despite this discrepancy between the two frameworks, LCA and the ES approach share environmental sustainability objectives [1].

Consequently, the aim of this study was to conduct an scoping review (ScR) and raise the potential and limitations of the traditional types of LCA that are used to assess the impacts of construction materials on the environment with LCA's that are based on the precepts of ecosystem theory, to assess these same impacts.

This review is justified by the need to provide an up-to-date overview of research published on the subject, which is still in its beginnings, and to outline the current debate on the subject. Likewise, the relevance of this research is evident since there are no recent reviews that have targeted the survey proposed in this investigation. Furthermore, the aim is to demonstrate that the LCA approach, as it is currently applied, is limited, concerning its understanding of impacts on ecosystem. And finally, by providing a compilation of the characteristics of existing methods, this research contributes to make a conscious choice about the type of LCA that should be adopted in assessment situation.

2 Materials and Methods

The research used the scoping review technique using Parsifal to conduct it. The publications searched were limited to the time interval 2003 to 2023. The initial year chosen as a milestone was due to the fact that it was the year in which the Millennium Ecosystem Assessment was published [8], a scientific reference for the approach to the theory of ecosystem services. Searches for open-access publications were conducted in the ScienceDirect database, which hosts a substantial number of journals and studies in the environmental field, as indicated in prior research. This approach was adopted because, in addition to the fact that ScR can serve as a preliminary step for future in-depth investigations, it is also possible to adapt the method to resource constraints by developing a robust search string and limiting the investigation to a single database [9]. The review followed the PCC framework, and the search string used was: ("construction material" OR "building material") AND ("life cycle assessment" OR LCA OR "life cycle") AND "assessment" AND ("ecosystem services").

As shown in Table 1, the initial number of publications found was 188, which were exported to BibTex file that was uploaded to Parsifal. Two duplicates were eliminated and then a first selection was made manually. It was verified if the study focused on buildings, building materials and life cycle assessment or ecosystem services. 84 documents remained at the end of this initial filtering.

On the other hand, research that dealt with Building Information Modelling – BIM –, other sustainability assessments, water supply and sewage systems, energy systems (fuels and other sources), LCA of aquaculture, forests, plantations, aquatic or terrestrial biomes, algae, studies on materials or construction elements that did not deal with LCA or

Table 1. Steps of Scoping Review.

Step	Number of documents
Initial sample	188
Practical screening	84
In depth screening	16
Final Sample	12

ecosystem services, other environmental studies (e.g. environmental impact assessment – EIA, climate study, performance of materials and building elements, remediation, state of the art on new technologies, pollution, environmental risks and artificial reefs), research focused on policies and the role of stakeholders, as well as other LCA studies that did not deal with buildings or building materials and congress proceedings, were discarded. 16 texts advanced to the next stage, as shown in Table 1. The 16 publications were saved in a folder in the Mendeley software and submitted to a second filter based on content compatibility assessment. In total, 12 studies were selected to make up the *corpus*. Therefore, 10 articles and two book chapters remained to make up the textual basis for data extraction.

The purpose of the data extraction, using Parsifal, was to map: The occurrence of the expression "ecosystem services" in different parts of the text; Whether the focus of the research was on buildings, materials or entire urban areas; What the target material of the study was, when relevant; Which phases of the object's life cycle were assessed; Which types of traditional LCA or ecosystem-based methods were presented; Which potentialities and limitations of these procedures were listed and the name of the new method, if proposed. At the end of this process, a .csv file was exported and opened in Microsoft Excel. The information collected was reviewed, then completed in there were missing passages, and finally summarised.

3 Results

It is important to emphasise that only half of the 29 methods mapped are discussed in terms of their advantages and limitations. The methods listed were divided into four classes: LCA methods, economic methods, ecosystem methods, and energy analyses, as seen in Table 2.

3.1 LCA

There are eight LCA methods mentioned. However, only traditional LCA and the Life Cycle Model of Carbon Emissions for Urban Building Systems - LCCE Model - were explored. LCA assesses the main types of impacts, such as global warming, acidification and eutrophication, at different spatial scales, in addition to the embodied energy [10, 11]. Azari [10] also mentions that it is a solid and well-established quantitative methodology that can be used for comparing materials, elements and buildings. Besides, Li and Wang

Table 2. Main strengths and limitations of each method class.

Strenghts	LCA	Economic	Energy	Ecosystem
Complete and well-established LC assessment	X			
Specific to construction sector	X	X		
Easy comparison			X	
Multi-sector impact assessment	X	X		
Link BE to nature			X	X
Easy cost-benefit analysis		X	X	X
Limitations	LCA	Economic	Energy	Ecosystem
High /local data requirements and complexity	X		X	X
Subjectivity and uncertainties	X	X	X

Focus on specific life cycle stages or impacts	X	X	X	
Quantification of non-commercial services		X		
No social aspects considered	X	X		
Market-based models' dependency		X		
Complexity in system boundary definition	X		X	X

[11] state that it is a product-oriented method, in which the environmental effect of the life cycle belongs to the downstream impact indicators.

On the other hand, there are many limitations. Izaola and Akizu-Gardoki [12] affirm that LCA is still very much focused on assessing global warming potential. This method makes difficult to compare its results with the ones from other studies, due to the different metrics and approaches used. Yi, Srinivasan and Braham [13] and Yi et al. [14] explain that in conventional and recent approaches, accounting for the impacts of the building's life cycle does not include the environmental formation phase of renewable and non-renewable resources. In general, these approaches ignore the direct link between the built environment (BE), and the larger geobiological system. In other words, the contribution of energies, including solar, wind and other renewable and non-renewable resources and ecosystem services to the formation of raw materials, geobiophysical materials and human or social services are not calculated as inputs.

As stated by Azari [10] and Cao et al. [15], LCA can induce subjectivity, whether in determining the weight of each impact, in the objectives and definitions and assumptions of the LCA. In addition, they can provide incomplete information and uncertainties due to lack of knowledge and data from regional and local bases on the environmental contribution to the social economy of that process. Furthermore, Azari [10] emphasizes that uncertainties are inherent to the LCA process. They result from a lack of knowledge about the functioning of the system under study or the inaccuracy of a model in representing the physical system, measurement errors caused by small sample sizes used in data collection or errors in data collection. Furthermore, according to Azari [10], LCA

is a modeling tool that is not very friendly to architects to utilize during the early stages of design analysis.

Finally, as stated by Yi, Srinivasan and Braham [13], LCA is based on temporal and spatial scales of impacts and processes corresponding mainly to initial production phases. Like EmA, it does not take into account the energy incorporated into the material formation process. And this can limit the window in which this method can be employed. The authors also pointed out that among the index related to energy accounting in LCA, few provide information that can be summarized in a single unit. While Srinivasan et al. [16] conclude that traditional LCA does not fully account for impacts on the provision of ecosystem services.

3.2 Economic Methods

There are three methods covered is this category: Economic Input-Output based method of LCA - IOE-LCA Cost Benefit Analysis and Economic Analysis - EA. For the latter two, no advantages are added and Srinivasan et al. [16] say that Cost-Benefit Analysis is an example of a reductionist tool, which evaluates performance by reducing a complex system to a smaller set of variables, integrating only its measurable characteristics. Cao et al. [15], state that EA ignores the impact of the production process on the environment and the environmental contribution to the social economy, meaning that environmental costs can be underestimated.

Azari [10] and Srinivasan et al. [16] state that IOE-LCA is tool that is more comprehensive and specific to the construction sector. It makes possible to compare products and components from different sectors. However, it carries the same LCA uncertainties. Besides, this procedure is based on average US data from more than 20 years ago, which leads to inaccuracies and a mismatch in the results with the present day.

3.3 Energy Analysis

With regard to energy analyses, six sub-methods are discussed: exergy analysis, extended exergy analysis, embodied energy analysis for buildings, emergy or emergy analysis - EmA -, modified or improved emergy analysis and emergy analysis for buildings.

In relation to exergy analysis and expanded exergy analysis, Yi, Srinivasan and Braham [13] state that in the first case, the link between the built environment and many of the larger geobiological systems, including solar, wind, other renewable and non-renewable resources and ecosystem services, is generally ignored. Furthermore, the no-extended method only refers to the current state of energy available for use. These authors make the same complaint about the method that analyses embodied energy for buildings. They also state that in this method the energy demands are calculated only from the extraction of the material, ignoring the environmental loads in the process of forming the input in nature, which is corroborated by Yi et al. [16]. Finally, they add that this procedure does not account for the energy of human labour and supporting services.

Concerning the Emergy method or Emergy Analysis - EmA - Song, Lin and Wu [17] state that the unit of energy per mass is suitable for assessing the recyclability of building materials, obtaining what can be called a total ecological cost. In this way, it is possible to quantify the real-life cycle cost of material production, taking into account

the losses both to the ecosystem and people due to CO2 emissions. Li and Wang [11] emphasise the ability of this method to assess benefits and costs together.

In addition, Yi, Srinivasan and Braham [13], Yi et al. [18] and Srinivasan et al. [15] state reaffirm the holistic nature of this approach, which can analyse systems of different types and scales and human communities with a common indicator, the emergy. It provides synthetic information, facilitating the comparative assessment of energy in the overall contextual energy flow and allowing for an easier comparison of much broader environmental effects. Yi et al. [18], also argue that emergy analysis has an ecological understanding that allows buildings to be conceptualised as locally designed ecosystems, i.e. part of the micro-geobiosphere, incorporating them into the dynamic energy demand of the global environment. Furthermore, according to Yi et al. [14] and Srinivasan et al. [16], this method also assesses the quality, hierarchy and direction of energy flow (from high quality to low quality) for all human services and products.

Regarding the limitations of the emergence technique, Cao et al. [15], Li and Wang [11] and Yi, Srinivasan and Braham [13] state that the impact of emissions of environmental pollutants, such as SO2 and NOx, and acidification, and the waste discarded from the transformation process are often ignored in studies because the relevant emergy accounting ends after the product or service has been generated. This is because Emergy Theory is derived from natural ecosystems, and there is no waste in natural ecosystems. The authors also criticise this method because of the strange generalisation of transformation values, its uncertainty in the synthesis process and its unstable definition of the global energy baseline. Finally, another weakness pointed out by Cao et al. [15] is that in classical EmA all purchased inputs are considered to be non-renewable ones.

Concerning the modified or improved Emergy Analysis, Cao et al. [15] claim that, as an advantage, this method distinguishes between inputs acquired from renewable sources and inputs acquired from non-renewable sources, surpassing the traditional EmA in this aspect. EmA also distinguishes the quality differences of a variety of resources compared to other methods.

However, as pointed out by Cao et al. [15], modified EMA lacks information related to the system under study. Therefore, it is necessary to improve the value databases, which should cover the main industries in various regions.

The last method derived from emergetic analysis is the Building Emergy Analysis - BEmA. Yi et al. [18] emphasise that the environmental information obtained by this method identifies the building's environmental metabolic performance. And Yi et al. [14] report that it accounts for the environmental performance of a building in a macroscopic view, thus allowing it to be compared with other environmental systems, being useful in Net-Zero Energy Building (NZEB) studies, due to its ability to evaluate the costs indirectly incorporated and invested to generate renewable energies. No limitations are mentioned for this technique.

3.4 Ecosystem Methods

The three ecosystem methods mentioned are Ecosystem *Services Analysis* (ESA), Ecological LCA (Eco-LCA) and Habitat Change Potential for which no details are given on the limitations. However, Izaola and Akizu-Gardoki [12] state that only the inclusion of ecosystem functions or structure is an advantage. Besides being a freely available *online*

tool, Ecological LCA, according to Srinivasan et al. [16], it expands the boundaries of the system and examines the impacts on ecosystem services that are not studied by other tools [13]. On the other hand, the authors state that the Eco-LCA model uses only monetary values as inputs and has similar problems to those inherent in EIO-LCA. Azari [13] states that this method does not allow the comparison of buildings that use products of different origins within a construction sector.

And as far as Ecosystem Services Analysis is concerned, it is the only one that directly relates the impacts of building materials to ecosystem services. However, Zari [19, 20] states in her studies that due to the lack of development and research on the subject, there are no concepts or relationships between the various types of materials and the exact quantitative impact they have on ecosystems. There are no quantifiable ecosystem service metrics for each material, except when calculated for specific projects in specific locations. Applying this method, therefore, requires a complex, multi-scalar and multidisciplinary approach. In addition, the globalisation of production makes it difficult to obtain data on the various processes used in manufacturing.

4 Conclusion

We conclude that numerous methods are currently available, grouped into four classes, which incorporate ecosystem concepts into LCA for the construction sector to varying degrees. This study also highlights the advantages and, in particular, the limitations previously identified in the literature regarding these methods, such as the absence of a common metric for assessing the impacts of construction materials on different ecosystem services, the subjectivity and uncertainties involved, the high data requirements, the inherent complexity of the approaches, the challenges of quantifying non-market aspects, and the difficulties associated with defining and assessing system boundaries and life-cycle stages.

Consequently, the results indicate that ES are still not adequately integrated into LCA for buildings and construction materials, as existing methods face substantial constraints. Based on the findings, "methods" may not be the most effective means through which ecosystem services can be incorporated into LCA, which opens possibilities for future reviews aimed at answering the question: *what types of artefacts or assessment tools are currently being used to integrate ecosystem services into LCA?*

It is also recommended that future reviews draw upon additional databases, as other relevant studies may not have been captured in the present search and could contribute to answering this question. Therefore, there is a clear need to develop a new assessment tool capable of evaluating the impacts of construction materials on ES, overcoming the limitations identified here and supporting built-environment professionals in material selection—potentially functioning as a certification mechanism and contributing to greater circularity in the built environment.

Abstract. Reducing CO_2 emissions in the built environment requires a comprehensive understanding of impacts across all life-cycle stages of buildings. Current Life Cycle Assessment (LCA) frameworks predominantly focus on operational energy use and, increasingly, on the embodied impacts of construction materials. However, heating, ventilation, and air-conditioning (HVAC) systems - despite their critical influence on both operational performance and embodied emissions - remain largely underrepresented in existing LCA practices. This omission risks overlooking substantial carbon contributions associated with the production, maintenance, replacement, and end-of-life stages of mechanical equipment. This paper addresses this methodological gap by examining how HVAC systems can be systematically integrated into building LCAs, with particular emphasis on highly efficient and renewable energy systems. First, key characteristics of HVAC components and their material compositions are analyzed to identify the inventory data required for embodied carbon calculations. Second, the study proposes an approach for linking equipment lifespans, maintenance cycles, and replacement schedules with the building's operational phase to produce more accurate long-term emission profiles. The interaction between the embodied impacts of energy systems and their operational performance is discussed, highlighting potential trade-offs and synergies when selecting low-carbon technologies. Therefore, the case study highlights that differences in the HVAC system configuration affect the total life-cycle emissions and underlines the need to explicitly integrate HVAC equipment into whole LCAs to avoid substantial underestimation of true building emissions.

Keywords: HVAC systems · Building LCA · Operational energy demand · Embodied Carbon

1 Introduction

The building sector is of critical importance in achieving national and international climate protection goals. In addition to reducing operational greenhouse gas (GHG) emissions, research and regulation are increasingly focusing on the entire life cycle of

buildings. In Germany, the energy efficiency of buildings is regulated primarily by the Building Energy Act, which aims to minimize the non-renewable primary energy requirement during operation [1]. Alongside this, holistic assessment approaches are gaining importance, incorporating not only the use phase but also the construction, maintenance, replacement, and demolition of buildings. In parallel, holistic assessment approaches are gaining importance, extending the scope to include construction, maintenance, replacement, and demolition [2]. Methodologically, these assessments build on LCA principles according to DIN EN ISO 14040 and DIN EN ISO 14044, which define goal and scope, life cycle inventory, impact assessment, and interpretation [3, 4]. In the building context, DIN EN 15978 specifies the life cycle phases and environmental impact categories to be considered, thereby operationalizing these general principles [2].

Despite the fact that this normative framework calls for the comprehensive coverage of all building-related components and systems, practical applications have often focused on structural elements and the building envelope, and thus increasingly on the embodied carbon of construction materials. Conversely, building services engineering, HVAC systems, are frequently modelled in a simplified or relatively generic manner and are mostly not accounted for in detail in LCA assessments. This is problematic, as HVAC systems significantly affect both operational energy performance and embodied GHG emissions: depending on building type and system configuration, building services equipment can account for approximately 5–20% of the total life cycle GHG potential of residential buildings [5]. For office buildings, contributions between 15% and 36% of total embodied emissions have been reported, while conservative reviews estimate typical shares in the range of 10–12% [6]. HVAC systems therefore cannot be regarded as marginal components; they constitute a substantial source of building-related emissions.

The integration of HVAC systems poses specific challenges due to their comparatively short service lives relative to the building structure. While load-bearing structures are typically designed for reference periods of 50 years or more, many components of technical building equipment exhibit significantly shorter life cycles. In Germany, VDI 2067 is widely used to estimate the economic service life of building services systems; the guideline values provided are often adopted as a basis for replacement assumptions in Module B4 according to DIN EN 15978 [2, 7]. However, these tables were developed primarily for economic evaluations rather than for LCA purposes. Their direct transfer into environmental assessments therefore requires additional assumptions concerning technological development, modernization cycles, actual operating conditions, and the influence of regulatory or innovation-driven replacement decisions, all of which introduce further uncertainty into long-term emission forecasts.

The relevance of technical building equipment is increasingly reflected in the scientific literature. Research on net-zero energy residential buildings shows that the choice of HVAC system has a decisive impact on overall performance, with configuration-dependent trade-offs between operational and embodied emissions. Efficiency gains during the use phase can be accompanied by higher manufacturing impacts, leading to tensions between short-term emission reductions and long-term life cycle optimization [8]. At the same time, methodological uncertainties are highlighted: product-specific environmental declarations are usually only available for a limited set of complex systems, which is why simplified approaches such as material-based estimation methods

or standardized guidelines like CIBSE TM65 are often applied [9]. Comparative studies demonstrate that these methodological choices can result in substantial deviations, particularly for manufacturing impacts and assumptions regarding refrigerant losses during use and at end-of-life.

Systematic reviews further emphasize that building services, despite their material complexity and high replacement frequency, are underrepresented in holistic sustainability and circular economy strategies. A recurring issue is the lack of a consistent linkage between the embodied emissions of building services equipment and their influence on the operational energy performance of the building as a whole. While operational energy use is typically analyzed in detail in Module B6, the underlying technical systems are often represented in an aggregated or simplified manner, which obscures the interactions between efficiency gains and additional material use [10].

In summary, the current state of research shows that the normative framework allows for the comprehensive integration of technical systems, yet practical implementation remains methodologically inconsistent – particularly with regard to data availability, modelling of service lives and replacement cycles, and the coupling of manufacturing and operational phases. Against this background, the present paper aims to address this methodological gap by proposing a structured approach for integrating HVAC systems into building-related LCAs, establishing a robust basis for quantifying both embodied and operational emissions of technical building equipment and thereby enabling more informed decisions on climate-compatible building technologies.

2 Methodology

In order to address the HVAC embodied energy impacts, the LCA is carried out to evaluate the global warming potential (GWP) associated with (1) embodied impacts, (2) maintenance, (3) operation and (4) recycling. The first step is to determine the energy requirements for heating, cooling, and ventilation based on the building's usage requirements and the requirements for thermal comfort and indoor air quality in accordance with DIN EN ISO 7730 and DIN EN 16798-1. The resulting specific energy requirements in kWh/(m^2·a) and the building area form the basis for the selection and dimensioning of the HVAC systems. In this study only the climate impact, expressed as GWP in kg CO_2 equivalents is considered.

Environmental Product Declarations (EPDs) and generic data sets from publicly accessible databases, including ÖKOBAUDAT and EPD International, are used to quantify the embodied emissions of individual components. Since complete product-specific EPDs are not yet available for many components of technical building equipment, embodied emissions are estimated in part using generic material data sets in accordance with the methodology from CIBSE TM65. This is based on a life cycle inventory of the materials used, in which the mass and material composition of the individual products are recorded. The emission factors for the manufacturing phase are taken from modules A1–A3, which cover raw material extraction, material processing, and manufacturing up to the factory gate.

Embodied emissions are initially calculated on the basis of a product's material composition. The emissions from material procurement in module A1 are calculated as

the sum of the products of total product mass, material content, and material-specific emission factor.

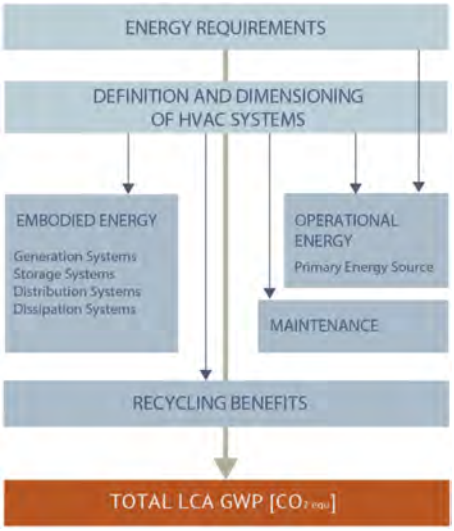

Fig. 1. Aspects of the LCA of a HVAC system.

Further, energy-related emissions from manufacturing are considered. These are allocated to the total quantity produced based on the annual energy consumption of the production facility and assigned proportionally to the product under consideration.

The HVAC systems include all components from energy generation and supply to energy distribution in the building and transfer to room-side components such as air diffusers, panel heating systems, or fan coils. The energy demand at room level determines the dimensioning of the system components and their interactions. For example, heat recovery in ventilation systems reduces ventilation heat losses and thus influences the required output of the heat generators. The efficiency of heat pumps or chillers depends largely on the system temperatures, which is why corresponding flow and return temperatures are considered in the system design. With the increasing share of renewable energies, it is also expected that electrical and thermal storage will be increasingly integrated into building systems.

In addition to embodied emissions, operational emissions during the use phase are also taken into account. See also Fig. 1. These depend largely on the CO_2 intensity of the final energy used. Since both the electricity mix and district heating in Europe will be decarbonized in the long term, it can be assumed that the operational emissions of future building systems will decrease. At the same time, a large proportion of embodied emissions are generated at the beginning of the life cycle during the manufacturing phase. Against this background, the relative share of embodied emissions in the total greenhouse gas emissions of buildings and their technical systems is expected to increase significantly in the future.

3 Case Study: Centralized vs Decentralized Ventilation of a School Room

This study is a scenario-based LCA using representative default parameters due to limited availability of product-specific environmental and service life data for HVAC systems. The results therefore represent comparative system behavior rather than absolute validated emission values. To provide a practical example for the application of the methodology approach, a two-story school with six classrooms is used as a case study. The net floor area of the building is 760 m^2, and a typical classroom has an area of 67 m^2. Two ventilation concepts are compared: (i) a centralized ventilation and air conditioning system (HVAC) with a central ventilation unit in the basement and air-side access to all rooms via a network of air ducts, and (ii) a decentralized solution with one ceiling-mounted ventilation unit per classroom. In both variants, a maximum air volume flow of 1000 m^3/h per classroom is provided in order to limit the CO_2 concentration to around 1000 ppm. In both cases, the air volume flows are regulated as needed via CO_2 sensors. The air is distributed in the room via diffusers and control components integrated into a reversible metal panel ceiling, while the main differences lie in the overall air flow and the arrangement of the system components (centralized vs. decentralized). Furthermore, the two systems differ in their operating hours. By decentralizing the system, the hours can be reduced, resulting in fewer operating hours. The boundary conditions of the study are summarized in Table 1.

For the decentralized variant, the embodied emissions are related to the relevant components of the ventilation system in the classroom. The largest contributions derive from the decentralized ventilation unit itself (ventilation unit AHU: 29 kg CO_2eq; production AHU: 15 kg CO_2eq), as well as the air distribution in the room (diffusers: 28 kg CO_2eq) and the metal panel ceiling (20 kg CO_2eq). Additional emissions are generated by silencers (7 kg CO_2eq), which are required for the maximum permissible sound level of approximately 35 dB(A) in classrooms. In practice, the installation of the units is often supplemented by a ceiling coffering made of metal panels, which serves both design and acoustic functions (Fig. 2a).

In the centralized variant, the highest embodied emissions are attributable to the air distribution network, including outside air intake and exhaust air ducting (centralized air distribution + air intake and exhaust tower: 85 kg CO_2eq). The centralized ventilation unit (33 kg CO_2eq), the metal panel ceiling in the classroom (26 kg CO_2eq), and the room-side diffusers (26 kg CO_2eq) also contribute significantly to the overall balance. The ventilation room itself causes comparatively low emissions (ventilation room: 7 kg CO_2eq). See Fig. 2b. This shows that, in the centralized solution, the overall air ducting and the duct system dominate the embodied carbon balance, while the room-side components are similar in both concepts.

For better comparability, GWPs are based on a single classroom and one year and include embodied carbon (A1–A5), emissions from maintenance (B2–B5), operational emissions (B6), and credits from end-of-life recycling (D). In the decentralized variant, 115 kg CO_2eq/a are attributable to embodied carbon and 26 kg CO_2eq/a to maintenance processes, while the operational emissions of the ventilation system amount to 92 kg CO_2eq/a. In addition, the recycling results in a credit of −20 kg CO_2eq/a.

Table 1. Boundary conditions of the school room used as case study.

School building with two floors, net ground area 2 x 380 m2, 6 class rooms	
Centralized air conditioning system	Decentralized air conditioning system
max.1000 m^3/h/room (1000 ppm CO_2)	
Supply air control bei CO_2-concentration (variable air ventilation)	
Centralized Air-Handling-unit (AHU) in basement	6 decentralized, ceiling based AHU in class rooms
1536 h/a hours of operation per year	1350 h/a hours of operation (natural ventilation)
Centralized preheating at 20 °C (winter)	Decentralized electrical preheating at 17 °C
Supply air cooling optional	
Centralized air distribution in building	Decentralized air distribution in class room
Outdoor air intake-exhaust tower	Facade-integrated weatherproof grille in classroom
Decentralized air distribution, diffusers, controllers installed inside of a reversible suspended metal ceiling	Decentralized AHU, diffusers, installed inside of a reversible suspended metal ceiling

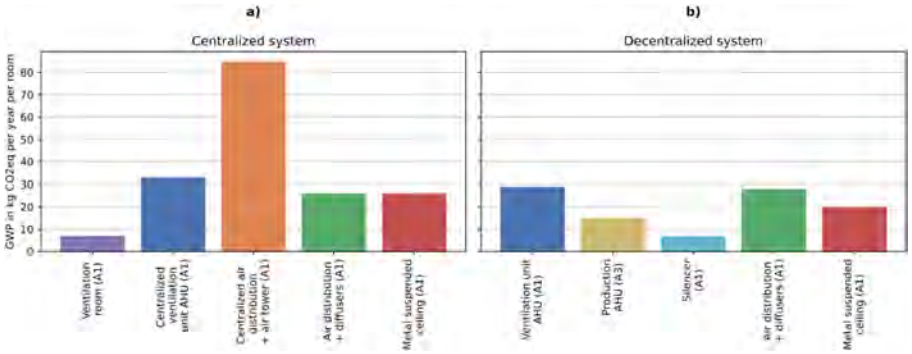

Fig. 2. GWP of the embodied carbon of a) the centralized system and b) the decentralized system.

For the centralized solution, embodied emissions are 181 kg CO_2eq/a, which is significantly higher than the decentralized variant; maintenance causes 32 kg CO_2eq/a. Operational emissions from ventilation amount to 168 kg CO_2eq/a, which is mainly due to higher pressure losses in the central air distribution network. The credit from recycling amounts to −23 kg CO_2eq/a.

Overall, the comparison shown in Figs. 3 and 4 indicates that the decentralized solution results in lower embodied and operational GHG emissions, mainly due to shorter air paths, demand-based control, and reduced fan power.

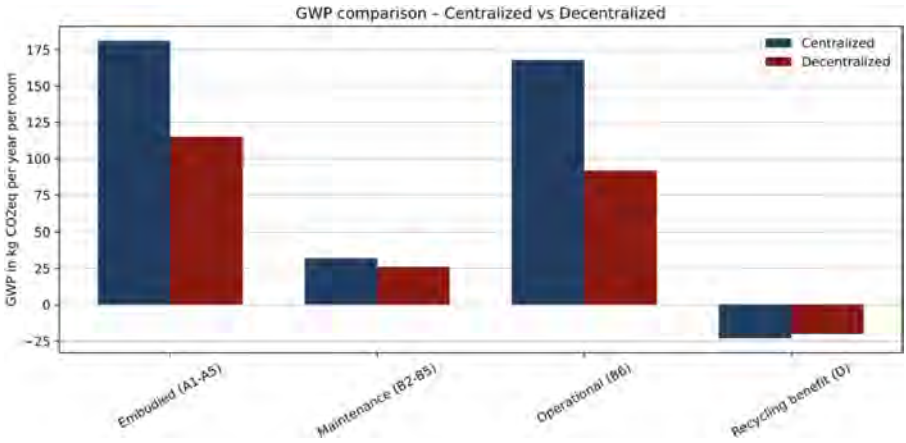

Fig. 3. GWP comparison of centralized and decentralized system in different life cycle stages.

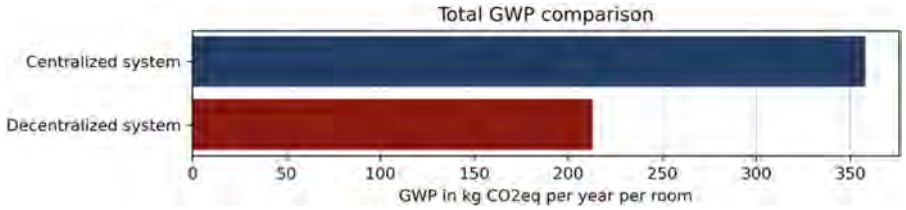

Fig. 4. Total GWP comparison of centralized and decentralized system through the life cycle.

4 Conclusion

In the context of climate protection in the building sector, it will increasingly no longer be sufficient to optimize operational energy efficiency and minimize investment costs for building services engineering alone. The study indicates that HVAC systems can contribute a notable share of total life cycle GHG-emissions, particularly when both embodied impacts and system dependent operational effects are considered. Their relevance is therefore strongly dependent on system design, building type, and boundary conditions, highlighting the importance of their explicit inclusion in building-level LCAs. With the new edition of the Ecodesign Directives (e.g., EU Regulation ESPR 2024/1781 and digital product passport) and the ongoing decarbonization of end-use energy, purely operational metrics are becoming less meaningful, while embodied carbon, material efficiency, and recyclability are gaining in importance.

The proposed approach links material balances, service lives, maintenance cycles, and replacement rates of HVAC components with the operating phase, thus enabling reliable, long-term emission profiles, including possible credits from reuse and recycling. The case study on a school ventilation demonstrates that differences in design and system architecture have a significant impact on both embodied and operational emissions, and that supposedly “efficient” solutions can be relativized ecologically during operation due to high material and replacement costs. For planning, standardization, and

legislation, this highlights the need to explicitly integrate HVAC systems into whole-life-cycle assessments, to focus on renewable and material-efficient concepts at an early stage, and to base system decisions not only on energy performance indicators but also on holistic GWP balances.

An ESG-Integrated Environmental Impact Assessment Method for Circular Transformation of the Built Environment

Nadezhda Afyan(✉)

Armenian State University of Economics, 128 Nalbandyan, 0025 Yerevan, Armenia
nafyan15@gmail.com

Abstract. This study proposes an ESG-integrated Environmental Impact Assessment (EIA) method for evaluating sustainability and circular economy performance in the built environment. The research extends conventional EIA by incorporating environmental, social, and governance (ESG) dimensions into a unified lifecycle framework that assesses resource circulation, material and energy flow efficiency, social inclusion, and governance transparency. The method is developed through a comparative analysis of key international ESG frameworks, including the GRI Standards and the EU Taxonomy, and environmental management principles reflected in ISO 14001. It is aligned with Armenia's sustainable finance architecture and the ESG Risk Radar logic of the Central Bank of Armenia. The method is pilot-tested on three Armenian built-environment projects from the manufacturing and infrastructure-related sectors using national EIA documentation, production information, and sectoral risk-screening logic. The proposed ESG-EIA method combines risk-based screening, a 15-indicator ESG matrix, sector-sensitive weighting, ecosystem services assessment, material and energy flow modelling, heat-map visualization, and composite ESG performance scoring. Pilot results demonstrate improved early identification of resource inefficiencies, decarbonization gaps, and social and governance risks compared with conventional EIA practice. The findings show that integrating ESG metrics into EIA enhances the robustness of sustainability assessment and supports evidence-based investment, urban planning, and circular transformation decisions in line with national sustainable finance priorities.

Keywords: Environmental Impact Assessment · ESG Integration · Built Environment · Circular Economy · Risk-Based Screening · Cumulative Impacts

1 Introduction

The transition to circular and low-carbon development models in the built environment has become a major priority of sustainability policy, investment governance, and urban transformation. The sector is closely connected with material extraction, energy use, water demand, land transformation, waste generation, and community impacts. Therefore, assessment methods need to capture direct, cumulative, and lifecycle-based risks.

Environmental Impact Assessment (EIA) remains the main regulatory instrument for identifying and mitigating project-level environmental risks. Yet conventional EIA is not always connected to social accountability, governance transparency, financial risk screening, and circular economy performance. Issues such as material efficiency, decarbonization potential, stakeholder impacts, and monitoring capacity may therefore remain fragmented across separate documents.

Environmental, social, and governance (ESG) frameworks have become central to sustainable finance and investment decisions. The EU Taxonomy supports sustainable investment classification, while the GRI Standards structure impact reporting and ISO 14001 supports environmental management systems [1–3]. For Armenia, this creates an opportunity to connect project-level EIA evidence with finance-oriented ESG risk assessment.

The Armenian context illustrates this need. Circular initiatives in the Pambak and Spitak communities, including greenhouse production, stone veneer manufacturing, dairy production, cold-storage services, and slaughterhouse operations, show both environmental pressures and circular opportunities. Large enterprises more often operate under formal EIA, ESG disclosure, and management systems, while SMEs usually have weaker reporting capacity but greater flexibility in resource reuse and process adjustment.

Building on these observations, this study proposes an ESG-integrated EIA method for evaluating sustainability and circular economy performance in the built environment. The method is designed for both large enterprises and SMEs and assesses resource circulation, material and energy efficiency, social inclusion, governance transparency, and sustainable finance relevance.

2 Literature Review

The literature emphasizes the increasing role of ESG criteria in infrastructure planning, corporate governance, and investment decision-making. ESG can complement EIA by translating environmental evidence into indicators understandable for regulators, investors, and enterprise managers [5–8].

International frameworks provide the basis for this integration. The EU Taxonomy links sustainable activities to climate, circular economy, pollution, water, and biodiversity objectives [1]. The GRI Standards structure sustainability impact reporting [2], while ISO 14001 emphasizes planning, monitoring, corrective action, and continual improvement [3].

SMEs represent the majority of enterprises [9], but ESG reporting and certified environmental management systems remain concentrated mainly among larger companies. SMEs represent the majority of enterprises, but ESG reporting and certified environmental management systems remain concentrated mainly among larger companies. This creates a governance gap: SMEs may have significant cumulative material, energy, water, and waste impacts, yet limited administrative capacity for complex reporting.

For Armenia and similar transition economies, sustainable finance initiatives increase the need for comparable ESG information. The Central Bank of Armenia's sustainable finance work and ESG Risk Radar logic emphasize sectoral exposure to climate-related, environmental, social, and governance risks [4].

Overall, the literature reveals a methodological gap in the systematic integration of ESG indicators and circular value-chain logic into EIA. This study addresses that gap by proposing a 15-indicator ESG-EIA framework for cumulative impact assessment, lifecycle interpretation, and finance-oriented decision-making.

Environmental assessment effectiveness depends on its influence on decisions and implementation [10]. However, ESG indicators and circular value-chain logic remain insufficiently integrated into EIA. This study addresses that gap by proposing a 15-indicator ESG-EIA framework for cumulative impact assessment, lifecycle interpretation, and finance-oriented decision-making.

3 Methodology

3.1 Research Design and Conceptual Framework

The research applies a conceptual and pilot-testing design. International ESG and environmental management frameworks were compared to identify indicators relevant to circular transformation. These indicators were then translated into an ESG-integrated EIA matrix and tested on three Armenian pilot cases: "Qaradzor Agro", "Hope Labe", and "Makur Bnutyun". The assessment used EIA documentation, project descriptions, available production and resource-use information, and sectoral risk-screening logic aligned with Armenia's ESG Risk Radar approach [4].

The framework covers five lifecycle stages: input, production, distribution/use, end-of-life, and reintegration. This structure moves the analysis beyond isolated project impacts and shows how environmental, social, and governance risks accumulate across the value chain. The reintegration stage is essential for circular economy assessment because it captures reuse, secondary materials, and waste-to-resource feedback loops (Fig. 1).

3.2 ESG Indicator Matrix and Parameters

To improve transparency and reproducibility, the framework uses 15 indicators grouped into environmental, social, and governance sub-indices. The indicators were selected according to relevance to circular transformation, measurability through EIA or enterprise-level information, and applicability to both large organizations and SMEs. Table 1 operationalizes each indicator.

Table 1. ESG-EIA indicator matrix and operational parameters (Source: author's own elaboration)

Sub-index	No.	Indicator	Specific parameter	Measurement	Main source
E	E1	Material intensity	Quantity of primary or secondary material per unit of output	kg or t/unit	EIA, production records

(*continued*)

Table 1. (*continued*)

Sub-index	No.	Indicator	Specific parameter	Measurement	Main source
E	E2	Energy intensity	Energy consumed per unit of output or service	kWh or MJ/unit	Energy records, technical data
E	E3	Water intensity	Water consumed per unit of output, area, or service	m3/unit	EIA, permits, enterprise records
E	E4	Emissions intensity	Direct and indirect emissions related to production or operation	tCO2e/unit	EIA, fuel and energy data
E	E5	Waste and recycling rate	Share of waste reused, recycled, or diverted from disposal	%	Waste management plan
S	S1	Occupational safety	Accident exposure, safety measures, and worker risk controls	score 0–1	EIA, enterprise data
S	S2	Local employment	Share of jobs or contracts involving local communities	%	Project records
S	S3	Community impact	Noise, traffic, odour, land-use conflict, and nuisance exposure	score 0–1	EIA, public consultations
S	S4	Inclusion and access	Participation of vulnerable groups and access to benefits	score 0–1	Project documentation
S	S5	Health and sanitation risk	Potential sanitary, hygiene, and public health risks	score 0–1	EIA, sanitary assessment
G	G1	Compliance status	Permits, EIA decision, legal conformity, and reporting duties	score 0–1	Regulatory documents
G	G2	Risk management system	Presence of procedures for identifying and managing ESG risks	score 0–1	Management documents

(*continued*)

Table 1. (*continued*)

Sub-index	No.	Indicator	Specific parameter	Measurement	Main source
G	G3	Monitoring and responsibility	Existence of monitoring plan, indicators, and responsible persons	score 0–1	EMP, EIA report
G	G4	Transparency and disclosure	Availability of public information, reporting, and stakeholder feedback	score 0–1	Reports, website, hearings
G	G5	Financial and ESG alignment	Compatibility with banking ESG risk screening and sustainable finance criteria	score 0–1	Loan documents, ESG radar logic

3.3 Normalization, Weighting, and Sector-Sensitive Interpretation

Each indicator is normalized on a 0–1 scale, where 0 reflects weak performance or high unmanaged risk and 1 reflects stronger performance or lower managed risk. Quantitative indicators are normalized using benchmark or relative values, while qualitative indicators are scored through documentary evidence, expert judgment, and the presence of formal procedures. Sub-indices and the composite ESG-EIA score are calculated as weighted averages.

The weighting system was designed as a baseline framework applicable across the pilot cases. However, sector-specific sensitivity was considered during interpretation because ESG risks differ by project type. For example, sanitary and community risk indicators receive greater analytical attention in slaughterhouse-related activities; resource efficiency, process waste, and material circularity are more significant in stone manufacturing; while greenhouse production requires closer attention to water and energy intensity. Therefore, the proposed weighting approach combines a common ESG structure with sector-sensitive interpretation rather than applying a mechanically uniform assessment logic across all sectors.

The assessment process includes five steps: risk-based screening, ecosystem services assessment, material and energy flow modelling, heat-map visualization, and composite ESG scoring. This sequence identifies high-risk lifecycle stages, evaluates land, water, and biodiversity impacts, estimates circularity opportunities, and summarizes ESG performance for decision-making.

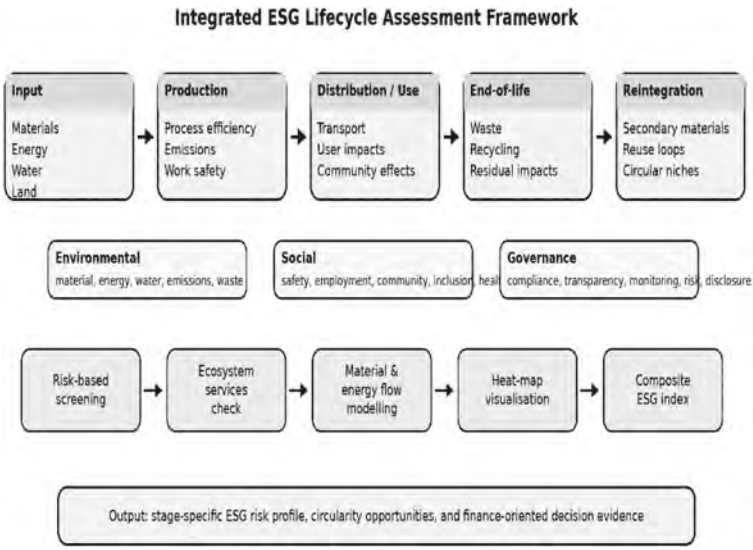

Fig. 1. Integrated ESG lifecycle assessment framework (Source: author's own elaboration)

4 Results and Discussion

4.1 Pilot Results

The pilot application shows that ESG-integrated EIA enables earlier identification of resource inefficiencies, decarbonization gaps, and social and governance risks. Compared with conventional EIA, it better captures how environmental impacts interact with social vulnerability, monitoring capacity, and finance-oriented ESG risk signals.

In "Qaradzor Agro", the input and production stages revealed potential water savings of approximately 14% and energy savings of about 9%, mainly linked to irrigation and greenhouse energy management. In "Hope Labe", the production stage showed approximately 15% potential for material flow optimization through process waste reduction and partial use of secondary materials. In "Makur Bnutyun", production and distribution stages showed higher emissions, water, sanitation, and community-impact risks, indicating that conventional EIA alone may not fully capture the combined ESG profile (Table 2).

Table 2. Comparative pilot results of the ESG-integrated EIA method (Source: author's compilation based on the pilot assessments)

Case	Dominant lifecycle risk	Key ESG issue	Circular opportunity	Assessment implication
Qaradzor Agro	Input and production	Water and energy intensity	Irrigation optimization and energy saving	Environmental indicators dominate, but monitoring capacity determines bankability
Hope Labe	Production and reintegration	Material intensity and process waste	Secondary material use and waste reduction	SME flexibility supports circular niche development
Makur Bnutyun	Production and distribution	Water, emissions, sanitation, and community impact	Wastewater control and logistics improvement	Social and governance safeguards require stronger weighting

4.2 Reintegration and the Role of SMEs

The results also clarify the role of SMEs during the reintegration stage. Although SMEs often perform weakly in formal governance and accountability indicators, they may have advantages in circular experimentation because they usually have shorter decision-making chains, flexible production routines, and closer control over material flows.

For example, stone veneer manufacturing may reintegrate secondary material streams, greenhouse production may introduce water- and energy-saving practices quickly, and food-processing activities may improve waste separation and by-product handling when technical support is available. SMEs should therefore be viewed not only as compliance-limited actors, but also as potential niche innovators in circular economy implementation.

This finding is important for sustainable finance because ESG-EIA results can help banks distinguish between weak documentation and genuine circular improvement potential. This supports targeted lending, technical assistance, and staged compliance pathways for SMEs.

4.3 Contribution to EIA Practice and Sustainable Finance

The framework contributes to EIA practice by linking project-level evidence with ESG indicators, expanding assessment to lifecycle stages, and enabling comparison across activities through a common matrix with sector-sensitive interpretation.

The method supports Armenia's sustainable finance priorities by improving the traceability of environmental and social information. EIA documents often contain data on resources, emissions, waste, land use, and mitigation measures, but these data are not always organized for ESG risk assessment. The proposed method reorganizes this information without replacing the legal EIA procedure.

At the policy level, ESG-integrated EIA can strengthen circular economy governance in the built environment, support differentiated requirements for large enterprises and SMEs, and improve information quality for sustainable investment decisions. Its accuracy depends on EIA data quality, enterprise-level resource records, and consistent expert scoring.

5 Conclusion

This study developed and pilot-tested an ESG-integrated Environmental Impact Assessment method for circular transformation of the built environment. The method extends conventional EIA through a lifecycle-based 15-indicator ESG matrix, sector-sensitive weighting, risk-based screening, ecosystem services assessment, material and energy flow modelling, heat-map visualization, and composite ESG scoring.

The pilot cases show improved early identification of resource inefficiencies, decarbonization gaps, and social and governance risks. "Qaradzor Agro", "Hope Labe", and "Makur Bnutyun" demonstrate that environmental risks concentrate mainly in input and production stages, while cumulative and indirect effects become more visible during distribution, end-of-life, and reintegration. SMEs may be weaker in formal governance, but stronger in flexible circular experimentation.

The main contribution of the study is the methodological bridge between EIA, ESG assessment, circular economy logic, and sustainable finance. The framework can help regulators improve sustainability assessment, banks evaluate ESG-related project risks, and enterprises identify practical circular transformation opportunities.

The Relevance of the End-of-Life for Earth Blocks to Evaluate Their Circularity Potential and Environmental Impact

Laura Claes(✉), Griet Verbeeck, and Elke Knapen

Faculty of Architecture and Arts, Hasselt University, Diepenbeek, Belgium
laura.claes@uhasselt.be

Abstract. In the shift toward the use of low-impact and more circular materials, there has been an increase in life cycle assessments (LCAs) of earth-based constructions to quantify their environmental impact. In these evaluations, the end-of-life (EOL) plays a crucial role, as it can significantly enhance their circularity potential and, therefore, reduce their environmental impact. However, benefits and loads related to the EOL are often overlooked in current LCAs. Hence, this study aims to contribute to the ongoing debate on EOL evaluation for circular earth products, specifically earth blocks, through a targeted literature review and an LCA to assess the environmental impact of earth block applications. Given the relatively recent reintroduction of earth blocks in contemporary construction, their EOL processing has yet to be established. Therefore, specific attention is given to current key factors concerning present and possible future EOL scenarios for earth blocks. In addition, qualitative indicators that are currently not included in the LCA methodology, such as longevity, regenerative potential, and renewability (multiple life cycles), relevant for the circularity potential and environmental impact, are investigated. The study revealed that EOL scenarios for earth blocks are underdeveloped, leading to neglect of the aforementioned indicators in the current LCA methodology. Together with its quantitative nature, LCA is only partially suited for EOL evaluation of circular earth products, failing to capture their environmental and circular potential. A better understanding of the importance of the EOL and its associated impact will facilitate the further development of possible EOL scenarios for earth block applications.

Keywords: Life Cycle Assessment · Earth blocks · End-of-life · Circularity · Environmental Impact

1 Introduction

Over the past decades, the growing awareness of the high embodied energy of conventional construction materials and the ongoing depletion of natural resources [1] has led to renewed interest in low-impact and more circular materials. As a result, the use of earth-based building materials, such as earth blocks, is becoming more prevalent in real-life applications, as their possible environmental benefits are increasingly recognised

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 1076–1083, 2026.
https://doi.org/10.1007/978-3-032-34930-9_125

[2]. To quantify their environmental impact and facilitate comparison with conventional building materials [3], in the last few years, a growing number of life cycle assessments (LCAs) of earth-based building materials have been conducted [4]. In these environmental evaluations, the end-of-life (EOL) is essential. Any associated impacts, both positive and negative, must be considered, especially for building materials that can be reused or recycled, such as earth blocks [5]. For this reason, how earth products are treated at the EOL can enhance their circularity potential and thereby reduce environmental impact. However, the EOL is often not included in current LCAs and, if it is, landfill is the only possible EOL scenario considered, as the chosen system boundary for the majority of the LCAs is cradle-to-gate [2, 4]. This exclusion of the EOL results in a limited understanding of its potential benefits and loads, and, moreover, the relationships between EOL scenarios, environmental impact and circularity. Hence, to address this knowledge gap, the main objective of this study is to add to the ongoing discussion on EOL evaluation of circular earth products, with a specific focus on earth blocks. Provided that possible EOL scenarios are not yet established due to the recent adoption of earth blocks in contemporary construction, current key factors concerning present and potential future EOL scenarios are examined through a targeted literature review. In addition, the study explores qualitative indicators that are currently overlooked in LCAs and can contribute to the environmental and circular potential of earth blocks. The limitations of EOL evaluation in LCA methodology are investigated, building on the authors' ongoing research, namely an LCA study of non-load-bearing, earth-block-based partition walls, with the aim of providing a more complete perspective on the potential of earth blocks.

2 Methods

The methodology follows a two-step approach to identify qualitative indicators that are frequently omitted from current LCAs. Initially, key factors related to present and possible future EOL scenarios were determined through a targeted literature review. This phase focused on synthesising common hurdles in today's industry related to the EOL of earth blocks, highlighting recurring gaps in EOL treatment. Subsequently, building on this review of existing literature and the authors' ongoing LCA study of non-load-bearing, earth-block-based partition walls, a set of overlooked qualitative indicators was developed. By conducting the LCA study and, therefore, experiencing its boundaries, specific, often underrepresented indicators critical to evaluating the EOL of earth blocks were derived. Modelling the different LCA stages, particularly the EOL, revealed qualitative variables that the current LCA methodology does not capture. While the LCA study provides empirical grounding for identifying these indicators, the quantitative results of this LCA are outside the scope of this paper. It focuses strictly on the indicator framework itself.

3 Results

3.1 Key Factors Concerning Present and Possible Future End-of-Life Scenarios

As earth blocks are non-standardised products and their application in mainstream construction remains relatively novel, there is a limited understanding of their EOL handling. While their manufacturing and construction techniques have been studied, EOL

constraints and drivers have received less attention [6]. Nonetheless, the EOL is crucial since the use phase of earth blocks will eventually end [7]. Hence, key factors related to EOL scenarios, focusing on the incorporation of recycled materials, stabilisation and waste treatment strategies, are investigated.

Incorporation of Recycled Materials and Stabilisation. Over the years, in the production of earth blocks, efforts have focused on integrating reclaimed excavated material and construction and demolition waste (CDW) to enhance their environmental performance. Excavated material can be recovered from construction sites, offering environmental benefits over disposal [8]. Additionally, the use of CDW (e.g. crushed concrete or brick rubble) has been explored [9]. Nevertheless, although secondary raw materials are used for production, the recycling of earth blocks remains unestablished in practice, despite promising mechanical performance results [10].

Furthermore, unstabilised earth blocks have limited water resistance [11] and lower strength [12] than conventional materials. To improve these properties, additives such as lime or cement are sometimes added as stabilisers. However, this increases the environmental impact during production [13] and affects EOL processing, compromising recyclability [10]. Hence, the recyclability potential of earth-based materials and the effects of stabilisation should be investigated.

Waste Treatment Strategies. At the EOL, earth-based building materials can be reused, recycled, or disposed of, with reuse preferred. However, reuse may not always lead to lower environmental impact due to transportation impacts and disassembly processes [14]. Recycling is complicated by the mixing of earth block waste with conventional materials [7], hindering its effectiveness. Concerning disposal, unstabilised earth products can return to nature because they are chemically unaltered [15], but challenges remain, including legal restrictions on environmental disposal and changes in soil composition from mixing different earth sources and using CDW. For stabilised products, this is even more challenging, as chemical transformations occur.

Therefore, a thorough evaluation of these EOL scenarios and their effect on the environmental impact is required. Fig. 1 shows the current situation for unstabilised and stabilised earth blocks, along with future scenarios. Currently, these materials are treated like conventional building materials, with a small percentage being landfilled and most repurposed as gravel. Some Environmental Product Declarations [16, 17] explore reuse and recycling for new earth blocks, through take-back programs. A more differentiated approach in the future could enhance EOL management, promoting recycling and reuse and encouraging a return to nature rather than landfill.

3.2 Overlooked Qualitative Indicators in LCA Methodology

Current research employs LCA to quantify the environmental impact of building materials. This method allows for the assessment of the EOL, which involves both waste treatment and benefits and loads beyond the system boundary. However, as a quantitative tool, it has its limitations. It often omits qualitative indicators essential to EOL evaluation, thereby obscuring the circular and environmental potential of earth blocks. Therefore, this section discusses three valuable, though underrepresented, qualitative indicators: the material's longevity, regenerative potential, and renewability.

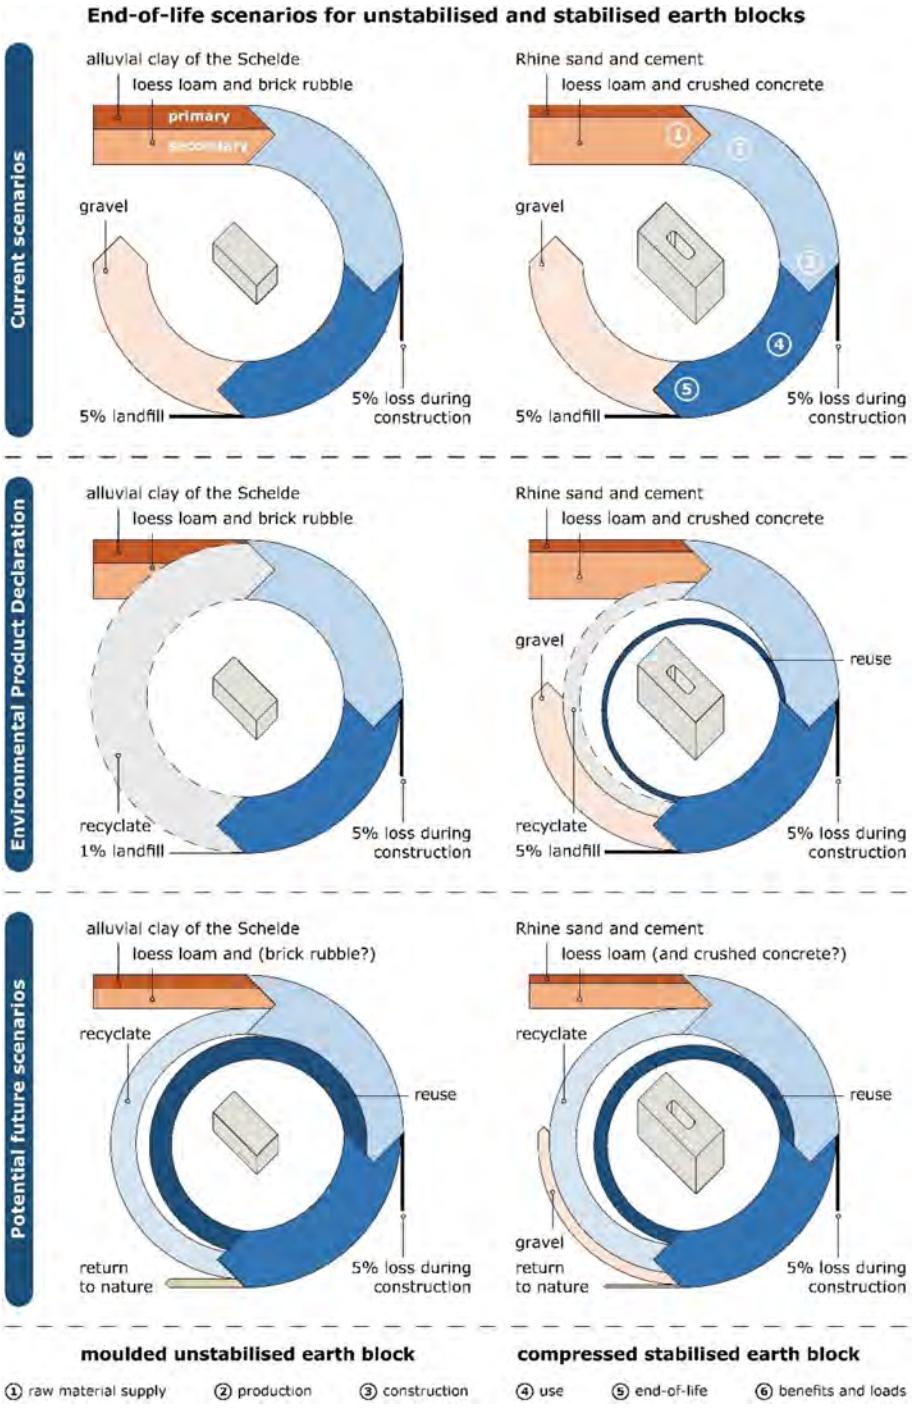

Fig. 1. Present and possible future EOL scenarios for unstabilised and stabilised earth blocks

Longevity. While the EOL of building materials can provide benefits, extending their lifespan should be prioritised. Preventing replacement reduces environmental impacts associated with waste and production. Therefore, longevity is critical, and its inclusion has been recommended for LCAs [18]. However, maintenance and repairs are often not accounted for, or lack transparency in LCAs, and replacement is assumed instead [2]. Furthermore, in Europe, the lifespan is estimated at 50 to 60 years, though the benefits of repair may only be evident over longer periods. A longer reference service life would encourage the use of repairable materials, but it would shift the focus away from the initial environmental impacts [19].

For earth-based materials, repairability is crucial. Unstabilised earth blocks can be repaired with leftover soil, enhancing their lifespan, whereas stabilised earth blocks pose greater challenges due to chemical changes induced by the stabilisation process.

Regenerative Potential. To transition to a circular economy (CE), it is integral to adopt a model that promotes regenerative materials. One aspect of regenerative architecture focuses, namely, on long-term resource availability and maximising the material's value [20]. Nevertheless, the regenerative potential of earth-based materials, such as earth blocks, is undervalued in current LCA methodology. Although these materials are geo-based and non-replenishable, two key attributes of regenerative building are often disregarded: their local resource availability and reversibility.

Local Resource Availability. Using recuperated earth from excavation activities for earth block production is well established. In LCA studies, these benefits are accounted for by attributing the environmental impact of soil extraction to the original excavation activity [2]. Despite allocation concerns, this reduces the impact of earth block production, as shown in Fig. 1, where primary and secondary resources are distinguished. Additionally, local sourcing, which is possible due to soil's wide availability, minimises transportation impacts, a significant factor in the overall environmental performance of earth-based materials [2]. However, LCA methodology does not recognise all advantages of local earth availability, overlooking, for example, its contribution to local economic development, including supply chain resilience.

Reversibility. One possible future EOL scenario for the material is a return to nature, as shown in Fig. 1 for both stabilised and unstabilised earth blocks. The benefit of this scenario is that no waste is left behind, as the material integrates into the ecosystem. Yet, regulatory frameworks remain inadequate, and an LCA does not indicate reduced environmental impact for this scenario. The avoided-burden approach, used to calculate benefits and loads per the EN15804 standard, considers reuse, recycling, and incineration, but does not account for a return to nature. Consequently, by only recognising these scenarios as beneficial EOL options, the continued production of building materials may inadvertently be encouraged.

Renewability.
Traditional LCA studies often focus on a single life cycle. However, the advantages of circular EOL scenarios only become evident when evaluating multiple life cycles [21]. For earth blocks, this multi-cycle perspective is crucial, as they could have closed-loop

material flows [22]. Therefore, their renewability through reuse and recycling, along with the associated benefits and loads, should be assessed.

Reuse. Reusing building materials can significantly reduce environmental impacts by decreasing resource extraction, lowering the risk of depletion, and minimising waste [23], as demonstrated in Fig. 1. While some studies have shown that reusing earth-based materials is feasible, standards for this EOL scenario are lacking [22]. Nevertheless, current LCAs use multiple allocation approaches for EOL impacts, leading to different distributions of benefits and loads among subsequent life cycles [21]. This lack of consensus on assigning environmental impacts associated with the EOL [4] limits the recognition of reuse's advantages.

Recycling. Recycling can reduce environmental impacts by processing waste into new building materials [23], which affects primary resource demands, as shown in Fig. 1. Unstabilised earth blocks can be crushed and sieved to restore their original components [15], while stabilised blocks can be crushed and used to replace coarse granulates. As a result, this recycling process minimises the impacts of excavation, transportation and mixing, and reduces raw material requirements [22]. However, in a classic LCA, recycling yields only limited additional benefits in the next life cycle since the use of secondary raw materials is already integrated into earth block production. This complicates its quantification, making the expression of its benefits unclear.

4 Discussion and Conclusion

While the EOL is crucial for enhancing the circularity and environmental performance of earth-based applications, it is often excluded from LCAs. This omission hinders the understanding of EOL benefits and loads. To fill this gap, this research aims to contribute to the ongoing discussion on EOL assessment of earth products, particularly earth blocks. Key factors regarding their EOL scenarios, along with overlooked qualitative indicators in LCA methodology, were examined.

The study highlighted that, while earth blocks can be reused, recycled, or disposed of, their EOL scenarios are underdeveloped and similar to those of conventional materials. This affects EOL evaluation in LCA methodology, as qualitative indicators are often overlooked. Longevity is frequently neglected, with the reference service life in a classic LCA being too short, and repairing earth blocks is rarely considered. Regarding regenerative potential, local material sourcing and recovery yield benefits, though these benefits primarily stem from reduced transportation and excavation impacts. A return to nature at the EOL does not reduce impact, since it does not prevent manufacturing or energy impacts. Concerning renewability, reuse avoids production processes, yet its benefits are unevenly distributed across life cycles due to multiple allocation methods. Recycling has limited advantages, as the use of secondary resources is already embedded in earth block production, resulting in a lower initial impact.

The findings suggest that, while established, the LCA method needs improvement in its EOL evaluation. Its quantitative nature excludes factors such as longevity, regenerativity and renewability, limiting the tool's suitability for circular earth products. Future research should analyse current and future EOL scenarios for earth blocks and similar

materials to enhance understanding of waste management and the role of stabilisation. Additionally, examining EOL evaluations for circular products will help model EOL pathways and consider multiple life cycles. Overall, this study underscores the importance of the EOL and its assessment for developing earth products.

Exploring Timber–Mycelium Hybrid Components for Circular Building Construction

Giorgio Castellano(✉), Federica Pradella, Pietro Augusto Falcinelli, and Ingrid Maria Paoletti

Politecnico di Milano, Piazza Leonardo da Vinci 32, Milan 20133, Italy
giorgio.castellano@polimi.it

Abstract. European policy agendas increasingly position the built environment as a priority field for deep decarbonization and resource efficiency. This paper investigates how bio-based and regenerative materials can support circular construction through the development and preliminary assessment of a timber-mycelium hybrid box-based infill unit for prefabricated timber building systems. The methodology combines targeted literature review, material exploration and iterative prototyping within a material-driven, bottom-up framework. The unit reinterprets sheet-based CNC plywood panel logics as an assembly scaffold and integrated permanent formwork for mycelium-based composite growth, enabling dry assembly and potential selective replacement within timber structural frames (e.g., CLT). Prototyping confirms the feasibility of a compartmentalized plywood frame that supports more uniform colonization and repeatable fabrication. A comparative screening LCA benchmarks the hybrid unit against a conventional insulation proxy, indicating lower embodied impacts under the tested baseline assumptions and highlighting key sensitivities, particularly drying/deactivation electricity. Overall, the study provides proof of concept for circular envelope components and a transparent decision-support workflow for early-stage design iteration.

Keywords: Bio-based Materials · Mycelium · Circular Building Construction · Digital Fabrication · Design for Manufacturing and Assembly · Screening LCA

1 Introduction

Embodied impacts are increasingly recognized as a decisive lever for building decarbonization, especially as operational energy decreases in high-performance envelopes and retrofits [1]. Circular construction frameworks therefore emphasize material efficiency, modularity, and end-of-life strategies that preserve value through reuse, repair, and high-quality recycling rather than downcycling or disposal [2–4]. Disassembly-oriented approaches support maintenance, selective replacement, and higher-value recovery pathways, although environmental outcomes remain scenario-dependent and require consistent life-cycle evaluation [3, 4].

Digital design and fabrication enable these strategies by supporting off-site manufacturing, repeatable part families, dry assembly, and controlled tolerances that facilitate dismantling and component replacement [5]. Prefabricated façade systems and

timber-based modular envelopes for retrofit and new construction highlight the role of standardized modules and interface logic in feasibility and scalability [6–8]. In this context, Computer Numerical Control (CNC) based sheet timber systems provide an established "grammar" of interlocking joints and connector keys that reduces assembly complexity and part variability while remaining compatible with industrial workflows [9]. Mycelium-based lignocellulosic composites are attracting growing attention as low-density insulation and infill materials, with properties dependent on fungal species, substrate, growth conditions, and post-processing [10, 11]. While experimental studies report promising insulation performance, moisture sensitivity and process control remain key barriers to wider adoption [12]. Recent Life Cycle Assessments (LCAs) indicate potential advantages compared to conventional options but consistently identify manufacturing energy (especially drying/deactivation) and yield as dominant sensitivities that can overturn benefits if not managed [14–16]. More broadly, early-stage LCA integration in bio-based panel development is valuable for hotspot identification and design iteration without over-claiming precision under prototype conditions [13]. Against this background, this study develops a timber–mycelium hybrid infill concept that reinterprets CNC-cut plywood "box" logics as an assembly scaffold and integrated permanent formwork for mycelium growth, enabling dry assembly and selective replacement within timber structural frames (e.g., Cross-Laminated Timber CLT). A screening comparative LCA is used as a decision-support tool and is reported consistently with modular construction LCA logic (A1–A3 as core model) [17].

2 Methodology

The research approach combines (i) targeted literature review, (ii) material exploration and bio-fabrication trials, (iii) iterative prototyping supported by CNC fabrication, and (iv) a preliminary evaluation framed by circularity principles and screening LCA. The workflow (Fig. 1) is informed by circular construction frameworks and disassembly-oriented design lenses, where end-of-life considerations and process constraints guide geometry and system decisions [2–4]. In parallel, a Design for Manufacturing and Assembly (DfMA) oriented perspective supports repeatable part families, simplified fabrication and dry installation workflows enabled by digital fabrication [5, 9].

Bio-fabrication and prototyping steps and parameters are summarized in Table 1.

A comparative screening LCA was structured to support early-stage decision making and hotspot identification rather than definitive quantification. The core model is reported as cradle-to-gate (A1–A3) consistently with modular construction LCA logic [17] and following ISO 14040/44 principles [20, 21]. Background processes were modelled in SimaPro using Ecoinvent v3 (allocation, cut-off) system model datasets [18]. Manufacturing electricity (CNC cutting and drying/deactivation) is treated as a sensitivity parameter, consistent with recent mycelium-composite LCAs that highlight energy demand and yield as dominant drivers [14–16]. The impact indicator used for reporting is GWP100 (IPCC 2021) [19].

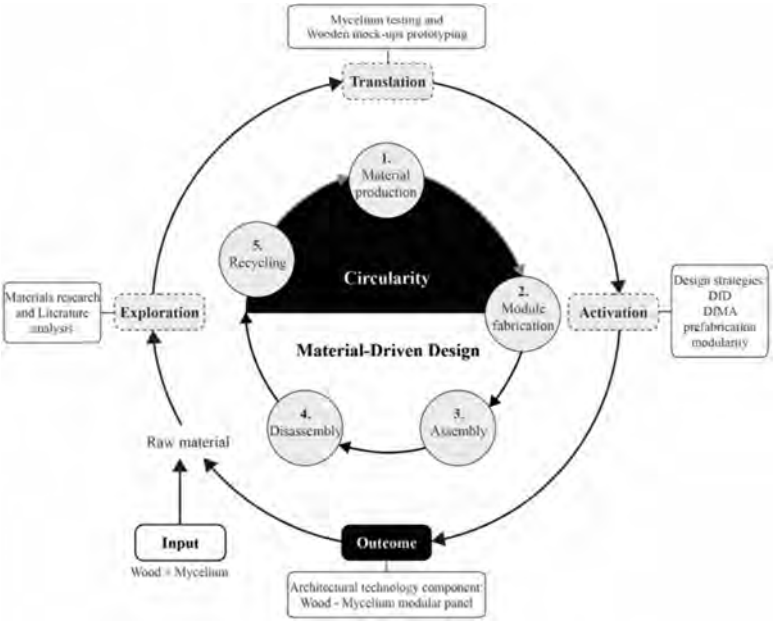

Fig. 1. Diagram of the adopted methodology, integrating material exploration, prototyping and screening LCA within a circular design framework.

Table 1. Bio-fabrication and prototyping steps and parameters

Stage	Key parameters / inputs	Conditions / notes
Recipe (batch)	100 g fibers (substrate) + 25 g flour (nutrient) + 153 g distilled water + 42 g mycelium spawn	Laboratory batch used for prototype trials
Sterilization + Inoculation	Substrate sterilized; inoculated with *Pleurotus ostreatus*	Hygienic protocol to minimize contamination
Incubation	–	7 days at 25–30 °C
Scale test	Colonized substrate transferred to 1:2 mock-up	Behavior within mould geometry; validation of open-box formwork
Pilot unit assembly	CNC-cut plywood open-box disinfected and filled	Internal ribs define cavities; dry assembly
Closed colonization	Unit closed with final back element	~10 days colonization; mould thickness ≈ 7 cm
Deactivation	–	Drying at 70 °C to deactivate metabolism and stabilize [10, 11].

3 Timber–Mycelium Hybrid Component Development

The timber–mycelium element is presented as a prefabricated box-based infill unit assembled from CNC-cut plywood parts. The unit integrates a bio-based core within a dry-assembled frame and compartmentalized cavities, enabling selective replacement and potential recovery within a modular timber envelope. At building scale (Fig. 2) it acts as a non-structural enclosure layer hosted by a load-bearing timber structure (e.g., CLT grids). Interface flexibility is restricted to the unit-to-frame connector set; alternative interfaces (e.g., metallic brackets) are treated as project-specific adaptations that may affect disassembly potential and circularity scenarios [2–4].

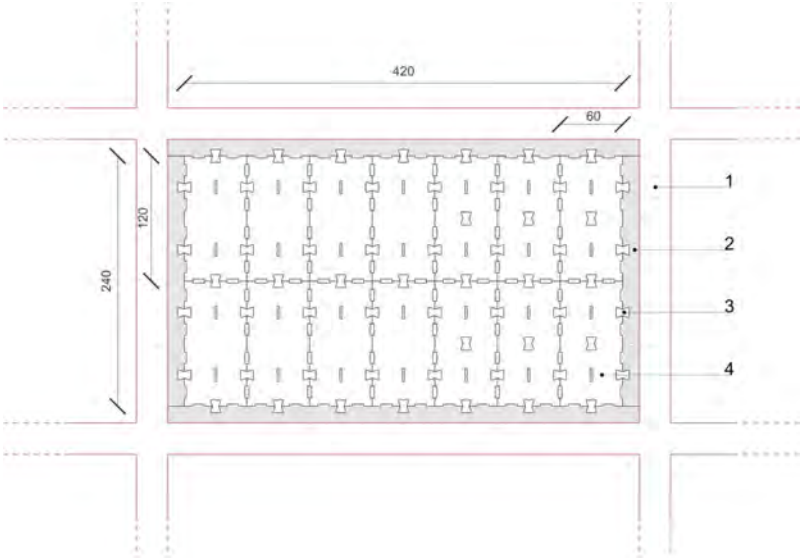

Fig. 2. Façade-scale modular layout of the box-based infill system within a timber structural grid (e.g., CLT). Infill units are tessellated to form the non-structural enclosure layer and connected through dry reversible keys. (1) host structural frame; (2) unit-to-frame connector set; (3) unit-to-unit connector key; (4) box-based infill unit. Credit: by Authors

The unit is engineered as an integrated permanent formwork for a mycelium-based composite core. Sheet-based interlocking logics typical of CNC timber systems (tab/slot assembly and connector keys) are adapted to a hybrid bio-based infill while keeping fabrication compatible with standard CNC routers and dry assembly [9]. This approach is consistent with open-source, CNC-cut timber systems such as WikiHouse, where tab/slot assembly and connector keys enable rapid dry assembly from sheet materials [9]. The core is treated as a non- or semi-structural insulation/infill material whose properties can be tuned through fungal species, substrate selection and process variables [10, 11]. A pilot unit (Fig. 3) was developed to validate joinery, compartmentalization and bio-fabrication workflow and to define the functional unit for the screening LCA (Sect. 4); the pilot geometry should not be interpreted as a prescribed façade module size.

Fig. 3. Prototype development of the timber–mycelium box-based infill unit: (a) CNC-cut plywood parts prior to assembly; (b) assembled open-box frame with internal ribs, filled with inoculated lignocellulosic substrate for colonization. Credit: based on C. Assirelli & A. Crocicchia (MSc Thesis, Politecnico di Milano, 2024). Pictures: G. Castellano.

The manufacturing workflow integrates bio-fabrication within CNC-based timber fabrication through a repeatable sequence (Fig. 3): (i) CNC cutting of plywood parts; (ii) dry assembly of an open-box frame with internal ribs; (iii) filling with inoculated lignocellulosic substrate and incubation to complete colonization; (iv) closure to stabilize confinement; and (v) drying/deactivation to stabilize the composite core and bonding to internal surfaces. This sequence minimizes auxiliary formwork materials and translates mycelium growth into a reproducible workflow suitable for iterative prototyping and scale-up.

4 Screening Comparative LCA

A comparative screening LCA was conducted to provide early-stage feedback on the embodied climate impacts of the timber–mycelium box-based infill unit. The assessment follows ISO 14040/44 principles and is reported as cradle-to-gate (A1–A3) in line with EN 15804 modular terminology; modules beyond A1–A3 are treated as optional scenarios and are not included in baseline claims [17, 20, 21]. The impact indicator is GWP100 (IPCC 2021) [19]. Functional unit (FU): one pilot infill unit (600 × 600 × 180 mm), including the plywood frame and full core volume. A performance-based FU (e.g., per m^2·K/W) is not adopted because prototype thermal performance is not yet validated. Foreground quantities derive from the pilot geometry and manufacturing workflow. Background processes were modelled in SimaPro using Ecoinvent v3 (allocation cut-off) system model datasets [18]. At prototype stage, core inputs are represented via transparent proxies reported explicitly in the inventory: lignocellulosic substrate (straw proxy), nutrient additive (dry-milling flour proxy), and inoculum (organic grain production proxy).

Manufacturing electricity was modelled using a European medium-voltage electricity mix and treated as a sensitivity variable to reflect uncertainty in drying/deactivation requirements (low/medium/high), while baseline electricity accounts for CNC cutting

only. The conventional insulation baseline was modelled using Ecoinvent "polystyrene foam slab for perimeter insulation" as a proxy for XPS-type insulation.

Results are sensitive to the choice of conventional insulation dataset; the baseline is therefore interpreted within the uncertainty of early-stage modelling rather than as a definitive product declaration. Results are reported as (i) comparative GWP100 fossil between Hybrid (H) and Baseline (B) (Table 2, Fig. 4) and (ii) a contribution analysis for hotspot identification (Table 3).

Table 2. Comparative results (GWP100 fossil, kg CO_2-eq per FU).

Scenario	Hybrid (H)	Baseline (B)
Low drying	11.003	14.696
Mid drying	12.312	14.696
High drying	14.276	14.696

Table 3. Contribution analysis for Hybrid (H), mid scenario (IPCC 2021 GWP100 fossil), highlighting dominant drivers and sensitivity parameters.

Contributor	Hybrid (mid)	Baseline
Plywood	8.64	8.64
Electricity (MV)	2.13	0.16
Conventional insulation (polystyrene foam slab, perimeter)	–	5.89
Inoculum proxy	0.76	–
Flour proxy	0.68	–
Substrate proxy	0.10	–
Total	**12.31**	**14.70**

Overall, the screening shows that plywood production dominates the embodied impacts, while drying/deactivation electricity is the main sensitivity driving the variation across scenarios. This supports the use of screening LCA as a decision-support tool to identify hotspots and prioritize primary data collection (process energy and yields) before industrial scaling.

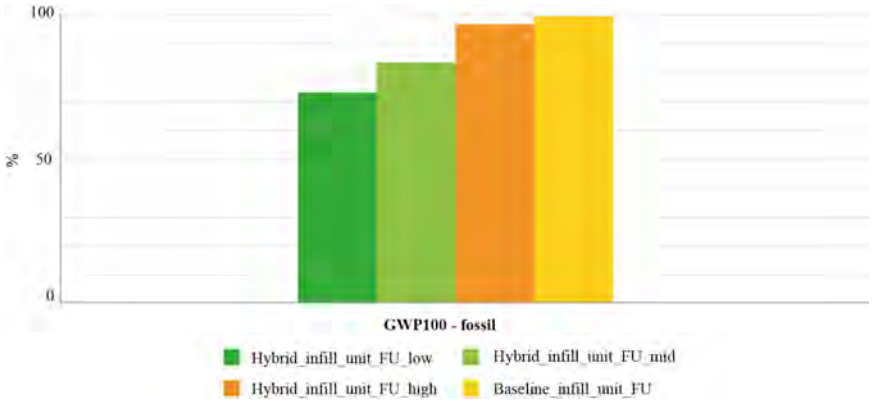

Fig. 4. Comparative GWP100 fossil results (A1–A3) for Hybrid (H) and Baseline (B), including drying-energy sensitivity (low/mid/high). Method: IPCC 2021 GWP100 V1.03

5 Conclusion and Future Work

This study proposes a timber–mycelium hybrid box-based infill unit combining CNC-fabricated plywood joinery with a bio-fabricated mycelium composite core, designed for dry assembly and selective replacement within circular construction logics [2]. The screening LCA (A1–A3) shows that plywood production dominates embodied impacts, while drying/deactivation electricity is the main sensitivity driver, consistent with mycelium-composite LCA evidence [14]. Future work will prioritize primary data collection for process energy and yields and extend the assessment through scenario-based modelling of end-of-life and reuse pathways beyond cradle-to-gate to support scale-up. Overall, integrating CNC timber fabrication, bio-fabrication and early-stage LCA provides a transferable workflow for evidence-based development of bio-based building components under circular construction strategies.

Abstract. The long-term performance of structural timber products is strongly influenced by time-dependent phenomena such as creep and stress relaxation due to moisture fluctuations, temperature variations, and sustained mechanical loading. This performance determines the service life of such products and directly affects their reusability potential after the building disassembly at the end of its design life. Components that maintain dimensional stability and mechanical integrity can be recovered, reconditioned and reused, supporting circular economy principles and reducing environmental impact. Conversely, excessive creep, relaxation or cracks caused by moisture induced stresses limit reuse potential, necessitating downcycling or energy recovery of the material. Understanding these mechanisms enables engineers to design structures for deconstruction and reuse, ensuring that timber remains a sustainable choice in modern construction. This paper discusses strategies to assess and improve reusability through accurate prediction of the structural components' service-life based on state-of-the-art finite element modelling (FEM) of hygro-thermal and mechanical behaviour of wood. The rheological model for predicting the long-term behaviour of timber members includes a description of creep and moisture-induced reversible and irreversible deformations in compression and tension in three anatomical directions and includes shear deformations. The paper demonstrates the possibilities offered by the integration of FEM results in the life cycle assessment (LCA) of the reusable timber component.

Keywords: Timber · Reuse · Finite Element Method · Service Life · Life Cycle Assessment · Circular Economy

1 Introduction

The construction sector is a major consumer of raw materials and a significant source of greenhouse gas emissions and waste [1]. To address these challenges, circular economy principles promote extending product service life and enabling reuse after building deconstruction. Reuse of structural timber usually preserves material value and embodied

energy more effectively than recycling, but its feasibility depends on long-term mechanical behaviour under sustained loading and environmental exposure. Timber elements experience time-dependent deformations and damage accumulation, which influence their residual service life at the time of building disassembly. These effects directly determine whether it is more efficient to reuse the component, recycle it or recover as energy.

Wood rheology is therefore a key factor for circular timber construction. Viscoelastic and mechano-sorptive behaviour leads to creep, stress relaxation or accumulation, and moisture-induced deformations, particularly under variable humidity and temperature [2]. Modelling of these phenomena enables realistic prediction of long-term performance and residual service life. The service life can be integrated into the life cycle assessment, forming a basis for informed decisions about end-of-life treatment of such components. By accounting for these effects, timber structures can be designed for deconstruction and multiple life cycles (such as the example in Fig. 1), strengthening the role of timber in circular construction.

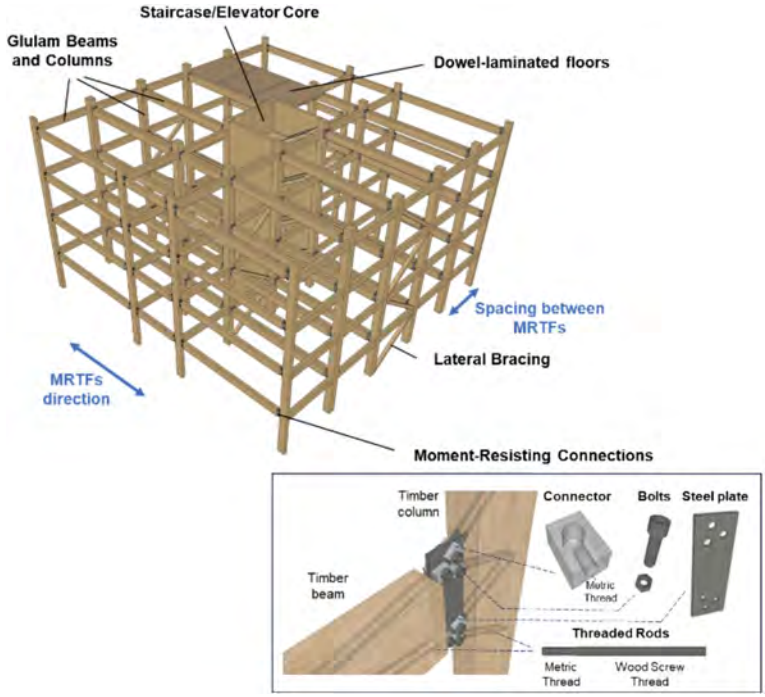

Fig. 1. Timber structure designed for deconstruction and reuse [3].

Such reusable structures are for instance timber frames with the components connected through steel coupling parts fastened to the timber elements [3]. The example in Fig. 1 shows a structural system consisting of demountable, moment-resisting connections with pre-installed steel parts in the timber elements joined with reversible, friction-based connections.

2 Methodology

This study is based on the life-cycle assessment (LCA) of a timber beam from the structural system described in Fig. 1 [3] in the building designed for 50 years, assuming the beam initially outlasts the building and can be reused after its demolition with a certain residual service life. Two scenarios are considered: (a) the beam is replaceable and reusable even if its remaining service life is shorter than the next building's design life and (b) the beam is non-replaceable and only reused if its residual service life meets or exceeds the next building's design life. The assessment focuses on the Global Warming Potential (GWP) and covers the following selected life-cycle stages according to EN 15804 and EN 15978 [4, 5]: production (LCA modules A1–3), replacement during the use (B4), deconstruction or demolition (C1), recycling or reuse (C3), and net benefits and loads from material recovery beyond the system boundary (D1).

2.1 Moisture Induced Stresses and Deformation

Long-term performance of structural timber components can be predicted using numerical simulations based on the Finite Element Modelling (FEM). The moisture content in the timber component resulting from environmental humidity and temperature variations is usually determined using a one- or two-phase moisture transport model [6, 7]. Subsequently, a mechanical model is applied to determine the long-term response of the timber component under the combined effects of external loads and moisture-induced stresses and deformations, where the total strains are assumed to be the sum of mechanical, mechano-sorptive, viscoelastic, and hygro-expansion strains [2, 8, 9]. Numerical simulations are commonly supported by experimental results that provide data for parameter calibration or model validation.

Most experimental results on the long-term performance of timber subjected to external loads and variations in humidity and temperature cover short time periods, typically less than one year [10–12]. Experimental studies covering longer time periods, i.e., up to ten years, are relatively rare [13–15]. Therefore, numerical simulations are also used to extrapolate experimental results beyond the experimentally observed time periods and estimate the performance of timber components over their service life, which may extend to several decades.

The methodology presented in this paper relies on the results obtained by FEM analysis of multi-phase moisture transport in wood [17] sequentially coupled with a mechanical model for the evaluation of internal stresses and deformations over a long period of time. This model was already used for the structural verification of load-bearing timber components of bridges [17].

2.2 Service Life Prediction

Service life can be determined from the Eurocode limit states [18], defining it as the time when time-dependent effects of actions reach the Serviceability Limit State (SLS) or Ultimate Limit State (ULS). By calculating utilisation over time and accounting for moisture-induced changes in stiffness and internal forces, the service life is identified when the utilisation reaches unity, providing a performance-based durability and reuse

assessment. This method can be in practice applied according to the illustrative FEM example presented in the earlier study [17].

The service life of structural timber components depends on the geometry of cross-sections, span lengths, connection details, material properties, and external loads (mechanical, temperature, and moisture). In the case of internal building structures with controlled temperature and humidity (Eurocode Service Class 1 and 2 [19]), the service life can significantly exceed 50 years, the standard design life for buildings according to EN 1990 [18]. Accordingly, a range of 50 to 200 years is adopted in this study to reflect both the typical and extended service life scenarios for timber in these service classes.

2.3 Allocation of LCA Impacts

The unit impacts allocated directly to the product life-cycle stages A and C are presented in Table 1 as e_A and e_C parameters. These selected values fall within the typical GWP ranges of glue laminated timber frames [20] but do not represent any specific product. The effect of biogenic carbon storage always cancels out when the impacts from all life-cycle stages are aggregated and therefore is not considered. Module D1 is calculated according to the Annex E of EN 15804 [4] with index "1" for reuse and "2" for recycling, and parameters E_{VM} and E_{MR} in Table 1.

Table 1. Parameters of the LCA model.

Unit impacts and wood waste recovery parameters	GWP [kgCO_2e/t]
Production of the new component ($e_{A,\,\mathrm{new}}$, $E_{VM,\,1}$)	70
Reuse of the component ($e_{A,\,\mathrm{reuse}}$, $E_{MR,\,1}$)	10
Demolition and waste processing ($e_{C,\,demolition}$)	10
Deconstruction and preparing for reuse ($e_{C,\,deconstruction}$)	5
Substituted production of wood chips from virgin materials ($E_{VM,\,2}$)	40
Recycling wood into chips ($E_{MR,\,2}$)	20

It is assumed that the component can be completely reused, or 80% of its mass can be recycled into wood chips and the remaining 20% of its mass can be incinerated. If the component is replaceable during the design life of the building, the impacts of its production and end-of-life recovery were allocated to the use stage of the building (LCA module B4) according to the EN 15978 [5] as illustrated in Fig. 2.

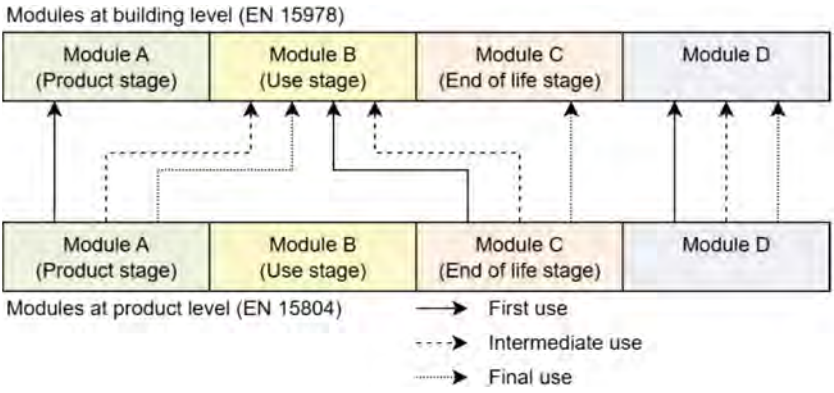

Fig. 2. Allocation of impacts from the product LCA according to EN 15978 [5].

3 Results

The average Global Warming Potential (GWP) of the component installed in one or more buildings during its service life is presented in Fig. 3 for non-replaceable component and Fig. 4 for replaceable component. Life-cycle impacts are aggregated from stages A to C, and the benefits of future reuse and recycling (module D1) are presented separately as negative values.

In the case of non-replaceable component, the results are constant for any service life of this component exceeding the design life of the building up to 50 years because such component cannot be reused anymore. If the component can be replaced, the GWP is also allocated to the use phase of the building (yellow in Fig. 4) excepting the cases when the replacement happens at the building's end of life because the residual service life of the component is equal to the multiplier of the design life of the building (for instance 100 or 150 years, or some cycles with 75 or 125 years) and the impacts are allocated to the modules A and C.

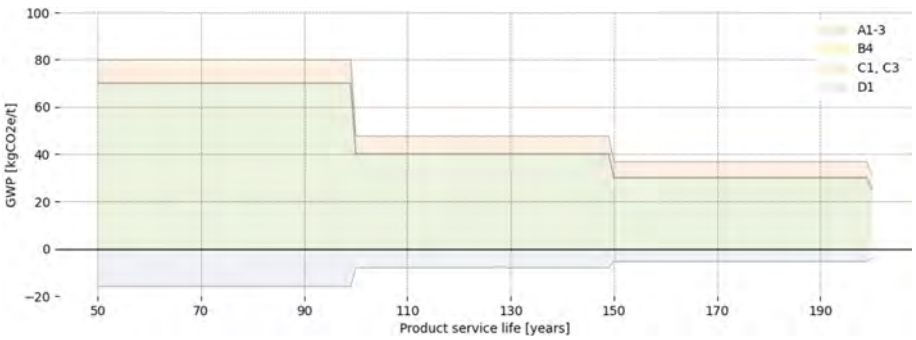

Fig. 3. Global Warming Potential of non-replaceable product in a building with 50 years of design life.

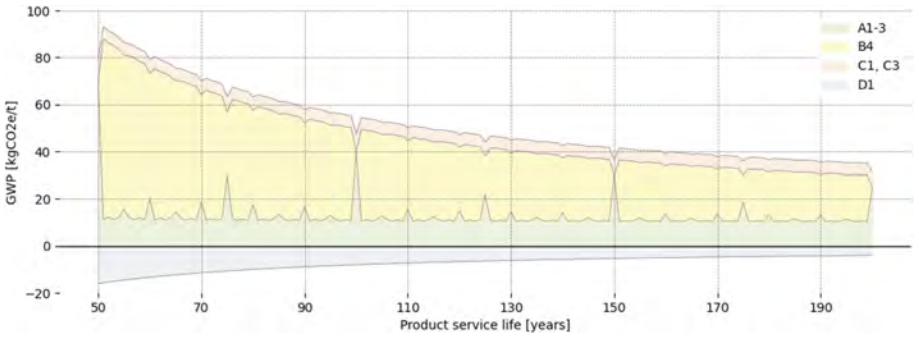

Fig. 4. Global Warming Potential of replaceable product in a building with 50 years design life considering optional product replacement at the end of building's design life.

The calculated scenarios show that in some cases it is more environmentally efficient to avoid reusing the product with short residual service life and produce the new one instead of it. Although, such cases are rare, they show the complexity of decision making at the end of the building life. In our examples, the lowest total GWP can be achieved by replacing or not replacing the product within the design life of the building depending on its service life (see Fig. 5).

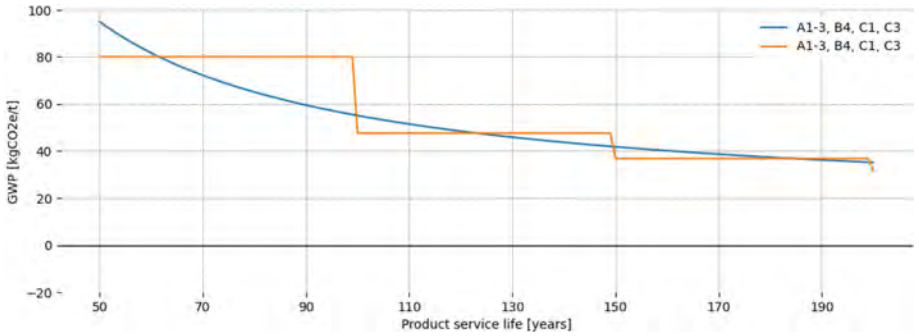

Fig. 5. Comparison of total Global Warming Potential of replaceable product (blue line) and non-replaceable product (orange line) in a building with 50 years design life.

It can be demonstrated that reuse is more environmentally efficient than recycling when the condition of formula (1) is fulfilled:

$$\left(e_{A,reuse} + e_{C,deconstruction}\right) + (nr - 1)\left(e_{A,new} + e_{C,demolition}\right) > 0 \qquad (1)$$

where the replacement rate of replaceable component $r = T_{lf}/T_{rsl}$ is the ratio of the building's design life T_{lf} and component's service life T_{rsl} defined in [18], and the number of life cycles of the non-replaceable component is $n = floor(T_{rsl}/T_{lf})$.

4 Summary and Conclusions

Long-lasting and well-designed timber structures can significantly contribute to climate-neutral and circular construction when service life of their components explicitly considered. The product manufacturers can therefore exploit the possibility to declare reference service life of their products under pre-determined conditions beyond the typical design life of the building.

Reuse, recycling and other waste management options are usually considered in a hierarchical manner at the building's end-of-life, but the European Waste Framework Directive [21] encourages to prioritize scenarios that deliver the best overall environmental outcome even if it requires departing from this hierarchy. The present study shows that realistically determined service life of timber products can justify a specific priority based on overall environmental impacts and highlight the cases when different recovery options might be superior to reuse.

Abstract. Embodied carbon has become a critical dimension of building-sector decarbonization, yet its quantification remains largely restricted to formally designed buildings with detailed documentation. In countries such as Brazil, where informal settlements constitute a significant share of the urban fabric, this methodological dependency excludes millions of dwellings from environmental accounting. This paper proposes a structured, replicable system to quantify embodied carbon in informal housing, developed through an iterative empirical process in the São Remo community, São Paulo, Brazil. The first stage tested and calibrated data-collection strategies, digital capture methods, parametric reconstruction procedures, and computational integration pathways. Mobile lidar scanning, structured field protocols, locally grounded material assumptions, BIM-based modeling, and Python automation were progressively consolidated into a coherent and scalable workflow capable of transforming undocumented geometries into structured material quantities linked to regional emission factors. The methodological architecture introduced enables informal settlements to be integrated into climate mitigation and circular-economy strategies. By bridging digital reconstruction and environmental accounting, it expands embodied carbon assessment to data-scarce urban contexts across the Global South.

Keywords: Embodied carbon · Informal housing · Building Information Modeling (BIM) · Benchmarking · Construction decarbonization

1 Introduction

The decarbonization of the built environment has become a central priority in global climate mitigation agendas. While operational emissions have historically dominated policy and research [1], embodied carbon—associated with the extraction of raw materials and the manufacturing of construction products—accounts for around 18% of global emissions related to buildings and construction [2] and has gained increasing relevance, particularly in rapidly urbanizing regions in the Global South. In Brazil, embodied

https://doi.org/10.1007/978-3-032-34930-9_128

emissions account for a substantial share of housing life-cycle impacts [3], especially in low-income contexts where operational energy demand is limited.

Despite advances in Life Cycle Assessment (LCA) methodologies and digital quantification tools, embodied carbon accounting remains restricted mainly to buildings designed for formal use, particularly in the Global North, where data availability is greater [4]. Studies in the Global South are scarce and often rely on Global North data as proxies [4], which may lead to inconsistent decision-making due to a lack of regionalization [5]. Additionally, conventional assessments depend on project documentation and standardized specifications, resources typically absent in informal settlements.

Informal settlements are residential areas developed outside formal legal and regulatory frameworks, characterized by insecure tenure, limited infrastructure, regulatory non-compliance, and predominantly self-built, incrementally expanded housing with irregular geometries and no technical documentation [6, 7]. These conditions hinder their inclusion in environmental inventories, leaving the embodied carbon of such dwellings largely unquantified because of methodological limitations. Within this spectrum of informality, slums represent the most extreme condition, where precariousness, density, and construction heterogeneity are intensified. This gap is especially critical in Brazil, where 40.8% of urban dwellings present some form of inadequacy [8], 16.39 million people live in slums [9], and self-construction remains the predominant mode of housing production [10].

This paper addresses this gap. It proposes a structured and replicable system for quantifying embodied carbon in informal housing, especially slums, developed through an empirical testing phase and subsequently consolidated into a conceptual workflow. Rather than presenting embodied carbon results, this paper focuses on the methodological architecture itself: how undocumented built reality can be transformed into structured environmental data in a consistent and scalable way.

2 Research Design

The research design is structured as a circular-iterative process aimed at bridging the gap between standardized embodied carbon accounting and the complexities of informal urban environments. The study was conducted in two major phases: an exploratory-operational phase dedicated to testing data-collection and computational-modeling pathways, followed by a conceptual-consolidative phase that formalized these procedures into a replicable workflow.

2.1 Case Study Selection and Site Characterization

Following the logic of an instrumental case study [11], this research utilized multiple sources of evidence to investigate contemporary phenomena within their real-world context. The empirical focus was the São Remo slum in the western part of the city of São Paulo, Brazil—a settlement of approximately 3,000 dwellings that serves as a representative laboratory for Brazilian informal urbanization [12].

The site exhibits key characteristics of self-construction, including incremental verticalization and self-construction logic, absence of formal technical documentation,

and varied levels of consolidation and finishing [12]. To ensure structural diversity, 39 dwellings were selected based on location, height, degree of consolidation, and material finishing. Rather than a mere application site, the community functioned as a methodological laboratory where tools and assumptions were iteratively refined.

2.2 Methodological Macro-Stages

The investigation was organized into five distinct macro-stages, providing a systematic approach to quantifying embodied carbon in data-scarce environments: 1) Preparation: Definition of parameters and preliminary site assessment; 2) Data Collection: Empirical gathering of physical and material data; 3) Processing: Technical analysis and carbon quantification; 4) Methodological Proposal: Final synthesis and workflow formalization; and 5) Model Revision: Adjustments and updates to ensure the replicability of the method in other locations.

To ensure technical consistency, all analytical stages underwent internal validation cycles through peer review within the research group. This study is integrated into the Research Network MORE: Well-being and Low Carbon in Housing (https://hubic.org.br/rede-more/), a collaborative initiative focused on measuring CO_2 emissions in the housing sector. The network's broader objective is to support the transition to a low-carbon economy while aligning climate mitigation with human well-being and evidence-based public policy.

3 First Stage: Methodological Testing and Operational Calibration

The first stage aimed to determine how embodied carbon could be quantified in the absence of formal documentation. This required reconstructing quantities directly from built reality. Multiple tools and approaches were tested before arriving at the final procedure.

During Preparation, initial exploratory visits assessed urban morphology, accessibility constraints, façade conditions, and feasibility, including interior measurements. Different geometric capture methods were evaluated in Data Collection, including terrestrial laser scanning (TLS), digital photogrammetry, mobile lidar applications, and traditional laser tape measurement. While TLS offered high precision, its cost and operational complexity limited scalability. Photogrammetry demonstrated significant potential, particularly through residents' participatory data collection, which could democratize the documentation process. However, the method remained sensitive to lighting conditions and image quality, especially in cluttered interiors. Ultimately, mobile lidar, supplemented by laser tape validation for larger spans, was identified as the most viable compromise between accuracy, data richness, cost-effectiveness, and replicability. A dedicated application was developed to systematically store and structure the data collected for each dwelling.

Simultaneously, semi-structured interviews with local masons were conducted to understand typical concrete and mortar compositions, construction sequences, and decision-making processes. These interviews were essential for defining realistic material assumptions, particularly regarding cement consumption. A calculation protocol was

developed to translate informal mix descriptions into standardized mass-based ratios suitable for integration with emission factors.

For Processing, point clouds obtained through mobile scanning were converted into parametric BIM models. Digital reconstruction exposed limitations in structural visibility, wall thickness measurement, and slab composition identification. To address these gaps, technical assumptions were formulated based on local construction practices and Brazilian standards. These assumptions were progressively refined as additional dwellings were modeled. Simultaneously, early iterations exposed inconsistencies in naming conventions, parameter assignment, and quantity tables. A BIM Execution Plan and a dedicated template were therefore developed and calibrated through the first 10 models, which served as stabilization exercises. Once consolidated, the template ensured standardized outputs compatible with automated data processing.

After digital modeling, the quantities of five material groups—ceramic tiles, clay bricks, concrete, mortar, and reinforcing steel—were extracted, and their embodied carbon was calculated using Brazilian data from the Information System for Environmental Performance in Construction (Sidac) [13] or international environmental product declarations (EPD). These materials account for 82% of the global warming potential (GWP) of a standard Brazilian social housing unit [3].

The final component involved computational integration. Manual processing of BIM outputs identified operational risks, prompting the implementation of Python scripts to automate data cleaning, emission factor integration, and aggregation. This step consolidated a reproducible pipeline linking undocumented geometry to emission-based material quantification.

4 Second Stage: Consolidation of the Conceptual Workflow

The second stage consolidated the tested procedures into a coherent, sequential framework (Fig. 1). The workflow begins with preparation and standardized field data collection, combining digital capture with structured metadata registration. It advances to parametric reconstruction within a stabilized BIM environment, where locally grounded technical assumptions are embedded explicitly. Material quantities are then extracted in a structured format that enables automated integration of emission factors and calculation of indicators. The method's review is necessary to ensure its replicability in other locations, in accordance with local construction and cultural characteristics.

Rather than relying on any single tool, the robustness of the framework derives from the coordination between its components: field protocol, parametric modeling rules, emission-factor hierarchy, and computational automation. This alignment transforms fragmented and undocumented geometries into consistent datasets suitable for environmental assessment.

The modular architecture allows for regional recalibration through material substitution, adapting the workflow to quantify alternative local bio-based materials or industrial by-products; data elasticity, as the "multisource" approach makes it resilient to varying levels of technological access; and adjustment of input assumptions, enabling refinement of parametric models and embodied carbon estimates for the housing units. By

Fig. 1. Conceptual workflow to estimate embodied carbon in informal housing.

identifying material-intensive patterns, it also supports incremental upgrading strategies to improve environmental performance and housing quality, while informing circular-economy policies tailored to the metabolic flows of informal settlements.

In this way, informal housing is translated from undocumented built reality into structured environmental information through a transparent and auditable process (Fig. 2). The framework is scalable due to its operational simplicity, reproducible through explicit parameterization, and transferable because its logic remains stable even when regional assumptions or material datasets are modified.

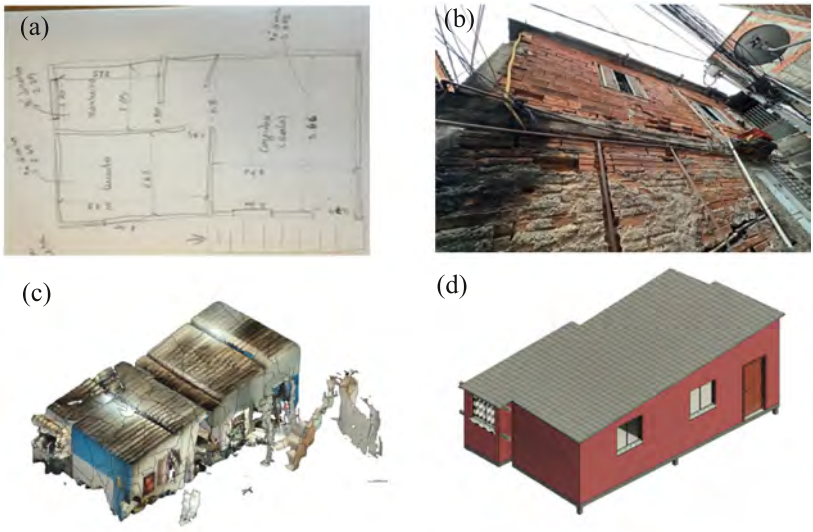

Fig. 2. (a) Example of a hand-drawn sketch surveyed from a second-floor dwelling; (b) External photograph of the dwelling; (c) 3D model resulting from the housing's 3D scanning; (d) 3D model of the housing generated in BIM (Revit 2026).

5 Implications and Limitations

By enabling embodied carbon quantification in informal settlements, this framework expands the scope of environmental accounting to territories traditionally excluded from global climate mitigation strategies. This inclusion is technically and ethically critical, as informal housing constitutes the primary mode of urban expansion across the Global South. The methodology moves beyond site-specific observation to offer a scalable diagnostic tool for regions with similar socio-technical profiles.

The methodology acknowledges unavoidable uncertainties inherent in self-construction, such as digital capture distortions and structural invisibility (e.g., hidden reinforcements). However, rather than viewing uncertainty as a barrier, the framework treats it as a quantifiable parameter. By documenting assumptions and applying carbon emission factors within defined ranges, the model ensures that the resulting baselines are both transparent and technically robust.

Future research will focus on revising the model (step 5) and expanding the sample size across diverse geographical latitudes to establish regional embodied carbon baselines. Additionally, conducting sensitivity analyses on the most volatile parameters will further stabilize the workflow for global implementation.

6 Conclusions

This research established a robust methodological framework for quantifying embodied carbon in informal housing, bridging the gap between undocumented built environments and formal environmental accounting. By integrating site-specific data, local knowledge, 3D scanning, Building Information Modeling (BIM), and Python-based automation, the study demonstrated the technical viability of transforming the morphological complexity of self-constructed settlements into structured, auditable data.

The core contribution lies in a circular-iterative workflow that standardizes quantification criteria across heterogeneous constructions, ensuring data traceability despite the absence of original technical documentation. The application in the São Remo community demonstrated that carbon estimation in data-scarce contexts depends on a coherent protocol that aligns high-tech acquisition with local empirical insights.

The framework offers high adaptive potential for other contexts in the Global South. Its modular design allows for recalibration based on local emission factors and construction techniques, providing the analytical foundation for incremental upgrading strategies. Ultimately, this study demonstrates that informal settlements—often excluded from conventional inventories—can be integrated into climate mitigation strategies, underscoring the need to align spatial justice with carbon neutrality in the transition to a low-carbon economy.

Acknowledgments. This study was developed within the research network "MORE: Well-being and Low Carbon in Housing" and within the scope of the project "CO_2 Mitigation and Quality of Life in Housing: MCMV & Self-Managed Housing," with support from Caixa Econômica Federal, the Fundação para o Desenvolvimento Tecnológico da Engenharia (FDTE), and hubIC (ABCP-USP). We are grateful for the funding and partnership that made this research possible.

Abstract. The use of resource-efficient and circular building materials is gaining increasing relevance in sustainable construction. Compressed earth blocks (CEBs) represent a promising alternative to CO_2-intensive materials such as concrete due to their low embodied energy and potential recyclability. To improve mechanical performance, earthen materials are often stabilised with hydraulic binders or bio-based additives. However, the implications of such stabilisation for recyclability and environmental performance remain insufficiently understood. This study investigates the influence of different additives on the compressive strength, recyclability, and environmental impact of CEBs. The investigated additives include hydraulic binders and bio-based stabilisers. After initial mechanical testing, the fractured specimens were crushed, reprocessed, and remanufactured to evaluate strength retention after one recycling cycle. The results show that additive selection plays a crucial role for both the mechanical performance and recyclability of the material. At the same time, the stabilisation mechanism strongly influences strength retention after recycling. A screening life cycle assessment further highlights that the choice of additives can also significantly affect the environmental impact of compressed earth blocks. The findings highlight the importance of balancing mechanical performance, recyclability, and environmental impact when developing stabilised earthen materials for circular construction.

Keywords: Compressed Earth Blocks · Additives · Circular construction materials · Reuse potential · Mechanical performance · Recycling methods

1 Introduction

The transition towards circular construction requires building materials that combine structural performance with recyclability and low environmental impact. Reinforced concrete, while structurally efficient, is associated with high embodied carbon and limited material recovery. Compressed earth blocks (CEBs) offer a promising alternative due to their low embodied energy, the regional availability of raw materials and potential for full recyclability. To enhance mechanical performance, CEBs are often stabilised with hydraulic binders or bio-based additives. While such additives can significantly increase compressive strength, they may affect recyclability and long-term circular performance.

In particular, hydraulic binders involve irreversible chemical reactions, raising questions about strength retention after recycling. It can be hypothesised that hydraulic binders provide superior initial strength, whereas natural additives may perform more favourably after reprocessing.

This study investigates the circularity of stabilised CEBs (SCEBs) by analysing the influence of selected additives on compressive strength, strength development after one recycling cycle, and environmental implications compared with conventional construction materials. The investigated additives include hydraulic binders (cement and calcium hydroxide), bio-based stabilisers (ammonium lignosulfonate, sodium alginate in combination with calcium chloride, xanthan gum, and methyl cellulose), as well as a proprietary mineral-based mixture (Oxabrick LOKO). The results contribute to the development of structurally reliable and circular earthen building systems.

The paper builds on the activities of the WG *Forschung* within the *Dachverband Lehm e.V.*, co-financed by the InDeckLe-Project (PAN-HAW-BW, 2684995).

2 State of the Art

Earthen materials are widely regarded as fully recyclable. Yet robust evidence for the recyclability of compressed earth blocks (CEBs), and for the associated changes in mechanical performance, remains limited, particularly for formulations containing different types of additives. Although additives can improve properties such as compressive strength, they may adversely affect vapour adsorption behaviour [1, 2], increase the carbon footprint, and compromise circularity [3–5].

3 Methods

Material and Composition. The clay fraction is approx. 13%, with illite identified as the predominant clay mineral. Prior to further processing, the material was homogenised in a compulsory mixer (Eirich) for 120 s at 1500 rpm with controlled water addition to ensure uniform particle distribution and moisture content.

As shown in Table 1, nine material series with different stabilising additives were produced. Series 1 served as the reference without any additives. Additive contents are expressed as mass percentages relative to the dry mass of the earthen material.

Manufacturing. After the homogenisation process, the fresh material was immediately stored in airtight containers for 14 days to allow uniform moisture redistribution, while minimising moisture loss. For specimen production, 700 g of the prepared material were placed into a cylindrical steel mould (Ø: 66.5 mm). For each series, four specimens were produced. Compaction was performed uniaxially using a universal testing machine (Zwick). The compaction regime was defined in two stages: an initial pre-compaction load of 20 kN at a loading rate of 10 kN/min, followed by main compaction at 30 kN/min up to a maximum load of 100 kN. The maximum load was maintained for 120 s to further enhance structural densification. After unloading, the specimens were immediately ejected from the mould and subsequently weighed. Conditioning was performed under ambient laboratory conditions, with the specimens drying at room temperature (T =

Table 1. Composition of the material mixture.

8	Methyl cellulose	2768.8	402.8	28.4	3200	1.0	12.0
9	Oxabrick LOKO	2768.8	402.8	28.4	3200	1.0	12.0

17.0 ± 8.2 °C) for more than four weeks to minimise effects related to ongoing cement hydration. Due to time constraints, the recycled specimens were additionally dried in an oven at 30 °C for 24 h. Mass loss was recorded at regular intervals. Drying was continued until mass change were less than 0.1% within 48 h. The moisture content was determined gravimetrically. Compressive testing was performed after reaching moisture equilibrium.

Testing. Uniaxial compression tests were conducted under controlled loading rate. The load was initially applied up to 100 N at a rate of 100–150 N/s. Subsequently, the loading rate was increased to 350–500 N/s and continued until specimen failure. These loading rates were selected based on the expected material strength to ensure that failure occurred within approx. 90 s. The maximum applied load ($F_{\max}$) was continuously recorded, and the compressive strength (σ_c) was calculated according to Eq. (1), where A_0 represents the initial cross-section area. Failure was defined as a 30% drop in load, ensuring consistent and reproducible identification of the material-specific failure point. Statistical evaluation of compressive strength was based on the calculated failure stresses.

$$F_{max}/A_0 = \sigma_c \tag{1}$$

Recycling. The fractured specimens from each series were collected and pre-crushed manually, and further comminuted using a jaw crusher. The moisture content of the crushed material was determined gravimetrically and deionised water was added to restore the original moisture content of each respective series. Then new specimens were similarly manufactured as before. Due to material losses during processing, only three specimens per series were manufactured and tested in this recycling cycle.

Life Cycle Assessment. A screening LCA was conducted to contextualise the environmental impact of SCEBs. The assessment focuses on Global Warming Potential (GWP) as the primary indicator, expressed in kg CO_2-equivalents (kg CO_2-eq). GWP is particularly relevant for construction materials, as production and binder-related processes contribute significantly to embodied emissions. The system boundary was defined as modules A1-A3, covering raw material supply, transport, and manufacturing.

Environmental data were obtained from established databases and environmental product declarations (EPDs). GWP values for the investigated additives and binders were sourced from ÖKOBAUDAT [6, 7] and CarbonCloud [8–11], supplemented where necessary by literature data [12, 13]. These datasets were used to quantify the climate impact contribution of each additive relative to the earthen matrix and to compare SCEBs with conventional construction materials.

For the CEBs, GWP values were derived from the UPD dataset [9]. As the dataset reports impacts per unit mass, block-specific GWP values were calculated based on a dry density of 2060 kg/m^3. The dataset assumes industrial drying using natural gas, although sun drying may be applied in practice for economic reasons.

Additive contents were defined as wt.% of the dry earth mass. Mixture-specific GWP values were obtained by multiplying component masses with their database-derived GWP factors and summing the contributions.

To contextualise the findings, the resulting GWP values were compared with typical ranges for conventional mineral construction materials, including fired clay bricks, concrete, and calcium silicate bricks, using the same data sources. This comparison enables assessment of whether strength enhancements through additives remain compatible with low-carbon and circular construction objectives.

4 Results

4.1 Effect of Additives on Compressive Strength

Figure 1 shows the mean compressive strength for the investigated material series before and after recycling.

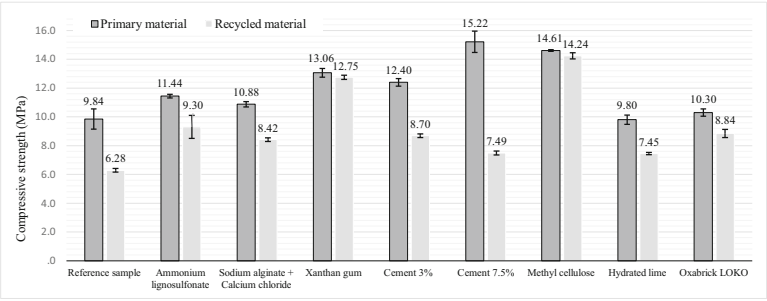

Fig. 1. Compressive strength of primary and recycled (S)CEBs with marked standard deviation.

The additive-free reference mixture reached a mean compressive strength of 9.84 MPa. Among the investigated additives, only hydrated lime led to a slight reduction in strength relative to the reference. All other formulations showed higher compressive strengths, with the highest values measured for 7.5% cement (15.22 MPa) and 1.0% methyl cellulose (14.61 MPa).

4.2 Effect of Recycling on Compressive Strength

Figure 1 also compares the compressive strength of the primary and recycled material. Remarkably, none of the series recovered its initial compressive strength after recycling. The highest strength retention was observed xanthan gum and methyl cellulose, which retained 97.6% and 97.5% of their initial strength, respectively. By contrast, the series containing 7.5% cement, showed the lowest retention reaching only 49.2% of its initial compressive strength. The reference series retained 63.8% of its initial compressive strength. The corresponding percentages are summarised in Table 2. In addition, the water content and dry density of the specimens at the time of compressive strength testing are also reported for both the primary material (1) and the recycled material (2). The dimensions of the specimens were height: (1) 91.6 mm ± 1.1 mm Ø: 65.8 mm ± 0.2 mm; (2) 92.6 mm ± 2.1 mm Ø: 65.9 mm ± 0.4 mm.

Table 2. Material properties and relative compressive strength of primary and recycled SCEBs.

Additive	Water content (1) [wt.%]	Water content (2) [wt.%]	Dry density* (1) [kg/m^3]	Dry density* (2) [kg/m^3]	Relative compressive strength (%)
Reference sample	2.4	1.9	2063	2057	64
Ammonium lignosulfonate	2.1	1.9	2049	2063	81
Sodium alginate + Calcium chloride	2.8	2.9	2071	2070	77
Xanthan gum	2.1	2.1	2056	2073	98
Cement (CEM I)	2.0	2.0	2044	2018	70
Cement (CEM I)	2.4	2.5	2047	1961	49
Hydrated lime	2.0	1.8	2039	2022	76
Methyl cellulose	2.1	2.0	2038	2038	97
Oxabrick LOKO	2.3	2.1	2077	2091	86

* The dry density refers to the moisture equilibrium state of the specimens at the respective water content reported in the table. The water content was determined gravimetrically by taking a material sample immediately after the compression test and oven-drying it at 105 °C.

4.3 Life Cycle Assessment of the Investigated Additives

The LCA reveal that the investigated additives can substantially increase the production-related CO_2 emissions of CEBs (see Fig. 2).

The reference sample exhibits a GWP of 113.7 kgCO_2-eq/m^3, mainly caused by artificial drying [13]. The addition of Oxabrick® LOKO increases this value moderately by 19% to 134.8 kgCO_2-eq/m^3 [14].

In contrast, mixtures containing sodium alginate and calcium chloride show a drastic increase, reaching 815.4 kgCO_2-eq/m^3, corresponding to more than 600% above the

reference [10, 11]. This effect is primarily driven by the high GWP of sodium alginate (21.3 kg CO_2-eq/kg). Approximately 63% of these emissions originate from seaweed cultivation, including aquaculture, harvesting, transport of wet bio-mass, and fertiliser production, while 35% result from energy-intensive processing steps such as extraction, precipitation, filtration, and drying [11].

Other additives also lead to notable increases in GWP. The addition of 1.0 wt.% xanthan gum raises emissions by approx. 140% [9], while mixtures containing 2.1 wt.% lignosulfonate or 7.5 wt.% cement increase the GWP by slightly more than 90% [6, 12]. Due to the lack of dedicated datasets, sodium lignosulfonate production was used as a proxy. Smaller but still significant increases were observed for hydrated lime (3.0 wt.%; GWP +58%), methyl cellulose (1.0 wt.%; GWP +54.6%), and cement (3.0 wt.-%; GWP +36.5%) [6–8].

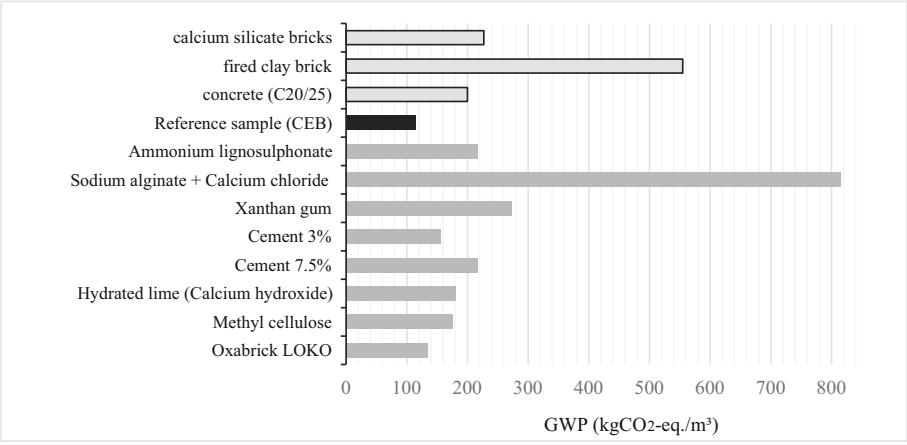

Fig. 2. Comparison of the GWP (A1–A3) of SCEBs listed in Table 1 with conventional construction materials (calcium silicate bricks, fired clay bricks, and concrete), based on [6–17].

However, compared with conventional mineral building materials (calcium silicate bricks, fired clay bricks, and concrete C20/25), most mixtures still exhibited lower GWP values. Among the conventional materials, concrete shows the lowest footprint, with approx. 200 kgCO_2-eq/m^3 [15]. Compared with concrete, only the mixtures containing hydrated lime (GWP –10.2%), methyl cellulose (GWP -12.2%), and cement (3.0 wt.%; GWP –22.4%) achieved lower GWP values.

In contrast, the mixture containing xanthan gum performed worse than calcium silicate bricks, while the combination of sodium alginate and calcium chloride even exceeded the GWP of fired clay bricks by 46.9% [16, 17].

5 Discussion

While most investigated additives increased compressive strength (av. +2.4 MPa), their incorporation consistently led to a substantial increase in carbon footprint, with GWP rising by an average of 136%. Only hydrated lime led to a slight reduction in compressive strength (−0.4%), while increasing the CO_2-footprint by 58%.

Notably, the reference sample showed a large decrease in compressive strength after recycling (−36%). A possible explanation may be insufficient mixture homogeneity, which should be investigated in further experiments.

The addition of cement, hydrated lime, sodium alginate combined with calcium chloride, and ammonium lignosulfonate significantly impaired the performance of the recycled material, resulting in an average reduction in compressive strength of approx. 3.7 MPa after recycling, which may be partly attributed to the relatively high additive dosage ($\geq$2.1 wt.%). This behaviour could also be explained by the irreversible hydration reactions of hydraulic binders during the first production cycle, which limits their contribution to strength development after reprocessing. Similar trends have been reported by Audren et al. [3]. Moreover, the combination of sodium alginate and calcium chloride increased the GWP by approx. 600%.

However, the addition of xanthan gum or methyl cellulose resulted in a considerably smaller reduction in compressive strength after the first recycling process, with an average decrease of only 0.34 MPa. In both cases, the additive dosage was only 1.0 wt.%, which further supports the assumption that additive content plays a decisive role in this effect. In contrast, the addition of 1.0 wt.% Oxabrick LOKO did not lead to a similar behaviour, as the compressive strength decreased by 1.46 MPa after recycling. However, an increase in the number of recycling cycles could further enhance the observed effects.

6 Conclusion

The results suggest that CEBs are difficult to recycle due to their high compaction. Given the low environmental impact ambition of these materials, the selection of stabilising additives needs a careful elaboration and targeted research on efficient recycling and processing methods is required. Methyl cellulose and xanthan gum showed high strength retention, suggesting that such additives can facilitate the loosening of the grain structure at the particle level and thereby improve the recyclability of the material. Overall, the results demonstrate that even small amounts of additives can considerably alter the environmental performance of SCEBs.

The study is limited to a single recycling cycle and compressive strength testing. Further research should assess repeated recycling, durability-related properties, alternative processing strategies, a additive reintroduction during recycling and the effect of dosage. It should also be noted that the results are based on a small-scale laboratory investigation; therefore, further studies under larger-scale or practical conditions are necessary to confirm the findings.

Environment-Carbon-Energy Relationships to Justify Climate-Responsive Economic, Technical and Nature-Based Solutions

Irina Kolupaieva(✉) and Yurii Romashov

Kharkiv National University of Radio Electronics, Nauky Ave. 14, 61166 Kharkiv, Ukraine
iryna.kolupaieva@nure.ua

Abstract. This study examines relationships between environmental indicators, carbon dioxide (CO_2) emissions from economic activities, and existing energy technologies to justify climate-responsive economic, technological, and nature-based solutions. The research purposes to develop qualitative representations of environment–carbon–energy relationships using mathematical tools and available statistical data. The methodology combines mathematical modeling and statistical analysis of environmental, energy, and emissions indicators, allowing identification of key dependencies between conditions, emissions, and energy systems. Results show that environment–carbon–energy relationships can be represented through qualitative models. The analysis highlights integrated climate measures, including reforestation, biotechnologies for high-carbon-sequestration plants, improved energy technologies, and reduced energy use, which may reduce CO_2 emissions and mitigate environmental degradation. The approach provides a basis for preliminary assessments and supports future research and policy development.

Keywords: Carbon-Dioxide · Energy · Production · Consumption · Environmental Resilience

1 Introduction

Rising atmospheric carbon dioxide (CO_2) concentrations are a major driver of global climate change, highlighting the need for climate-responsive solutions. Effective strategies should combine economic measures, technological improvements, and nature-based restoration to reduce environmental degradation. Because CO_2 emissions are largely energy-related, it is essential to analyze environment–carbon–energy interactions for understanding human impacts and informing policy development [1].

Environment–carbon–energy interactions differ across countries due to variations in economic development, technological capacity, and natural resources. Studies show that both developed and emerging economies face significant challenges related to carbon emissions and environmental pollution. Addressing these challenges requires coordinated international efforts and evidence-based policies that balance economic development with environmental sustainability. The increasing availability of environmental

and economic data enables the application of advanced computational methods to analyze these relationships. This research develops models that support climate-responsive economic, technological, and nature-based solutions for sustainable environmental management.

1.1 A Literature Review

Rising atmospheric carbon dioxide (CO_2), largely driven by economic activity, is a major contributor to global climate change. Because most emissions are energy-related, research increasingly focuses on environment–carbon–energy interactions [2]. These relationships differ across countries due to variations in economic development and technological capacity. However, all economies face similar challenges related to carbon emissions and environmental pollution [3, 4]. Addressing this global issue requires coordinated international action and sustainable policy frameworks [5, 6]. Mathematical methods are widely used to analyze these interactions and support evidence-based environmental policies aimed at reducing CO_2 emissions [2–4, 7].

1.2 A Principal Goal and Research Questions

This research focuses on the relationships between environmental, energy, and carbon dioxide (CO_2) emission indicators, which are essential for supporting climate-responsive economic, technical, and nature-based solutions. The principal objective of this study is to develop general qualitative representations of environment–carbon–energy relationships.

To achieve this objective, the research addresses the following research questions (RQs):

RQ1: How can environment–carbon–energy relationships be represented using mathematical tools and existing statistical data?
RQ2: Which economic, technical, and nature-based solutions can be implemented to support climate-responsive policies?
RQ3: What are the expected effects of implementing climate-responsive solutions?

The results of this research are intended to provide a conceptual framework that can be used other researchers for further analysis and policy development.

2 Methodology

The methodology of this research applies mathematical modelling and statistical analysis to examine the relationships between environmental indicators, carbon dioxide (CO_2) emissions from economic activities, and existing energy technologies. Using available statistical data, the study develops qualitative representations of environment–carbon–energy interactions. This approach enables the assessment of environmental responsibility within current energy systems and supports the evaluation of economic, technological, and nature-based solutions aimed at reducing emissions and improving environmental performance.

2.1 A Natural Environment

Influence of carbon dioxide emissions related to economic activities on the natural environment is considered through the by using the following ordinary differential equation:

$$dx/dt = -a(t)x + mE(t), \tag{1}$$

where $x = x(t)$ is the carbon dioxide concentration above the natural value depending on the time t; $a(t)$ is the integrated absorption parameter; $E(t)$ is the carbon dioxide emission related to all economic activities; m is the coefficient required to transform the mass of the carbon dioxide to its concentration.

The proposed Eq. (1) is indeed simplified Lotka-Volterra equations considering atmospheric carbon dioxide as the prey, but plants and other dioxide carbon absorbents as the predators, so that the simplification is due to representing the predators by means of the integrated absorption parameter depending on the time. The existing statistical data represent the carbon dioxide concentration and emission during the time, and they allow us to estimate the integrated absorption parameter:

$$t = t_k,\ \ x_k = x(t_k),\ \ E_k = E(t_k)\ \ \Rightarrow\ \ a_k = (mE_k - dx_k/dt)/x_k,\ \ k = 1, 2, \ldots, n, , \tag{2}$$

where t_k is the year associated with known statistical data x_k and E_k; $a_k = a(t_k)$ is the estimated value for the integrated absorption parameter at the time t_k; dx_k/dt is the derivative approximately computed through x_k values using well-known 3-nodes formulas; n is the count of available statistical data.

The values a_k estimated using Eq. (2) and the existed statistical data about forests' area allow us to make parametric identification to estimate the relationship:

$$a = \alpha F, \quad \alpha = \sum_{k=1}^{n} a_k F_k / \sum_{k=1}^{n} F_k^2, \tag{3}$$

where α is the parameter of the linear regression between the absorption parameter a and the forests' area F; F_k is the known forests' area related to the t_k year.

Thus, Eqs. (1) and (3) allow us to represent the influences of carbon dioxide emissions and deforestation on the carbon dioxide concentration.

2.2 Economics and Energy Technologies

The carbon dioxide emissions are economic activities requiring energy usages, so the energy consumption can be assumed as the economic indicator. The production of energy required to be consumed is responsible for carbon dioxide emissions, so this emission is depended on the energy consumption:

$$E = \beta C, \quad \beta = \sum_{k=1}^{n} E_k C_k / \sum_{k=1}^{n} C_k^2, \tag{4}$$

where β is the parameter of the linear regression between the carbon dioxide emission E and the energy consumption C; C_k is the energy consumption at the t_k year.

The value β defined by the Eq. (4) gives the carbon dioxide emission per unit of consumed energy, so environment-responsible energy technologies must provide smaller value of this value. Thus, this value, defined by Eq. (4), represents the overall level of environmental responsibility of energy technologies.

2.3 Climate-Responsive Solutions

An increase in atmospheric carbon dioxide (CO_2) concentration is a critical driver of climate change, making it essential for climate-responsive solutions to focus on preventing further rises. The Eq. (1) allows us to define:

$$dx/dt = 0 \Rightarrow -a(t)x(t) + E(t) = 0 \Rightarrow E(t) = a(t)x(t). \tag{5}$$

Substitutions of Eqs. (3) and (4) to Eq. (5) lead to the following relationship providing zero velocity of carbon dioxide concentration:

$$C = F\alpha x/\beta. \tag{6}$$

The Eq. (6) gibes the environment-responsible energy consumption (economic activity) providing zero velocity of carbon dioxide concentration for its already achieved concentration x and for the existing forests' area F under the existing level β of energy technologies and the and nature's ability α to absorb carbon dioxide.

3 Primary Data, Results, and Discussions

The Internet resources provides data on climate, biodiversity, and economic activity, enabling analysis of environment–carbon–human interactions. Databases from international and government sources support modeling and scenario analysis, helping to assess trends and guide climate-responsive policies.

3.1 Carbon Dioxide

Research on carbon dioxide (CO_2) is based on multiple data sources. Concentration data are obtained from the Copernicus Climate Change Service (C3S) [8], supported by the European Union. Total CO_2 emissions data are sourced from the World Bank's Open Data portal, Data360 [9], while emissions from energy combustion and industrial processes are provided by the International Energy Agency (IEA) [10]. These datasets form the empirical basis for analyzing environment–carbon–energy relationships and assessing climate-responsive solutions. The data [8, 9] are given in the tabled view, but the data from the site [10] are extracted manually from the corresponding diagram; all the data are collected in the single xlsx file. The data [8] are given for month periods, and they are averaged for calendar years. So, these accessible data provide primary quantitative estimations using Eqs. (2) and (5).

The coefficient m, which was introduced in Eq. (1), is defined in the view:

$$m = 10^{12}10^6/V, \quad V = \frac{4}{3}\pi(R+h)^3 - \frac{4}{3}\pi R^3, \quad R = 6371000 \text{ m}, \quad h = 10000 \text{ m}, \tag{7}$$

where m is the coefficient that allows us transform Gt to mg/m^3; V is the volume of the atmosphere's part containing the most of the carbon dioxide; R is the radius of the Earth, and h is the height of the atmosphere's part containing the most of the carbon dioxide.

Corresponding programs were developed using the R programming language and the related Anaconda open-source software to perform calculations and visualize the results, as shown in Fig. 1.

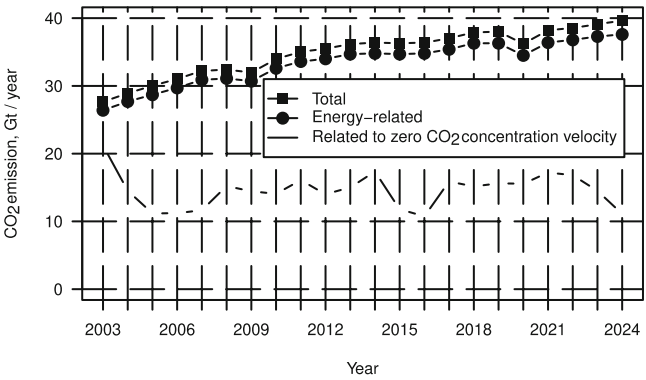

Fig. 1. Carbone dioxide emissions.

Analysis of the primary data and computed results indicates that the majority of carbon dioxide (CO_2) emissions are energy-related, and overall CO_2 emissions have increased over time. Actual CO_2 emissions exceed the computed values corresponding to a zero velocity of CO_2 concentration (see Fig. 1), indicating that current emissions contribute to a rise in atmospheric CO_2 levels. The difference between actual emissions and those corresponding to zero velocity was relatively small in 2003 (approximately 30%) but increased substantially by 2014 (approximately 300%), despite the total increase in CO_2 emissions from 2003 to 2014 being only about 30%. This discrepancy is attributed to a twofold decrease in the CO_2 emissions corresponding to zero velocity of concentration during this period (see Fig. 1). Therefore, the increase in CO_2 concentration results not only from rising emissions but also from the decline in the reference emission level corresponding to zero velocity. Reducing CO_2 emissions to the 2003 level has a mitigating effect but does not fundamentally alter the trajectory of environmental pollution.

3.2 Influences of Deforestation and Energy Technologies

Research on the influences of deforestation and energy technologies is based on data from the World Bank's Open Data portal [11, 12]. Data [11] are provided in tabular

form, while data [12] were manually extracted from the corresponding diagram. All data were consolidated into a single XLSX file. These datasets, together with results computed using Eq. (5), provide primary quantitative estimations through Eqs. (3) and (4). Corresponding programs were developed using the R programming language and related open-source software to perform calculations and visualize the results, as shown in Fig. 2.

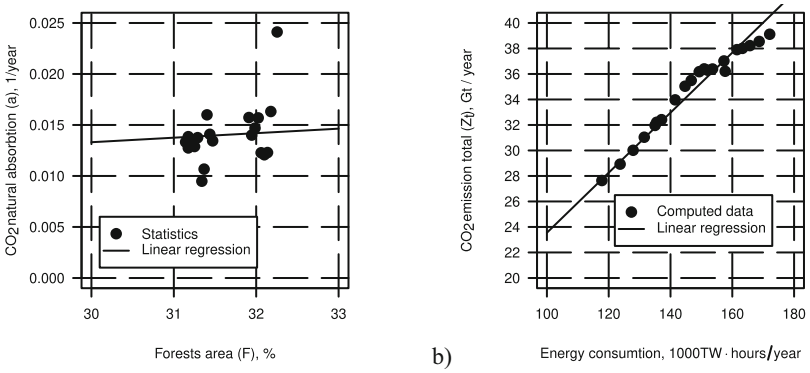

Fig. 2. Estimations for deforestation (a) and energy technologies (b)

Figure 2 a demonstrates that deforestation significantly influences the CO_2 absorption capacity. The linear regression model (Eq. 3) approximates the actual data reasonably well (see Fig. 2a), indicating that forest area is not the sole factor determining CO_2 absorption. Nevertheless, the regression model can be used for preliminary estimations of absorption capacity and provides a basis for further analysis.

The results (see Fig. 2b) show that the linear regression Eq. (4) allows us represent relationships between a carbon dioxide emission and an energy consumption. It proves, that energy technologies are the same during the times covered by the data.

3.3 Environment-Carbon-Energy Relationships

The results presented in Figs. 1 and 2 allow the application of Eq. (6), which is illustrated in Fig. 3 using programs developed in the R programming language and related open-source software for calculations and visualization.

As shown in Fig. 3, actual carbon emissions are approximately twice the values corresponding to zero velocity of CO_2 concentration, indicating that reducing emissions alone is insufficient to prevent environmental degradation. However, increasing forest cover from 31% to 33% and improving energy technologies to achieve a 50% reduction in carbon emissions, combined with reducing energy consumption to 2003 levels, can help prevent further environmental degradation.

It should be emphasized that CO_2 absorption capacity, as defined in Eq. (1), can be enhanced not only through reforestation but also by selecting plant species with higher carbon sequestration potential.

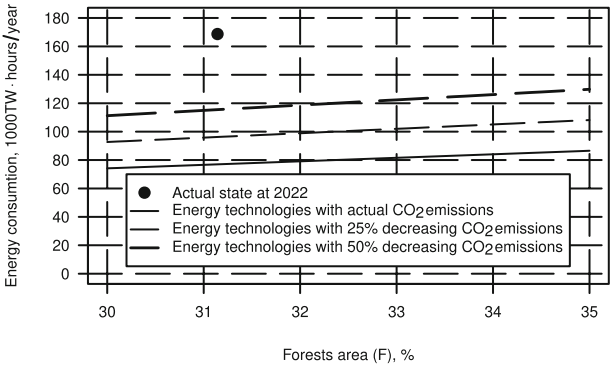

Fig. 3. Carbon dioxide emissions related to zero velocity of carbon dioxide concentration (curves) and an actual state (marker).

4 Conclusions

This study examined relationships between environmental indicators, CO_2 emissions, and energy technologies to support climate-responsive solutions. Results indicate that environment–carbon–energy interactions can be represented qualitatively using mathematical tools and statistical data, highlighting key links between environmental conditions, emissions, and energy systems. The findings emphasize the importance of integrated climate measures. Reforestation, biotechnologies for high-carbon-sequestration plants, improved energy technologies, and reduced energy use can help lower CO_2 emissions, mitigate environmental degradation, and support more effective environmental and energy policies. Despite these contributions, the study is limited by focusing mainly on forest area, with other environmental and ecological factors not fully incorporated. Future research should include additional environmental indicators and factors affecting carbon absorption, as well as more detailed statistical analysis and expanded datasets for more precise assessment of environment–carbon–energy relationships.

Integrating Circular Economy Principles into Industrialized Façade Renovation Systems: A Multi-KPI Assessment

Magdalena Zabek[1(✉)] and Thaleia Konstantinou[2]

[1] Chair of Resource-efficient Construction, TU Dortmund University, 44227 Dortmund, Germany
magdalena.zabek@tu-dortmund.de
[2] Department of Architectural Engineering, TU Delft University, 2628 BZ Delft, Netherlands

Abstract. This study investigates how circular economy principles can be integrated into industrialized building envelope renovation systems to reduce environmental impacts and support the EU's climate neutrality targets. In the context of a real-world façade renovation scenario, a multi-KPI methodology is applied to assess resource efficiency and sustainability across four European demonstration buildings. The approach combines the hierarchical alignment of Key Performance Indicators (KPIs) - particularly Global Warming Potential (GWP), reuse, recycling, and biobased content—with decision-making analyses that link material choices to quantifiable environmental effects. An assembly-level assessments support transparency in design decisions and highlight the influence of stakeholder engagement, regulatory constraints, and economic considerations. Results show significant variability in GWP across façade systems, largely driven by structural materials such as steel and aluminium, while biobased insulation contributes notable carbon reductions. The comparison of the façade renovation solutions with alternative material strategies demonstrates the potential for lower-carbon renovation systems through increased use of timber structures, biobased composites, and recycled materials. The study concludes that early integration of sustainability expertise and KPI-driven design processes is essential to achieving resource-efficient, low-carbon renovation outcomes, providing a practical roadmap for advancing circularity in the built environment.

Keywords: circular renovation · industrialized façade systems · life cycle assessment · KPIs · Global Warming Potential · circular economy

1 Introduction

The Circular Economy (CE) promotes resource efficiency by narrowing, slowing, and closing material loops [1]. Standardized methods such as Life Cycle Assessment (LCA) and the Level(s) methodology [2], provide a framework for assessing carbon emissions and resource consumption in the built environment.

Achieving climate neutrality by 2050 [3] requires decarbonization, resource efficiency, and large-scale renovation. Over 85% of European buildings fail to meet energy

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 1126–1133, 2026.

efficiency standards [4]. While deep renovations can cut energy consumption by 60–90% [5], the current renovation rate is insufficient [4]. The EU Renovation Wave [4] aims to double energy-based renovations by 2030 to accelerate progress. By 2027, life-cycle Global Warming Potential (GWP) calculations will be mandatory for construction projects [6], emphasizing the need for circular renovation strategies.

A shift from traditional to industrialized renovation systems is crucial to achieving efficiency and sustainability. Prefabricated solutions enhance speed, reduce disruption, and allow for modular adaptability. This study examines circularity considerations in developing an industrialized building envelope renovation system of a real case scenario [7] (illustrated in Fig. 1).

The study adopts a multi-KPI (Key Performance Indicator) approach, structured as follows:

- Hierarchical alignment of KPIs, aligning LCA [8, 9] and Level(s) framework [2] with common CE definitions.
- Decision-making impact assessment, linking design choices to environmental KPIs such as GWP.
- Assembly-level evaluation, providing granular insights into the environmental performance of a modular system and alternative solutions.

Analyzing building systems at the assembly level is crucial, as it allows design solutions and research findings to be transferred across projects due to their scalability and applicability to diverse construction contexts. The present research aims to support sustainable renovation practices by providing transferable strategies that enable measurable environmental benefits.

2 Methodology

The approach of the study targets the hierarchical alignment of a multiple-KPI perspective based on the following consideration:

- Identification and hierarchical alignment of KPI's (Sect. 3),
- Linking decisions to environmental effects and KPIs (Sect. 4), and
- Assessment at the Assembly-Level and proposing alternative solutions (Sect. 5).

The decision making is implemented in the renovation design and evaluation of 4 demo cases presented in Table 1.

3 Identification and Hierarchical Alignment of KPI's

KPIs guide design processes toward circularity. In the AEGIR project [7] and related studies [10–12] KPIs inform decisions on material reuse, lifespan extension, and modularity, supporting sustainability. They align with the European CE strategy and the UN 2030 Agenda [13], particularly SDG 12.

CE concepts, such as Cradle-to-Cradle (C2C) [14] and the R-strategies [15], emphasize continuous material flows and biodegradability. KPIs based on these models include material purity, recyclability and the use of renewable or biobased materials. Standard tools like LCA and Level(s) quantify environmental impacts, focusing on GWP and circularity [2]. Within the study framework, GWP and the amount of secondary resources were prioritized as KPIs, with biobased materials lowering GWP and secondary materials reducing resource extraction.

4 Linking Decisions to Environmental Effects and KPI's

As product selection plays a critical role in determining the future reusability, resource efficiency, and environmental impact of materials and components [16–18], the prioritized KPIs guided the decision-making process.

Environmentally responsible product selection requires comprehensive data collection at both component and material levels across multiple functional categories. Therefore, during the early design stages, a material database was developed to store all relevant product information, including quantitative data on the selected KPI's.

Architects, who significantly shape material choices and construction methods, often struggle to make environmentally responsible decisions [19] due to a lack of clear guidelines and the absence of harmonized benchmarks [20]. This highlights the crucial role of

sustainability experts in guiding the decision-making process toward environmentally friendly solutions.

4.1 Decision-Making in the AEGIR Project

In the AEGIR project, sustainability experts shaped decisions by evaluating products' GWP (Sect. 5) and fostering stakeholder collaboration. Across all demos, outcomes reflected the complex interplay of design, sustainability, and stakeholder interests, with regulatory, social, and financial factors strongly influencing decisions. The following sections outline stakeholder roles and key factors affecting sustainability and other project decisions.

4.2 Stakeholder Involvement

Across all demo projects, the involvement of sustainability experts proved to be pivotal. They played a key role in conducting LCA, advising on secondary materials, and guiding strategies for material preservation. A recurring challenge, however, was ensuring that sustainability considerations were integrated early enough in the process, as well as managing the additional costs associated with circularity strategies.

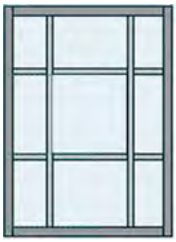
The Danish demo project highlighted the importance of clear and early communication between experts and building owners. Guidance from advisory bodies at an early stage was essential, particularly in conveying circularity principles to owners. This proved critical when economic concerns initially led to the project's rejection, demonstrating that informed dialogue can shift perspectives and enable more sustainable decisions.

Similarly, the Spanish demo project underscored the value of engaged ownership combined with early involvement of sustainability experts. This collaboration helped ensure that reused materials met both environmental performance requirements and availability constraints. Despite practical challenges, proactive engagement from the owner ultimately strengthened the project outcomes.

In the Romanian project, early involvement of contractors enabled greater flexibility in integrating circular materials and adapting construction processes accordingly. Nevertheless, the lack of stakeholders representing the end-of-life (EoL) phase limited opportunities for component reuse, pointing to the need for a more comprehensive inclusion of actors across the entire building lifecycle.

4.3 Sustainability Decisions in the Demonstration Projects

In the Danish demo, an early material inventory enabled the identification of reusable components, supporting material recovery and embodied carbon reduction, with ceramic tiles selected based on GWP and structural feasibility. The Spanish demo emphasized reclaimed eucalyptus wood for cladding to enhance durability and reduce carbon emissions, while also assessing laminated biobased panels for their GWP performance. In the French demo, low-carbon concrete was initially considered but ultimately replaced by aluminium cladding due to regulatory and weight constraints. In the Romanian demo, the owner's preference for virgin materials limited circular strategies, shifting the focus toward energy efficiency and influencing thermal performance decisions.



4.4 Other Influencing Factors

The French project illustrated how innovation is often constrained by timelines and approval processes. Lengthy regulatory procedures and concerns regarding material performance ultimately led to a shift from low-carbon concrete to conventional aluminum cladding. More broadly, decision making throughout the project was strongly shaped by regulatory and practical constraints, including weight limitations, structural requirements, fire regulations and approval timelines. In addition, cost considerations played a decisive role, with economic factors significantly influencing the final selection of materials.

5 Assessment at the Assembly Level

This study assesses the GWP (kg CO_2 eq.) of opaque façade modules used in the AEGIR demonstration projects. The system consists of modular units incorporating structural elements, internal and external enclosures, gaskets for airtightness, and insulation and cladding for thermal performance. The results are presented in Table 2.

Table 2 Assessment of the GWP (CO_2 eq.) of each AEGIR opaque panel

	Demo 1 (DK)	Demo 2 (SP)	Demo 3 (FR)	Demo 4 (RO)
				
Total Area	6.23 m^2	9.03 m^2	6.408 m^2	4.72 m^2
Technology	PV panels	/	/	2 Vents
Structure GWP	Aluminum 89.1	Steel 17.9	Wood -14.2	Steel 113.4
Anchorage GWP	Steel 0.2	Steel 0.1	Steel 0.3	Steel 9.7
Cladding GWP	Ceramic tiles 7.3	Ceramic tiles 1.5	Aluminum 51.5	Ceramic tiles 7.3
Insulation GWP	Woodfibre -8.4	Woodfibre -7.9	Woodfibre 7.7	Woodfibre -10.8
Enclosure GWP	Fiber cement 9.8	Fiber cement 9.8	Fiber cement 4.9	Fiber cement 9.8
PV panel GWP	28.5	/	/	/

(*continued*)

Table 2 (*continued*)

	Demo 1 (DK)	Demo 2 (SP)	Demo 3 (FR)	Demo 4 (RO)
Total GWP/m^2	**96.4**	**36.3**	**38**	**155.4**

The environmental performance of the façade systems varies considerably across the demo sites. The Danish system shows a GWP of 96.4, largely driven by the aluminium structure, which accounts for 62% of the total, while wood fibre insulation offsets emissions by 6%.

The Spanish system achieves a substantially lower GWP, supported by biogenic materials. Wood fibre insulation provides a reduction of 15%, while the steel key frame contributes to a total of 35% GWP.

The Romanian system records the highest GWP at 155.4, dominated by its steel structure, which accounts for 66% (113.4 GWP).

The French solution achieves the second-lowest GWP at 38, largely due to timber structures, which provide a reduction of 27%. However, windows and metal shading systems significantly increase the overall impact, accounting for 57% of the total GWP.

5.1 Development of Alternative Solutions

The AEGIR solution relies on steel and aluminium for structural components. While durable and recyclable, these materials have a high GWP due to energy-intensive production. Lower-carbon alternatives include Cross-Laminated Timber (CLT) or recycled steel and aluminium. For cladding, AEGIR uses ceramic tiles, aluminium sheets, or laminated biobased panels, which range from moderate to high GWP. Alternatives such as timber cladding, bio-based composites with improved EoL systems, or low-carbon concrete could significantly reduce emissions if recycling challenges are addressed. Biobased insulation materials like wood fibre or cellulose help offset emissions through carbon sequestration but require careful consideration of fire safety and EoL strategies. Alternatives include hempcrete or straw as biodegradable options, or recycled PET and fabric insulation, although these represent downcycling; upcycling should be prioritized.

Metal shading systems substantially increase GWP. Lower-impact alternatives include smart windows or fabric shading systems with better recyclability.

Finally, photovoltaic panels help offset embodied emissions over time, while metal-based ventilation systems contribute to GWP but are not included in the calculations. Thin-film photovoltaics, bio-based ventilation components, or manual ventilation systems could further reduce the overall environmental impact.

6 Conclusions

This study shows that industrialized building envelope renovation systems can significantly reduce environmental impacts when circular economy principles are embedded in early design decisions. Using a multi-KPI framework aligned with LCA and the Level(s) methodology, GWP and secondary resource use proved effective in guiding material selection toward circular solutions.

Results from the four AEGIR demonstration projects highlight that environmental performance is strongly influenced by structural systems, material choices, and stakeholder involvement. Biogenic materials consistently lowered GWP through carbon sequestration, while steel and aluminium structures dominated embodied emissions. Early involvement of sustainability experts supported informed decision-making, whereas regulatory constraints, costs, and limited end-of-life stakeholder integration often restricted circular options.

Assembly-level assessments revealed that structures, windows, and shading systems are key GWP drivers. The analysis of alternative solutions indicates further reduction potential through timber-based or recycled materials, improved EoL strategies, and lower-impact façade and energy systems.

Overall, the findings confirm that KPI-driven, industrialized renovation approaches can deliver measurable environmental benefits and support upcoming mandatory lifecycle assessments, while highlighting the need to address regulatory and process barriers to scale circular renovation practices.

Abstract. Achieving global emission-reduction targets in the building sector requires not only the construction of nearly Zero Energy Buildings and the renovation of existing stock, but also a rigorous assessment of the environmental impact and embodied carbon of these interventions. Life Cycle Assessment is the standardised methodology for quantifying such impacts, while Environmental Product Declarations (EPD) provide third-party verified information at the product level. To date, industry efforts have been focused on passive building components, such as insulation, windows, and façade systems. However, within the nZEB framework, Heating, Ventilation, and Air Conditioning (HVAC) systems, such as heat pumps, mechanical ventilation, or photovoltaics, play a crucial role in achieving decarbonisation. Despite this, their environmental impact remains insufficiently characterised. This study reviews the currently available data for assessing HVAC systems, including Life Cycle Inventory databases, EPD repositories, scientific literature, and a survey of manufacturers. The results show that the sector is not yet prepared to consistently quantify these impacts. The main barriers identified are the lack of regulatory requirements and the technical complexity associated with developing EPDs.

1 Introduction

The concept of planetary boundaries, introduced by Rockström et al. [1], defines the environmental limits within which human activities can safely operate. Several of these limits have already been exceeded, threatening the stability of global socio-economic systems [2]. In this context, buildings play a major role, accounting between 30 and

40% of global energy use and Greenhouse Gas (GHG) emissions [3]. Beyond climate change, the built environment also contributes to other environmental pressures, including water use, resource depletion, ozone depletion, acidification, eutrophication, and waste generation throughout the life cycle of construction products [4].

To comprehensively assess these impacts, Life Cycle Assessment has emerged as a key methodology. Standardised under ISO 14040 and ISO 14044, LCA evaluates the environmental impacts of a process or product across all its life cycle stages, from raw material extraction to end-of-life. A critical stage of the LCA is the Life Cycle Inventory (LCI), which consists of the systematic compilation and quantification of all relevant input and output flows of a product system throughout its life cycle. Additionally, in the European construction sector, LCA is formalised through standards such as EN 15978 for buildings and EN 15804 + A2 for Environmental Product Declarations (EPDs), which provide verified and comparable product-level data. These standards also establish harmonized system boundaries, impact categories, and reporting rules, ensuring consistency in the characterization and comparability of environmental profiles.

In recent years, LCA is evolving from a voluntary practice to a regulatory requirement. European policies such as the Energy Performance of Buildings Directive recast (EPBD, 2024) and the revised Construction Products Regulation (CPR) are driving the mandatory assessment and disclosure of life cycle environmental impacts. However, while EPDs are well established for construction materials, their development for technical systems, particularly HVAC, remains limited. This gap is mainly due to the complexity of these systems and their heavy dependency on operational conditions. Nevertheless, increasing regulatory pressure is expected to accelerate the availability of reliable environmental data for HVAC systems.

In this context, this work analyses the current state of EPD implementation within the HVAC sector and explores future trends. The study combines a review of public LCI and EPD databases together with a systematic review of LCA studies involving HVAC systems, focusing on data sources. Additionally, a survey of European HVAC manufacturers is conducted to assess the sector's readiness. This work aims to provide a comprehensive overview of current limitations and support the integration of HVAC systems into building-level LCA. Given the current scarcity and heterogeneity of publicly available HVAC environmental data, this work is intended as an exploratory state-of-practice assessment rather than a fully quantitative analysis.

2 Methodology

The three foundational aspects of this work are: an exploration of available data in public LCI and EPD databases; a systematic review of scientific studies on LCA, including HVAC systems; and a questionnaire for HVAC manufacturers regarding their knowledge and readiness for EPDs of HVAC systems. Due to extension limitations, a selection of the most used systems in residential buildings has been made, including boilers, Heat Pumps (HP), Mechanical Ventilation (MV) systems, Photovoltaic (PV) panels, and Solar Thermal (ST) panels. All these systems were indistinctly differentiated both for heating and/or Domestic Hot Water (DHW) services.

2.1 LCI and EPD Databases Review

The review of LCI and EPD databases was initiated through the analysis of platform search engines such as OpenLCA Nexus (nexus.openlca.org) and Global LCA Data Access (globallcadataaccess.org). Based on these generic search tools, a total of 32 databases were identified, prioritising open-access platforms. Of these, 23 correspond to platforms collecting EPDs, while the remaining 9 provide generic LCI datasets. The geographical scope of the analysed databases is presented in Fig. 1, showing that the highest number of platforms are located in Spain, followed by Germany and Australia. Additionally, 4 of the analysed platforms have an international scope. This approach ensures a broad and globally representative dataset. For each platform, a comprehensive search was conducted to identify available environmental data for the HVAC systems previously defined. Each database was manually screened and classified according to the presence and quantity of HVAC-related datasets for the selected technologies.

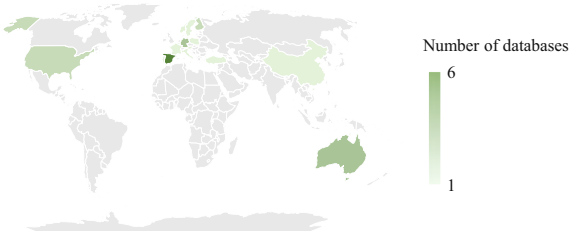

Fig. 1. Geographical scope of the LCI and EPD databases included in the review.

2.2 Scientific Literature Review

A systematic review approach was adopted for the literature analysis, using two widely used databases: Scopus and Web of Science (WoS). Due to the study's extension limitation, the search queries were strictly defined, limiting the search to studies published within the last 5 years and including keywords such as "EPD", "HVAC", or "built environment". The search has also been segmented by the type of HVAC system analyzed. For example, for boilers, the query used in Scopus is "*ALL ((“life cycle assessment”” OR LCA) AND (“environmental product declaration” OR EPD) AND (boiler* OR “natural gas boiler*”) AND (building* OR “built environment”) AND (HVAC OR “heating ventilation air conditioning”)) AND PUBYEAR > 2020*". Studies were included when they provided explicit environmental impact calculations for specific HVAC systems using identifiable LCI datasets or EPD sources. Review papers, methodological discussions, and studies without system specific inventory data were excluded from the final sample used for this study.

Figure 2 presents the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) flow diagram of the search process. A total of 110 studies were initially identified. Most of them involve MV systems, followed by PV and HPs. After removing 37 duplicates, a screening phase based on titles, abstracts, and keywords

reduced the sample to 40 studies. Finally, eligibility criteria were applied, restricting the analysis to high-impact (Q1) journal publications. The final sample comprises 29 studies, predominantly focused on MV, PV, and HP systems, with boilers the least represented. These studies were analysed in detail, examining the HVAC systems addressed, the data sources used, and the LCA stages considered.

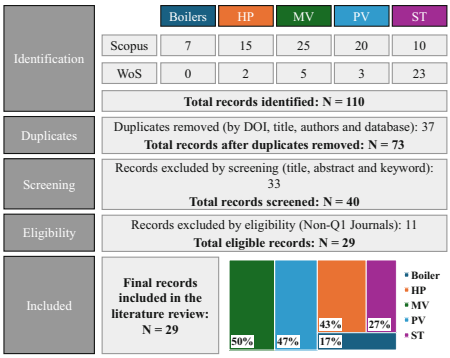

Fig. 2. PRISMA flow diagram used in the systematic review.

2.3 Questionnaire for Manufacturers

Finally, this study is supported by a questionnaire currently being distributed to HVAC system manufacturers to assess their level of awareness and readiness regarding the development of EPDs for their products. In short, the questionnaire is structured into three main sections. The first addresses general company information, including the types of HVAC systems manufactured and their geographical scope. The second focuses on the level of knowledge of LCA and EPD related regulations, as well as perceived barriers and incentives for conducting such assessments. The third directly examines whether manufacturers currently have any EPD for their products and whether they plan to develop them in the future. As the survey is still ongoing, only preliminary results are reported in this study. At this stage, the questionnaire results are considered indicative and exploratory, as the survey campaign is still ongoing.

3 Results and Discussion

3.1 Environmental Product Declarations (EPDs) Databases Review

Figure 3 presents the list of analysed EPD and LCI databases, including their geographical scope, names, and websites. For each database, the number of available items for the HVAC systems under study was assessed and categorised as follows: no items (white), at least one item (orange), between two and five items (blue), and more than five items (green). Regarding EPD databases, out of the 23 analysed, 8 contain no EPDs for the selected HVAC systems. In the remaining databases, available data are limited and highly

heterogeneous. Boilers and ST systems show the lowest data availability, whereas PV and MV systems are the most represented. From a geographical perspective, the French platform PEP Ecopassport stands out, providing more than five EPDs for each analysed system.

As for LCI databases, 7 out of 9 platforms include data related to HVAC systems. However, these are typically generic datasets rather than product-specific items, covering a range of system configurations. Notably, both the EPD and LCI databases include extensive data on passive building components, highlighting the significant gap relative to the data available for HVAC systems.

3.2 Scientific Literature Review

The bibliographic review analysed key aspects such as geographical context, building typology, LCA system boundaries, and the specific HVAC systems considered. Attention was given to the source of LCA data, distinguishing between manufacturer-specific EPDs and generic database inputs. Of the 29 studies initially included (Fig. 2), only 13 were deemed directly relevant for detailed analysis, as they provide explicit LCA calculations for HVAC systems. The discarded studies are not relevant because they are review papers or focus on methodological frameworks without analysing specific systems or using detailed LCI or EPD data. This result itself reflects the current limited maturity and transparency of HVAC specific LCA data within the scientific literature.

Figure 4 summarises the main findings of these 13 studies selected, whose references are [5–13]. The sample is internationally distributed, although predominantly European. Most studies focus on residential and office buildings, and primarily analyse HP, PV, and MV systems, with ST being the least represented. Most adopt a cradle-to-grave

approach, although with variations regarding the modules included, particularly in the operational phase. Regarding data sources, 9 studies rely on the Ecoinvent database, while 2 use One Click LCA, both of which are proprietary tools. Only 1 study uses the French open-access PEP Ecopassport database. Additionally, 5 studies report using manufacturer-specific EPDs, mainly for PV systems, although none explicitly reference the EPDs, limiting transparency and reproducibility. It is also worth noting that all the studies analysed do include the environmental impact of the thermal envelope elements in their analyses, emphasizing that there are no availability problems with these elements.

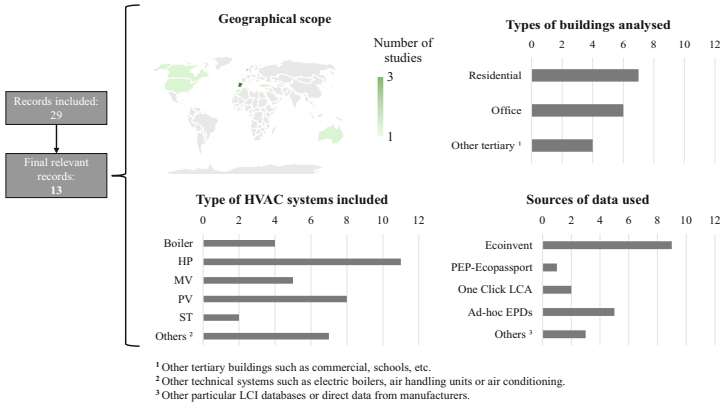

Fig. 4. Main results of the aspects analysed within the systematic review.

3.3 Discussion

The results from both the database analysis and the literature review reveal a clear lack of available data for conducting robust environmental impact assessments of HVAC systems within the building environment. Among the 29 databases analysed, only one (the French PEP Ecopassport) provides a substantial number of EPDs for multiple technical systems. Similarly, out of an initial sample of 110 studies, only 13 explicitly assess the environmental impact of HVAC systems. Although standards such as ISO 14040/44, EN 15978, and EN 15804 + A2 provide a common methodological framework, their practical implementation for HVAC systems remains inconsistent due to the limited availability of harmonized product-specific data

Several studies, Beneito et al. [5], Kayaçetin et al. [9], and Loli et al. [10], highlight this data gap, noting the difficulty of obtaining reliable, manufacturer specific EPDs. Seuntjens et al. [17] further suggest that generic data often require validation with real manufacturer data to ensure robust LCA results. At the same time, other studies, Norouzi et al. [14], Opher et al. [15], y Rabani et al. [16], indicate that HVAC systems account for an increasing share of total building impacts (between 17% and 31%) as building energy demand decreases with new construction standards. However, life cycle stages of HVAC systems such as production and end-of-life are often excluded due to their

complexity (Gobinath et al. [7]), and most studies only consider HVAC systems in operational stages. Preliminary results from the manufacturer survey confirm these findings. While respondents acknowledge the growing regulatory pressure to assess environmental impacts and develop EPDs, most indicate that they currently lack such data and have no immediate plans to produce it, mainly due to technical complexity and limited market demand.

4 Conclusions

In conclusion, this study analyses the significant gap in the availability and quality of environmental impact data for HVAC systems within the building sector. The results should be interpreted considering the limited availability and comparability of publicly accessible HVAC environmental datasets. Despite the increasing relevance of LCA in regulatory and research contexts, the results show that current data sources (both EPD repositories and LCI databases) remain limited, fragmented, and highly heterogeneous. The literature review further confirms that only a small subset of studies explicitly addresses HVAC systems using detailed and transparent datasets, with a strong reliance on private databases rather than manufacturer-specific information.

Moreover, the findings indicate that although HVAC systems are becoming increasingly important contributors to total building impacts, their embodied emissions remain insufficiently characterised, particularly beyond the operational phase. The preliminary results from the manufacturer survey reinforce this conclusion, revealing low readiness levels and highlighting key barriers, including technical complexity and limited market demand. Overall, the sector is not yet adequately prepared to consistently quantify the environmental impact of HVAC systems. As future work, further research will focus on a detailed assessment of the quality of available data, as well as expanding and consolidating the results of the manufacturer survey with a larger sample size.

Environmental Performance of Agro-Industrial By-Products as Circular Feedstock for Building Materials: Insights from Portuguese Residues

Chiara Turco(✉), Cláudia Jacinto, Elisabete Teixeira, and Ricardo Mateus

Department of Civil Engineering, University of Minho, ISISE, ARISE, Guimarães, Portugal
chiaraturco@civil.uminho.pt

Abstract. Agro-industrial by-products are increasingly explored as circular feedstocks for sustainable construction materials. However, their environmental performance is often assumed, while assessments frequently emphasise avoided impacts from substituted products overlooking the impacts embedded in the by-products themselves. This study evaluates the environmental profiles of three Portuguese residues–wheat straw (WS), cork granules (CG), and ground olive stones (GOS)–to assess their suitability for bio-based building materials. A cradle-to-gate life-cycle assessment was conducted using one tonne of by-product as the functional unit and considering multiple impact categories, including global warming potential, acidification, fossil resource use, land occupation, and water depletion. The results reveal marked variability among commonly classified "bio-based" materials. WS and CG show net biogenic carbon sequestration, although WS presents relatively high nitrogen-related eutrophication impacts linked to agricultural practices, while CG displays exceptionally high land-use impacts associated with cork oak management. GOS shows positive carbon emissions and higher fossil resource use due to energy-intensive processing. These findings demonstrate that circular biomass utilisation should rely on accurate life-cycle assessments accounting for specific agricultural practices and regional supply chains, to support more informed material choices and eco-design strategies.

Keywords: Agro-Industrial Residues · Circular Bioeconomy · Bio-Based Materials · Environmental Impacts · Sustainability · Resource Valorisation

1 Introduction

The construction sector is responsible for substantial resource consumption, greenhouse gas emissions and waste production, making it a priority domain for advancing sustainability and circularity strategies worldwide [1, 2]. In recent years, agro-industrial by-products have attracted growing attention as potential feedstock for low-carbon, bio-based construction materials [3, 4]. Their utilisation is often presented as a mutually beneficial strategy: diverting residues from low-value or environmentally burdensome pathways while replacing emission-intensive construction materials. However, this narrative tends to assume that all biomass-derived by-products offer similar environmental benefits, overlooking the heterogeneity of agricultural systems, processing technologies and regional resource conditions [5].

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 1143–1150, 2026.
https://doi.org/10.1007/978-3-032-34930-9_133

The shift from linear to circular models in construction demands more than simply identifying alternative material streams. It requires an understanding of how resource loops perform environmentally across their full life cycle, including trade-offs that may contradict the simplistic assumption that "bio-based equals sustainable". From this perspective, assessing agricultural by-products purely through carbon metrics is insufficient; a broader set of impact categories is required to understand their role within sustainable material ecosystems. Life cycle assessment (LCA) offers a robust framework for quantifying the environmental impacts of such materials and for revealing burdens that are not immediately visible from carbon metrics alone [6].

While many studies evaluate bio-based composites, insulation, or products that incorporate agricultural by-products, fewer examine the impacts of the by-products as standalone feedstock. This gap creates the implicit assumption that the upstream burdens of these residues are negligible or uniformly low, potentially leading to misguided material choices or incomplete circularity assessments. This study addresses this gap by performing a cradle-to-gate LCA of three agro-industrial by-products focusing on a comprehensive set of impact categories relevant to biomass systems, including climate change, eutrophication, acidification, fossil resource use, freshwater ecotoxicity, land occupation, and water depletion.

2 Materials and Methods

2.1 Materials and System Description

This study examines three agro-industrial by-products commonly available in the Mediterranean region: wheat straw (WS), cork granules (CG), and ground olive stones (GOS). Figure 1 shows them.

Fig. 1. Agro-industrial by-products examined: (a) WS, (b) CG, and (c) GOS.

These materials were collected in the Alentejo region, in southern Portugal, characterised by a Mediterranean climate, with hot dry summers, mild winters, and seasonal water scarcity. They were selected as they are representative of distinct biomass value chains (annual cereal agriculture, perennial agroforestry, and perennial fruit oil production) and have proven to be usable in the manufacture of bio-based materials with enhanced thermophysical properties or save raw material [7]. This variability makes them suitable case studies for analysing environmental impacts within biomass-derived resources.

Wheat Straw. WS is the fibrous residue remaining after wheat grain harvesting. In Portugal, it is typically baled directly in the field and used primarily for animal bedding, soil incorporation, or low-grade energy recovery [7, 8].

Cork Granules. CG are derived from the trimming, punching, and milling stages of cork processing. The Portuguese cork industry is globally dominant, operating within long-established cork oak agroforestry systems [9, 10].

Ground Olive Stones. GOS originate from the milling and separation phases of olive oil production. They are generated in large quantities in Mediterranean olive-growing regions. Olive stones are often valorised as biomass fuel, but their incorporation into construction materials is increasingly explored due to their hardness, lignocellulosic composition, and thermal properties [11].

2.2 Life Cycle Assessment Methodology

This study applies a cradle-to-gate LCA to quantify the environmental burdens associated with producing one tonne of WS, CG, and GOS. The methodology follows ISO 14040 standards [12], encompassing goal and scope definition, inventory analysis, impact assessment, and interpretation.

Goal and Scope. The goal of the LCA is to evaluate and compare the environmental profiles of three agro-industrial by-products commonly proposed as circular feedstock for bio-based building materials. The functional unit (FU) selected for this study is 1 t of dry by-product, defined at the point where each residue becomes available for use as a material input. The analysis focuses on upstream burdens only, excluding any downstream transformation into construction products, transportation to building sites, or end-of-life scenarios. This approach isolates the environmental characteristics of each by-product independently from any specific application, enabling generalisable insights for material selection.

Life Cycle Inventory (LCI). Inventory data for WS and CG were obtained from the Ecoinvent v3.9.1 database, while GOS were modelled using specific literature data [13]. The LCI includes impacts associated with the application of fertilisers, the use of diesel in harvesting machinery, electricity consumption in milling processes, and typical transport distances in Portuguese supply chains [13].

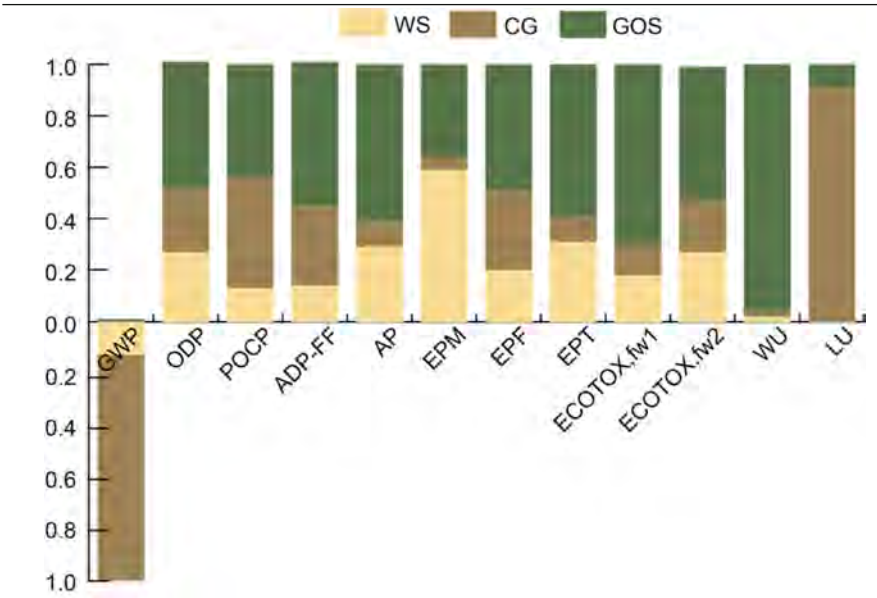
Allocation Procedures. Given that the selected materials are by-products with varying economic relevance, different allocation approaches were adopted, in accordance with ISO 14040 [12] and EN 15804 [14]: (i) economic allocation for processes where residues have market value (cork granules and olive stones); (ii) mass allocation for wheat straw due to its lower economic differentiation relative to grain.

Impact Assessment. For the environmental impact assessment, the following impact categories were selected: climate change (GWP), ozone depletion (ODP), acidification (AP), eutrophication (EP), photochemical ozone formation (POCP), fossil resource use (ADP), ecotoxicity (ECOTOX), land use (LU), and water use (WU).

This set covers both conventional LCA indicators and those particularly relevant to bio-based materials, such as land and water-related burdens. All characterisation calculations were performed using SimaPro v.9.5.0.0, with impact calculations performed through the life cycle impact assessment (LCIA) method.

3 Results and Discussion

The graph of Fig. 2 presents the potential environmental impacts associated with the production of one tonne of WS, CG and GOS across different categories of indicators.



The environmental impacts associated with the production of each by-product reveal significant contrasts between the different impact categories. As for climate change indicator (GWP), the production of WS and CG exhibit negative biogenic carbon values (−200 and − 1361 kg CO_2-eq, respectively), indicating net CO_2 sequestration. CG show particularly high sequestration values because the cork oak, a tree endemic to the Iberian Peninsula, acts as a prolonged carbon sink. Stripping does not kill the tree; on the contrary, it stimulates the regeneration of cork, which enhances CO_2 fixation [15]. Conversely, the production of GOS has a positive GWP impact (21.49 kg CO_2-eq), largely due to the high demand for fossil energy used in the pulp separation process and subsequent olive milling [13]. This high energy consumption is also reflected in the fossil resource consumption indicator (ADP-FF), with GOS ranked first (1339 MJ), followed by CG (735.1 MJ) and WS (334.2 MJ).

Acidification (AP) and eutrophication (EP) are mainly influenced by field management practices. WS has the highest potential for marine eutrophication (EP-M: 1.20 kg N-eq), while GOS has the greatest impacts on acidification (AP: 1.56 mol H + -eq), terrestrial eutrophication (EP-T: 6.13 mol N-eq) and freshwater eutrophication (EP-F: 0.029 kg P-eq), reflecting the intensive use of nitrogen and phosphate fertilisers in its cultivation. CG generally has lower values for these indicators, as the cork oak is a forest species that rarely receives intensive fertilisation.

Regarding POCP, the higher values for GOS (0.647 kg NMVOC-eq) and CG (0.631 kg NMVOC-eq) are linked to the industrial processing stage, specifically thermal treatments and grinding, which release volatile precursors. This is particularly relevant in the Mediterranean summer, where high solar radiation catalyses ozone formation from machinery exhaust and industrial emissions. ODP impacts remained negligible across all materials, though GOS (2.12E-06 kg CFC11-eq) showed a slight increase due to its higher fossil energy demand and associated upstream chemical processes.

The impacts on $ECOTOX_{fw1\&2}$ vary greatly between residues. Notably, GOS exhibits a significantly higher ecotoxicity impact compared to the others natural by-products, as this correlates with the use of pesticides and herbicides in olive grove soil management and with emissions of volatile organic compounds during industrial olive processing. WS, although also treated, has a shorter growth cycle and, in many cases, a lower pesticide load per tonne of biomass than intensive olive cultivation.

Finally, a considerable impact is associated to often overlooked but relevant categories, such as water and land use. In terms of WU, producing one tonne of GOS requires a substantial 552.2 m^3, mainly related to the intensive irrigation of modern olive groves. This figure is critical, given that water scarcity is severe in the Mediterranean region.

Fig. 2. Environmental impact of producing 1 t of by-products in different categories of indicators.

Meanwhile, WS and CG have considerably lower water demands (13.8 and 9.1 m^3, respectively). Conversely, LU is particularly high for CG (199,939 Pt as it requires large

areas of land due to low productivity per hectare and a waiting time of almost a decade for each harvest. For GOS (20,254 Pt) and WS (668.7 Pt), the values are significantly lower, as they produce annually, optimising LU per tonne produced.

The results presented demonstrate that the three agro-industrial by-products exhibit substantially different environmental performance due to the distinct agricultural, forestry and industrial processes from which they originate. Therefore, it is misleading to assume that they have a low environmental impact simply because they originate from organic systems. Although they are by-products of other processes, they can transfer significant environmental impacts to the materials into which they are incorporated. Likewise, treating different agro-industrial by-products as environmentally equivalent can lead to misguided material choices and incomplete circularity assessments. Processing intensity, determined by agricultural practices and regional supply chains–which vary considerably depending on the product–is a key determinant of environmental performance. Here, the results are strongly influenced by Mediterranean production conditions, including irrigation intensity, fertiliser use and the regional energy mix, which further underscores the importance of geographically contextualised LCAs. Lastly, is important to emphasise the need to analyse indicators other than GWP, as they can highlight local constraints. From a construction material selection perspective, WS may be preferable in applications prioritising low fossil energy demand, while CG may be advantageous where carbon sequestration is prioritised and land occupation is less critical. GOS may require careful consideration in water-scarce regions due to its high irrigation-related impacts.

4 Conclusions

In this study, the environmental impact of three agro-industrial by-products widely available in Portugal and in the Mediterranean region was analysed. These are wheat straw (WS), cork granules (CG), and ground olive stones (GOS). Suitable for use as additives in bio-based construction materials, they can serve different purposes: fibres for reinforcement, granules as lightweight aggregates, among others.

The results demonstrate that the environmental performance of agro-industrial by-products is far from uniform. WS and CG exhibit net carbon dioxide sequestration but carry high eutrophication and land-use burdens, while GOS present positive carbon emissions and significant fossil energy use. These distinctions remind us that the environmental performance of residues reflects the underlying production systems. Despite their biological origin, these materials are not zero-impact, particularly when indicators other than global warming potential and fossil resource consumption are examined. Adopting a circular bioeconomy perspective, this study argues that responsible valorisation of agricultural by-products requires a critical assessment of trade-offs across many impact categories, rather than relying solely on carbon-centric narratives. In doing so, it contributes to the design of more realistic and informed pathways for integrating bio-based residues into sustainable building materials and aligns with broader goals of reshaping the built environment towards circularity, resilience, and ecological performance.

4.1 Limitations

Results were analysed comparatively to identify the materials and categories with the greatest environmental challenges. Due to the lack of benchmarks, impacts could not be quantified in absolute terms. Future research should expand the analysis to full life-cycle impacts, include sensitivity analyses on allocation choices, and assess how regional energy transitions may affect energy-intensive residues such as GOS. Our findings also show that allocation choices can strongly influence the environmental profile of agricultural by-products, particularly when residues have economic value or energy recovery potential.

Abstract. The construction industry is a major contributor to global resource use and carbon emissions, making low-carbon alternatives essential to achieving climate neutrality. The European Performance of Buildings Directive (EPBD) requirements for whole-life carbon accounting are accelerating the adoption of materials with low embodied carbon. However, local factors such as climate and national regulations pose challenges to the expected functional performance of solutions, potentially altering their overall sustainability performance and how they are perceived. This study examines the feasibility of adopting earth-based construction techniques to support the building sector's low-carbon and green transition in contrasting contexts: Portugal's Mediterranean climate and Sweden's Nordic climate. Earthen solutions are assessed against conventional alternatives in both countries to ensure compliance with national performance requirements. The comparison applies the Methodology for Relative Assessment of the Sustainability of Construction Solutions (MARS-SC), a multicriteria decision-making tool that evaluates sustainability across three dimensions: environmental, functional, and economic. Environmental performance is informed by LCA, which uses both generic and specific data to compare impacts between earth-based and conventional construction systems. Results show that earth-based construction, particularly in Portugal, can provide substantial environmental advantages, achieving up to 50% lower Global Warming Potential than conventional solutions. In Sweden, however, higher labour costs, longer construction and drying times, and the need for additional thermal insulation layers tend to increase costs and can reduce overall sustainability performance despite potential environmental benefits. The paper discusses the key advantages and limitations of earthen materials in each country and highlights conditions under which earth-based techniques can become a robust low-carbon alternative.

1 Introduction

1.1 Framework

The construction sector is one of the largest contributors to global greenhouse gas (GHG) emissions and resource consumption. Buildings account for approximately 37% of global energy-related CO_2 emissions when both operational and embodied emissions are considered [1]. As operational energy demand decreases due to improved efficiency standards, embodied carbon accounts for an increasing share of total life-cycle emissions [2]. The European Union policy framework has accelerated this shift toward whole-life carbon accounting, requiring member states to integrate it into building regulations and Energy Performance Certificates [3].

In this context, a recent European Commission report emphasises that while operational emissions have historically received greater focus, addressing embodied emissions is crucial to achieving whole-life carbon neutrality [4]. The document proposes strategies such as using low-carbon bio-based materials, increasing circularity, and building reuse, noting that in some countries, embodied emissions are more relevant because operational emissions are lower. For example, in Portugal and Denmark, operational emissions are only slightly over half of total emissions, and in Sweden, they are even lower. Thus, the potential to cut emissions via operational measures is limited, making other strategies more important in these countries, such as higher use intensity, greater circularity, better use of existing buildings, and low-carbon materials. In the EU building stock, about 25% of life-cycle emissions are upfront embodied emissions from materials in new construction [4], and studies show they can reach 30–60% in highly energy-efficient buildings [5].

Therefore, to achieve climate neutrality, emissions from construction materials must be reduced. In this context, earthen construction is increasingly recognised as an ecological option that diversifies material choices. The aim of this paper is to compare the relative sustainability performance (environmental, functional and economic) of earthen techniques and conventional solutions in different contexts.

1.2 Earth Construction in Northern and Southern Europe

In Mediterranean climates, earthen materials provide performance benefits through their high thermal mass, which regulates indoor temperature fluctuations. Their high heat capacity and thermal inertia moderate indoor temperatures during large diurnal variations [6, 7]. This thermal mass reduces peak heating and cooling demand by absorbing heat during the day and releasing it at night [6]. Since heating needs are lower than in Nordic regions, earthen wall systems can often meet thermal requirements with less supplementary insulation, improving both environmental and economic feasibility.

In Nordic climates such as Sweden's, stricter thermal resistance and moisture safety requirements pose additional challenges. Because earthen materials have low insulation performance, they need extra layers to meet regulatory U-value thresholds [6, 8]. Moisture behaviour is also critical; hygrothermal analysis is required to avoid condensation, frost risk, and moisture accumulation in walls, which exhibit complex heat–moisture interactions [9]. Cold, humid conditions can prolong drying, extending construction

schedules and increasing labour costs. Thus, while environmental benefits may remain, overall sustainability in Nordic climates relies on well-designed hybrid systems that combine earthen materials with sufficient insulation and moisture control. In Mediterranean regions, earthen architecture is rooted in vernacular heritage, which can support social acceptance. In Nordic contexts, limited familiarity and regulatory conservatism may shape stakeholder perceptions despite documented environmental benefits. Earthen construction is also more labour-intensive than industrialised systems [10, 11], and in high-labour-cost settings such as Sweden, this can reduce its competitiveness relative to prefabricated timber or reinforced concrete.

1.3 Sustainability Assessment Needs Multicriteria Tools

Sustainability assessment frameworks stress that environmental gains must be weighed against economic and functional criteria. A material with lower embodied carbon may not be more sustainable if higher labour, time, or compliance costs offset its benefits. Because sustainability is multidimensional, multicriteria decision-making (MCDM) tools are valuable in construction research and practice. Integrated assessment models are needed to evaluate environmental, functional, and economic dimensions simultaneously. Life-cycle assessment provides environmental indicators, while cost analysis and performance compliance cover economic and functional aspects. This integrated approach underpins the MARS-SC method (described in later sections), which compares construction solutions under context-specific conditions. Moreover, technological transitions in construction depend not only on measurable performance but also on cultural and institutional acceptance.

2 Methodology

This paper presents a comparative analysis of conventional and earthen construction materials, using the Methodology for Relative Assessment of the Sustainability of Construction Solutions (MARS-SC), a multicriteria tool developed by Mateus & Bragança [12]. The MARS-SC methodology evaluates sustainability across three dimensions: environmental, functional, and economic. By assessing performance across each dimension, the tool identifies the most sustainable options tailored to specific project requirements, enabling the selection of construction solutions that strike an optimal balance among reduced environmental impact, enhanced functional performance, and economic feasibility. The MARS-SC scoring system normalises the indicators and aggregates them into a composite sustainability score ranging from 0 to 1, where higher values represent better performance.

The evaluation in this study relies on data from LCA studies [13, 14], environmental product declarations (EPDs), and construction cost databases [14, 15]. The conventional solutions were defined as the most common in each country. Earth-based solutions were defined as one of the traditional common in the Portuguese and Swedish contexts.

The maximum U-value for each country was defined in accordance with the legislation in force. In the case of Portugal, it was considered the max U-value allowed for the

most demanding winter season (0.35 W/(m^2.K)). The construction solutions assessed in the study are summarised in Table 1.

Table 1. Construction solutions defined for each country (PT – Portugal; SE – Sweden) [13–15].

Construction System	GWP kg CO_2 eq./m^2	U-value W/(m^2.K)	Cost €/m^2
PT-Ceramic Brick + ETICS	47.6	0.32	119
PT-Brick Cavity Wall Insulated	108.2	0.31	104
PT-Rammed earth wall	31.4	1.29	210
PT-CEB cavity wall insulated	36.5	0.34	286
SE-Typical Reinforced Concrete Wall	325	0.18	214
SE-Typical Fired Brick Wall	275	0.22	252
SE-Rammed earth + straw wall	6.8	0.17	2257
SE-Adobe + straw wall	−15	0.15	1615

3 Sustainability Performance Comparison

3.1 Multi-Criteria Assessment of Construction Solutions

In this study, the MARS-SC was applied to compare four construction systems in each country: two conventional and two earth-based. The environmental performance considered the GWP only, the U-value on the functional performance, and the construction cost on the economic performance. Since the solutions were tailored to comply with the energy performance requirements in each country, the functional performance of all systems is very similar in each country. The differences observed in the results reflect primarily the environmental impact of the materials and the construction costs associated with them. Table 2 summarises the performance scores obtained for the assessed construction systems, and Fig. 1 illustrates the comparative scores of the assessed building systems across the analysed countries.

Across all cases, the earth-based construction system achieved the highest environmental performance, mainly due to low carbon emissions from locally sourced materials and minimal processing. In contrast, conventional systems that rely on cement and fired materials exhibited higher emissions due to energy-intensive production. However, conventional solutions performed significantly better economically, as earth-based systems are more costly due to labour intensity, longer construction times, and limited industrialisation. This cost gap is especially pronounced in Sweden, where construction costs per square meter are considerably higher than in Portugal.

Table 2. Performance scores of the assessed construction systems (EP-Environmental Performance; FP-Functional Performance; EC-Economic Performance)

Construction System	EP	FP	EC
PT-Ceramic Brick + ETICS	0.79	0.99	0.92
PT-Brick Cavity Wall Insulated	**0.00**	**1.00**	**1.00**
PT-Rammed earth wall	**1.00**	**0.00**	0.42
PT-CEB cavity wall insulated	0.93	0.98	**0.00**
SE-Typical Reinforced Concrete Wall	**0.00**	0.64	**1.00**
SE-Typical Fired Brick Wall	0.15	**0.00**	0.98
SE-Rammed earth + straw wall	0.94	0.71	**0.00**
SE-Adobe + straw wall	**1.00**	**1.00**	0.31

In terms of functional performance, most systems showed similar results, as U-values were designed to meet regulatory requirements, with minor differences due to insulation thickness. In Portugal, the lower performance of rammed earth is not fully representative, as regulations allow uninsulated walls under certain conditions, recognising benefits such as thermal and moisture inertia, which can also improve environmental performance by reducing the number of material layers. The overall assessment depends on the weighting of environmental, economic, and functional criteria. Prioritising environmental performance is essential for decarbonisation, though higher costs of low-carbon solutions may require policy support, such as incentives. While earth-based systems are not suitable for all contexts, they are a viable option in many scenarios and help diversify low-carbon construction strategies. Differences between countries were observed (Fig. 1): conventional systems had lower impacts in Portugal than in Sweden, whereas for earth-based systems, the use of straw insulation, due to its biogenic carbon storage, resulted in lower emissions in Sweden than in Portugal.

3.2 Integrated Assessment of Construction Systems and Sustainability Implications

The results demonstrate a consistent hierarchy in environmental performance across all case studies. The earth-based construction systems achieved the highest sustainability scores, primarily due to their low embodied energy and reduced dependence on non-renewable resources. This was followed by the improved conventional system, which outperformed the standard conventional system due to enhanced material efficiency and lower manufacturing energy requirements. Despite these improvements, both conventional systems exhibited significantly higher environmental impacts compared to the earth-based alternative. This ranking remained stable across both countries, confirming the robustness of the findings. Minor variations in performance were observed, mainly influenced by differences in material sourcing, transportation distances, and national production technologies. In contexts where earthen materials were locally available showed greater environmental benefits, as reduced transportation further lowered emissions and energy use.

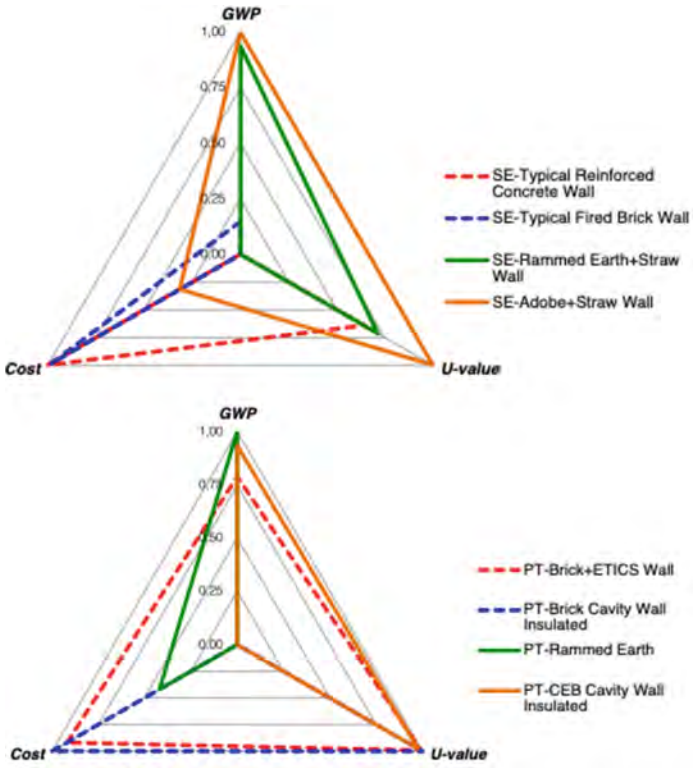

Fig. 1. Comparative environmental performance of construction systems using the MARS-SC method (up: Swedish Context; down: Portuguese context).

The analysis highlights the critical role of material selection in shaping environmental performance. Conventional materials such as cement, steel, and fired clay products were the main contributors to increased embodied energy and carbon emissions. These findings point to clear sustainability gaps in conventional construction, suggesting that improvements in material production or the adoption of lower-impact alternatives could substantially reduce environmental burdens. While earth-based systems demonstrated clear environmental advantages, some challenges remain regarding their broader implementation. These include issues related to standardisation, regulatory acceptance, and integration with contemporary building systems. Addressing these barriers is essential to fully realise their potential in modern construction.

Overall, the results confirm that earth-based construction systems offer a viable low-impact alternative with significant potential to reduce the environmental footprint of the building sector. The application of the MARS-SC methodology proved effective in comparing construction systems and identifying key areas for improvement, particularly in material use and production processes.

4 Discussion

The findings highlight important limitations in assessing the sustainability of construction systems. Although earth-based solutions show strong environmental performance, this outcome is influenced by reliance on a single indicator, which may not fully capture broader environmental impacts. As such, the results should be understood as partial rather than comprehensive. A key insight is the clear tension between environmental and economic performance. Earth-based systems remain significantly more costly, particularly in high-wage contexts, due to labour-intensive processes, limited industrialisation, and longer construction times. This economic constraint represents a major barrier to their wider adoption. The analysis also underscores the strong context dependency of sustainability outcomes. Variations in regulatory frameworks, climatic conditions, and market structures significantly influence performance. In more favourable contexts, earth-based construction becomes more feasible, whereas in stricter or high-cost environments, its limitations are amplified. This indicates that such systems cannot be directly transferred across regions without adaptation. In addition, current assessment methods provide limited insight into the full functional potential of alternative materials. By focusing on standardised performance metrics, important characteristics such as thermal inertia and moisture regulation remain underrepresented, potentially biasing evaluations towards conventional systems.

5 Conclusions

This study highlights that the sustainability of construction systems cannot be determined solely by environmental performance, as assessment methods and selected indicators significantly influence outcomes. It emphasises the importance of adopting a more comprehensive evaluation framework that captures environmental, economic, and functional dimensions. The findings indicate that alternative construction approaches, such as earth-based systems, require supportive regulatory conditions, greater efficiency, and more inclusive assessment methods to be evaluated fairly and implemented effectively. Ultimately, their role in sustainable construction depends on context-sensitive strategies rather than universal application.

Environmental Footprint Index for Industrialized Construction

Angelos Dampalis and Yiannis Xenidis(✉)

Aristotle University of Thessaloniki, Thessaloniki 54124, Greece
ioxen@civil.auth.gr

Abstract. The construction industry is challenged to address the longstanding problem of low productivity while simultaneously reducing carbon dioxide emissions, as it remains one of the largest emitters worldwide. This paper examines industrialization and climate neutrality as key pathways for tackling these dual demands. A literature review is conducted to identify existing approaches for quantifying both industrialization and carbon footprint. The calculation methods identified are compared and analyzed to provide the foundation for developing a new index that measures these two dimensions simultaneously in industrialized building projects. The research focuses on Stage A (product and construction process) of the construction lifecycle and particularly takes into consideration embodied carbon. The proposed Environmental Footprint Index for Industrialized Construction (EFIC) integrates productivity indicators and prefabrication - two primary measures of industrialization - while using life cycle assessment to evaluate carbon footprint. The study then determines the relation of these factors and establishes a normalization procedure to finalize the index's mathematical formulation. To validate the index, a case study is carried out on four industrialized buildings that employ different industrialization techniques. Three out of four buildings are drawn from analyses of previous research works while the fourth is a case of a real building under construction. The resulting scores and rankings indicate that the 3D-printed building performs best overall, achieving the highest level of industrialization while also demonstrating the lowest environmental impact. The limitations and directions for further elaboration of the validated index are discussed for future research.

Keywords: Construction Industrialization · Construction Productivity · Construction Carbon Footprint · Life Cycle Assessment · Environmental Footprint Index for Industrialized Construction

1 Introduction

Construction industry is considered as one of the most important sectors of the economy, generating annual revenues of approximately three trillion dollars, which corresponds to 6% of global Gross Domestic Product (GDP) (De Soto et al., 2018). Global population is estimated to reach 9.7 billion by 2050 thus increasing the demand for new infrastructure and buildings up to 415 billion square meters of total usable floor space (López-Guerrero,

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 1159–1167, 2026.
https://doi.org/10.1007/978-3-032-34930-9_135

Vera, & Carpio, 2022). This increase combined with urbanization forces the construction industry to scale up and implement construction methods, including industrialized solutions, technological innovations and effective management practices on project level that will enhance productivity and efficiency (Stehn & Jimenez, 2023).

At the same time, buildings are among the biggest polluters, producing some 34% of global greenhouse gas emissions (United Nations, 2025); therefore, a significant reduction of CO_2 emissions becomes imperative.

The potential of utilizing methods of industrialized construction towards fulfilling both goals, i.e., increased productivity and climate neutrality is recognized and even attempted through specific strategies and policies at global and regional levels (Yao et al., 2022). Yet, currently, no assessment methods or tools exist to provide quantified evidence of the success of such attempts at the component level, i.e., the building. The rest of this paper discusses the background and proposes such an index for assessing with a single value the degree of industrialization and climate neutrality of buildings.

2 Background

2.1 Industrialization of Construction

The adoption of new technologies and innovative solutions in the construction industry is at a low pace, mainly due to inherent features (e.g., great number of stakeholders, complex supply chains) of the industry that cause high risks (Van Der Heijden, 2023). The impact of these features on productivity could be mitigated by implementing Industrialized Construction and/or Construction 4.0 methods. Industrialized construction (IC) incorporates industrial principles, innovative processes, and smart technologies in design, factory production, transportation of structural elements, and assembly of structures (Wuni, Wu, & Shen, 2021). Construction 4.0 is defined as the digitization and automation of the industry that enables real-time, horizontal, and vertical integration and connectivity of stakeholders throughout the entire construction project lifecycle, promoting the advancement of construction processes by bridging the gap between the physical and cyber environments (El Jazzar et al., 2021).

The benefits originating from Construction 4.0 include reduced costs throughout the life cycle, increased productivity, improved construction quality, and reduced waste of building materials (Ismail et al., 2022). In addition, the number of workplace accidents is reduced and there is a noticeable decrease in energy consumption, air and soil pollution, noise, dust, and water consumption (López-Guerrero, Vera, & Carpio, 2022). Thus, there is a strong connection between industrialization of construction and the climate crisis that the world is facing.

2.2 Climate Neutrality

Climate neutrality is defined as a state of zero carbon emissions which can be achieved by balancing the total amount of carbon emissions over a certain period via carbon offset or removal initiatives (Chen et al., 2023). Climate neutrality and buildings are connected through embodied and operational carbon. Embodied carbon includes carbon dioxide

emissions related to the entire life cycle of the building, excluding its operation, a part which is called operational carbon (Fang et al., 2023). Embedded carbon emissions originate from building materials, the construction process, the transport of materials and waste, maintenance, repair and end-of-life activities (Greer & Horvath, 2023). The total carbon emissions associated with a building are typically attributed to embodied carbon (around 20%) and operational carbon (around 80%) (Fang et al., 2023).

In order to reduce carbon emissions, various strategies have been proposed focusing on different stages of a building's life cycle. These strategies include usage of low-carbon materials in construction, waste management during the whole life cycle and construction of nearly zero energy buildings (nZEB). Also, nZEB can be industrialized products constructed using Construction 4.0 technologies that promise even lower carbon emissions. The promotion of such an approach requires evidence on the efficiency of these buildings and such evidence is provided by relevant assessment methods.

2.3 Assessment Methods

Assessing industrialization of construction and climate neutrality of buildings is an essential, yet difficult to apply process (Stehn & Jimenez, 2023). The assessment of industrialization parameters is based on productivity indices, the prefabrication rate, technology valuation metrics, and economic valuation metrics:

- Productivity indicators are very commonly used in construction aiming at calculating the productivity of an activity or an entire project using numerical formulas, which usually assess the ratio of an output's size to the time required for its delivery (Lowe, 1987).
- The prefabrication rate refers to the percentage of construction elements that have been prefabricated off-site and contributes to measuring the degree of industrialization of a construction project (López-Guerrero et al., 2022).
- Technology valuation metrics measure the integration and application of new technologies and industrialization practices in construction (De Soto et al., 2018).
- Economic valuation metrics quantify the comparison between conventional and industrialized construction methods, in terms of cost and resource efficiency (De Soto et al., 2018).

The most widely used approach for environmental assessment of buildings is Life Cycle Assessment (LCA), which allows the assessment of CO_2 emissions and energy used in the various stages of construction (Aghasizadeh et al., 2022). Another way to environmentally assess buildings is green certificates, which verify a building's reduced energy consumption and carbon footprint and relate to its good thermal capacity and the sustainability of its construction (Allouhi et al., 2015). Lastly, embedded emissions and operational emissions are calculated using numerical models for the number of materials used in construction and for the operational energy consumption required (Hong et al., 2014).

3 Methodology

A new index called Environmental Footprint Index for Industrialized Construction (EFIC) is proposed to assess both the degree of industrialization and the climate neutrality of buildings by integrating approaches from existing assessment methods. The index comprises three factors, namely productivity, industrialization and carbon footprint. The first two are calculated with the use of Eqs. (1) and (2):

$$P = \frac{Building\ Area\ \left(m^2\right)}{Construction\ duration\ (hr)} \tag{1}$$

$$IR = \frac{100\%^{*}\ Volume\ or\ Mass\ of\ Industrialized\ elements\ \left(m^3\ or\ kg\right)}{Total\ Volume\ or\ Mass\ of\ building\ materials\ \left(m^3\ or\ kg\right)} \tag{2}$$

The Industrialization Rate of Construction is a variation of prefab rate, which renders it applicable to all types of industrialized buildings.

The building's carbon footprint is assessed through LCA with the use of appropriate software tools and reference to carbon emissions per square meter.

The three factors addressed in the proposed index are not interdependent; in fact, they are strongly related, yet the nature and, moreover, the quantification of these relations is very hard to explicitly determine. Therefore, the following general assumptions are made in the context of this study:

- Increased productivity leads to increased industrialization rate.
- Increased productivity leads to decreased carbon footprint.
- Increased industrialization rate leads to decreased carbon footprint.

While debatable, particularly when considering the construction methods and specific features of individual cases, these assumptions enable the determination of the boundary conditions required for a proof of concept of the proposed index: (a) increased productivity, high industrialization rate, and reduced carbon footprint result to an increased index value, which indicates an industrialized construction that achieves climate neutrality. On the other hand, low productivity, low industrialization rate and increased carbon footprint result in a reduced index value, which indicates a construction, which is not highly industrialized and/or environmentally friendly.

The incorporation of factors featuring different measures, units, and scales into a single index requires first data normalization. In the context of this research the Min-Max normalization method is selected for application as it is commonly used for the development of indices (Jahan & Edwards, 2014). The mathematical representation of the EFIC index is then formulated using the following normalized variables:

- $\boldsymbol{P}_{\text{norm}}$: Normalized productivity in the interval [0,1] (0: minimum value, 1: optimal value).
- $\boldsymbol{IR}_{\text{norm}}$: Normalized industrialization rate in the interval [0,1] (0: minimum impact of industrialization on the building, 1: fully industrialized building).
- $\boldsymbol{E}_{\boldsymbol{CO2}\ \text{norm}}$: Normalized carbon footprint in the interval [0,1] (0: minimum value, 1: optimal value (climate neutral building)).

Since all variables are assumed to be of equal importance and equally contributing to the final result, the Euclidean distance is used for the calculation of the index. The index values range from 0 to 100, a scale commonly adopted in similar indexes to enhance interpretability and facilitate comparison. Accordingly, the mathematical formulation of the EFIC index is given by Eq. (3).

$$EFIC = \frac{100^{*}\sqrt{((1 - Pnorm)2 + (1 - IRnorm)2 + (1 - ECO_2\text{norm})2)}}{\sqrt{3}} \quad (3)$$

The implementation of the proposed index is tested in four industrialized building projects, and its application and respective results are presented in Sect. 4.

4 Case Study

Life Cycle Assessments (LCA) were conducted with the use of the One Click LCA software tool for four buildings, based on: (a) the building area (set to a maximum of 500 m^2 to allow comparison and overcome a tendency of smaller construction projects to exhibit higher carbon emissions per square meter (Tavares, Lacerda, & Freire, 2018)), (b) the assumed lifecycle (set to 50 years and limited to stage A (A1-A5) of the Life Cycle according to EN 15978:2011 standards (Huang et al., 2022), while focusing on materials and the construction process, i.e., only to embodied carbon emissions), (c) the building location (set to the city of Thessaloniki as a common geographical context for the analysis), (d) the transportation distance of materials (set – based on real data – to 40 km for local suppliers, 200 km for the prefabrication plant, and 1,000 for the transport of the 3D printer), (e) the functional unit (expressed in m^2, and the result expressed in $kgCO_2e/m^2$), and (f) the life cycle inventory for each case. The four industrialized buildings considered in this study are briefly presented in Table 1, while Table 2 shows the summarized life cycle inventory of all buildings.

The data presented in Table 2 are then used for assessing the three factors addressed in EFIC. Table 3 presents the results for each factor both before and after normalization. The table's last column presents the EFIC value for each building.

As shown in Table 3, Building 3 presents the highest index value. This is consistent with the expectations, as the high level of industrialization, increased productivity, and low carbon footprint of Building 3 lead to significantly higher performance according to the proposed index. The comparison indicates that additive construction provides the most effective combination of industrialization and climate neutrality. The lightweight structural systems used in Buildings 1 and 2, also, show satisfactory performance and may represent a suitable solution for small-scale constructions due to their overall satisfactory profile.

Table 1. The selected buildings for the case study.

Building	Structural System	Total floor area (m^2)	Total duration of construction (hr)	Source of case study

4	0.149	1	22.98	0.125	685	0	23.30

5 Conclusions and Recommendations

This study proposes an Environmental Footprint Index for Industrialized Construction (EFIC) to simultaneously assess buildings' performance against industrialization and climate neutrality. The application of the proposed index in a case study reaffirmed that building materials are the main contributors to carbon emissions, while lighter structural systems demonstrate improved environmental performance. Also, it highlighted 3D printing as a very efficient construction method compared to traditional ones in the context of industrialization and climate neutrality. EFIC is a first step that with further improvements (e.g., LCA across the entire life cycle) could provide a useful tool for evaluating construction methods against environmental and productivity requirements.

Proposing a Dynamic Carbon Payback Time Approach for the Assessment of Green Roofs

Kleoni Ntouvli(✉) and Katerina Tsikaloudaki

School of Civil Engineering, Aristotle University of Thessaloniki, Thessaloniki, Greece
kntouvl@civil.auth.gr

Abstract. This study presents a dynamic carbon payback time (CPBT) approach, suitable for the dynamic life cycle analysis (DLCA) of green roofs (GRs). Previous studies focused on calculating CPBT according to the static LCA approach. The findings reveal that the extensive type achieved CPBT between 14 to 42 years. The semi-intensive type and the intensive type offset between 27–32 and 32–36 years, respectively. However, a DLCA approach improves the accuracy of LCA by addressing the inconsistencies of temporal assessment. By incorporating temporal factors, a more comprehensive understanding of how green roofs contribute to carbon offset over time is achieved. To assess the effects of unequal annual carbon emission flow, a dynamic CPBT (DCPBT) is proposed, considering a year-by-year carbon emissions examination analysis is considered. The analysis includes the annual carbon sequestration, the annual carbon savings, and the annual embodied carbon emissions. The DLCA involves five stages: production, transportation, construction, operation/maintenance, and end-of-life stages. This approach allows for a more accurate understanding of the long-term benefits of GRs in mitigating climate change.

Keywords: Carbon · Green Roof · Dynamic Carbon Payback Time · DLCA

1 Introduction

Climate change is considered one of the main challenges humanity is facing in the 21st century [1]. As the built environment contributes significantly to greenhouse gas emissions [2], the implementation of mitigation and adaptation strategies against climate change is required. Green roofs (GRs) are promoted as an effective green infrastructure strategy for reducing carbon emissions.

Based on the substrate thickness, two major types of GRs can be distinguished in the literature, i.e., extensive and intensive GR types. Another type is also considered in literature, known as semi-intensive [3]. A GR consists of several components, above the normal layers of a flat roof, including, from bottom to top: a waterproofing membrane, a root barrier, a protection layer, a water storage, and drainage layer, a filter layer, substrate (growing medium or soil), and vegetation [4, 5].

The emissions associated with the GR system are classified as both direct and indirect impacts [6]. The direct impact is related to the photosynthesis process. Through this

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 1168–1176, 2026.
https://doi.org/10.1007/978-3-032-34930-9_136

mechanism, GR systems capture and store carbon in plant biomass and the soil medium. The indirect impact concerns emission reductions resulting from energy savings. The processes of evapotranspiration and shading contribute to a reduction in indoor air temperature, thereby lowering a building's energy consumption for cooling, and thus leading to decreased CO_2 emissions [6]. However, the integration of a GR system is followed by the associated environmental impacts, which are identified as "embodied carbon." The additional structural requirements of GRs might increase the quantity of material required, thereby raising embodied carbon. As a result, the environmental impact of the upstream processes may outweigh the carbon savings from GRs.

The aim of the study is to propose a novel approach for calculating Carbon Payback Time using a Dynamic Life Cycle Assessment. To address the identified gaps, this study seeks to answer the following key questions:

Q1.	"What are the key methodological distinctions between conventional Life Cycle Assessment (LCA) and Dynamic Life Cycle Assessment (DLCA)?"
Q2.	"How many years are required for a GR system to offset its carbon emissions?"
Q3.	"In what manner can the Dynamic Carbon Payback Time (DCPBT) concept be implemented for evaluating a GR system?"

Firstly, the study presents the methodological differences of static and dynamic LCA, focusing on how the variables of DLCA are introduced into a GR system. Then it briefly outlines the methodology used to identify relevant papers in the existing literature on the CPBT concept, as applied to GR case studies and presents the main findings. Finally, a new approach for calculating DCPBT is proposed.

2 Background: LCA vs DLCA

Life cycle assessment is widely used to quantify the environmental performance of a product, process, and system throughout its life cycle. However, static LCA does not consider potential temporal or spatial variations over the assessment lifetime. The methodological differences between conventional and dynamic LCA are widely established in the literature, particularly regarding temporal differentiation of emissions, time-dependent inventory flows, and variables considered. Table 1 summarizes the main methodological differences between conventional LCA and DLCA.

DLCA considers when emissions are generated and how they evolve over time. This is particularly important for GRs, as their environmental benefits appear gradually and change over time. Dynamic variables related to buildings have been widely discussed in the literature [9, 13], however, dynamic variables specifically associated with GRs remain unexplored.

Table 2 highlights that several variables are relevant for both systems. However, variables such as energy evolution, technological advances, and device degradation are commonly addressed at the building scale. Carbon sequestration is mainly related to the GR system, while in the case of building, sequestration mechanisms are related to bio-based construction materials, known as biogenic carbon [14].

Table 1. Methodological differences between conventional LCA and DLCA

Criterion	Conventional LCA	Dynamic LCA	References
Temporal variation	Static emissions throughout the lifecycle	Time-dependent; emissions are generated at specific time-step	[7, 8]
Treatment of emissions	Assumes the same reference time for all emissions.	Considering the effect of the timing of the emissions	[9]
Life Cycle Inventory	All emissions for a given pollutant are added into a single aggregate	Each emission is a function of time	[10, 11]
Characterization factors	Constant over time	Dynamic; account for the atmospheric residence time of each GHG emission.	[11]
Weighting factors	Static values;	Time-dependent; influenced by economy and society	[10, 12]
Variables	Usually ignored	Technical, cultural, social, and environmental;	[9]
Spatial differentiation	Static	Considering spatial variability; local weather data etc.	[9, 12]
Accuracy for long-life systems	Steady-state models decrease the accuracy	Higher accuracy due to temporal differentiation	[9, 11]
Data requirements	Low; Available databases	Higher; Requires temporal datasets	[13]
Computational complexity	Relatively simple modelling	More complex modelling and calculations	[7]

3 Methodology

Sourcing GR's LCA case studies from the literature and identifying those that incorporate CPBT concept was one of the main goals of our research. Section 3 is part of a broader research study and focuses on presenting the CPBT results identified in the existing literature. The survey was based on Scopus and Web of Science (WoS) databases, applying three groups of search terms to titles, abstracts, and keywords: "green roof AND LCA", "green roof AND carbon payback time", "green roof AND carbon emissions". The analysis focused on peer-reviewed publications relevant to the research topic. It needs to be noted that there is quite limited exploration of the topic in the existing literature. Then, based on the identified gap in existing literature, a new approach for the calculation of DCPBT is developed and presented (Sect. 5).

4 Carbon Payback Time

The number of years required for cumulative cash flows to compensate for the initial investment costs is known as the simple payback time [15]. Even though it ignores cash flows after the payback period, it is a popular tool for appraising investments since it is simple to use and comprehend. Payback times have been created to offer a temporal perspective that reflects on the temporality of impacts. The basic idea is to figure out the period it requires to compensate up for the "cradle-to-gate" impact of any system [7]. The period required a GR system to compensate for its emissions, determining the environmental benefits of this system, which is known as the carbon payback time (CPBT) [16]. The simple CPBT method for GRs is calculated via Eq. (1)

$$\text{Carbon payback time} = \frac{C_e}{C_o} \tag{1}$$

where C_e is the initial embodied GHG emission, and C_o denotes the annual emissions savings and sequestration through operation stage.

Kuronuma et al., [17] developed two sequestration rate scenarios to calculate the CO_2 payback time of extensive modular GRs for different plant species. Their hypothesis in the first scenario was that GR plants would only start to sequester CO_2 in the first year following construction (Eq. 2), whereas in the second scenario, the plants sequester the same amount of CO_2 annually (Eq. 3).

$$CO_2 \text{ payback time} = \frac{CO_{2\,e-p} - CO_{2\,r-s}}{CO_{2\,r-e} - CO_{2\,e-m}} \tag{2}$$

$$CO_2 \text{ payback time} = \frac{CO_{2\,e-p}}{CO_{2\,r-s} - CO_{2\,r-e} - CO_{2\,e-m}} \tag{3}$$

where $CO_{2\,e-p}$ is the amount of CO_2 emitted during the production of the GR system, $CO_{2\,r-s}$ is the annual CO_2 reduction due to CO_2 sequestration, $CO_{2\,r-e}$ is the annual CO_2 reduction due to energy savings and $CO_{2\,e-m}$ is the annual CO_2 emission from maintenance of the GR.

Table 3 summarizes the carbon payback time (CPBT) reported in the literature for different types of GRs. The results indicate considerable variability depending on the roof type, climatic conditions, and system configuration.

Table 3. Carbon payback time of green roof types.

GR type	Lifespan (years)	CPBT (years)	Publication information (reference, country)

Most studies focus on the extensive GR type, while other types are less investigated. Regarding the extensive type, the CPBT period achieved between 14 to 42 years. Semi-intensive type counterbalance between 27–32 years, and intensive type counterbalance between 32–36. The CPBT values show significant variation between different types of GRs. The findings in most studies reveal that extensive GRs have a lower CPBT than semi-intensive and intensive systems, mainly due to the thinner substrate thickness, lower amount of materials, and decreased carbon emissions.

The results of the studies conducted in a Mediterranean climate [18, 19] demonstrate that, depending on climatic factors, the emissions CPBT for different types of GRs is frequently shorter than the expected lifetime (26–42 years). GRs appear to have the potential to offset their initial CO_2 emissions within their lifetime. To ensure that carbon payback periods for extensive GRs are relatively short (5.8 to 15.9 years) it is required to include both CO_2 sequestration by vegetation and energy savings [17] in the calculations. The differences in CPBT values between studies can be attributed to factors such as climatic conditions, the GR's design, geographical location., LCA process and associated methodology (system boundary, stages and components included). Since the conventional LCA depends on static data and is unable to convey dynamic variables, findings may result in notable differences between study outcomes and practical processes [20].

5 Dynamic Carbon Payback Time

Previous Eqs. (1), (2), and (3) are applicable in the case of GRs' static LCA, however, they are inappropriate in the context of the DLCA approach. Yet, the temporal dimension remains unexplored, in terms of CPBT concept. To assess the effects of unequal annual carbon emission flow, a dynamic CPBT (DCPBT) is required, which incorporates inconsistent annual carbon sequestration, annual carbon savings, and maintenance of the GR. The Dynamic Carbon Payback Time (DCPBT) is determined using Payback Period Method with Uneven Cash Flows [22].

$$\text{DCPBT} = (n-1) + \frac{C_o - \sum_{i=1}^{n-1} C_i}{C_n} (\text{years}) \tag{4}$$

where n is the year in which the cumulative cash flow exceeds the initial carbon emission.

The DCPBT is therefore equal to (n−1) plus a fractional part of year n. The first term $(n-1)$ of Eq. (4) represents 1 year less than the number of years the cumulative carbon emission flow takes to exceed the initial embodied carbon EC_o. The second term represents the fractional year required to offset the remaining portion of the initial emissions. C_o equals the initial carbon emissions (kg CO_2) in year 0, associated with production, transportation, and construction. $\sum_i^{n-1} C_i$ is the summation of net carbon flows ($C_1 + .. + C_{n-1}$) from years 1 to $n-1$, expressed in kg CO_2, and C_n is the net carbon flow in year n. Table 4 presents the annual carbon emissions for a hypothetical GR system, with a total service life of T years. The DLCA process includes five stages: production, transportation, construction, operation, maintenance, and end of life stage. Year-by-year records of carbon flows are required to identify the temporal distribution of both emissions and environmental benefits throughout the life cycle of the GR.

It is assumed that production, transportation and construction stages occur in year 0, thus the carbon emissions (C_0) are equal to initial embodied carbon (EC_0). Since the manufacturing stage has been identified as the most impactful [21] based on literature surveys, due to the high energy and raw material requirements during material production, the largest carbon emissions occur in year $t = 0$. Net carbon emissions flows are denoted C_0 to C_{T-1}. For each year $t = 1$ to $T-1$ the net emissions are calculated by subtracting emissions outflows (from maintenance activities) from the emissions inflows

Table 4. Dynamic Carbon payback time method.

Year	EC[a]	C_{SEQ}[a]	C_{SAV}[a]	C_{MAIN}[a]	Math Type	Carbon flows- C_i [CO_2 kg]	LCA Stages[b]
0	EC_0	0	0	0	EC_0	C_0	P + T + C
1	0	C_{SEQ1}	C_{SAV1}	C_{MAIN1}	$C_{SEQ1} + C_{SAV1} - C_{MAIN1}$	C_1	O + M
2	0	C_{SEQ2}	C_{SAV2}	C_{MAIN2}	$C_{SEQ2} + C_{SAV2} - C_{MAIN2}$	C_2	O + M
….	….	….	….	….	….	….	O + M
n−1	0	C_{SEQn-1}	C_{SAVn-1}	$C_{MAINn-1}$	$C_{SEQn-1} + C_{SAVn-1} - C_{MAINn-1}$	C_{n-1}	O + M
n	0	C_{SEQn}	C_{SAVn}	C_{MAINn}	$C_{SEQn} + C_{SAVn} - C_{MAINn}$	C_n	O + M
….	….	….	….	….	….	….	O + M
T−1	0	C_{SEQT-1}	C_{SAVT-1}	CMAINT−1	$C_{SEQT-1} + C_{SAVT-1} - C_{MAINT-1}$	C_{T-1}	O + M
T	EC_T	0	0	0	EC_T	C_T	T+ E

[a] EC = Embodied carbon, C_{SEQ} = Carbon sequestration, $C_{SAV=}$ Carbon savings

[b] P=Production, T = Transportation, O=Operation, C=Construction, Main = Maintenance, E = End-of-life

(carbon savings and sequestration during the operation stage) of the corresponding year. The end-of-life stage occurs in the year *T*. The end-of-life process involves demolition, transportation, and waste management activities.

Figure 1 provides a schematic representation of Eq. (4). The horizontal axis represents time (years), while the vertical axis corresponds to carbon flows. The curve shows the cumulative net carbon emissions flows (blue color). The annual embodied carbon emissions are indicated in red, while the annual carbon savings and sequestration are indicated in green. The cumulative net carbon emissions flow value reaches zero between t = n−1 and t = n, corresponding DCPBT. Then, DCPBT can be determined via linear interpolation. In case the cumulative net carbon emissions never become zero - due to low value annual carbon savings and sequestration relative to the initial embodied emissions - the DCPBT (Eq. 4) is undefined or considered infinite. This situation indicates that the GR system does not achieve carbon offset within its service life.

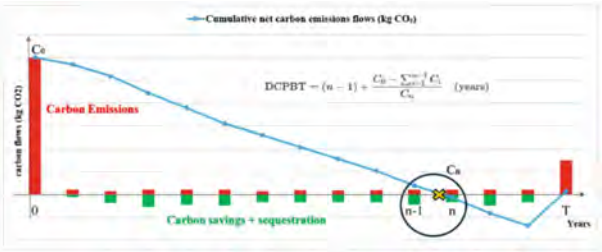

Fig. 1. Dynamic Carbon Payback Time (DCPBT) representation.

6 Conclusion

This study highlights the methodological distinctions between conventional LCA and Dynamic LCA, while summarizing the CPBT reported in the literature for different types of GRs (14–36 years). A novel approach for calculating the DCPBT was proposed, allowing for a more accurate, year-by-year assessment of carbon flows and environmental benefits over the life cycle of GRs. The DCPBT approach, which has been explained, is an important step in investigating the entire environmental performance of GRs, aiding practitioners and researchers in sustainable building design decisions.

Abstract. Infrastructure asset managers are under pressure to reduce embodied impacts and retain material value across assets, yet circular economy ambitions remain difficult to translate into portfolio-scale decision support. In bridge management, component reuse is often identified as a high-value circular strategy because it preserves functional value more effectively than conventional methods, but its implementation is hindered by fragmented information, reverse logistics challenges, operational disruptions, and environmental and regulatory constraints. This paper develops an indicator-based regional screening approach to support the early identification of bridges with promising circular potential. This was derived using a PRISMA-guided scoping review of 52 studies from Scopus and Web of Science and structured into five factors: supply readiness and remaining value; harvesting and reverse logistics feasibility; network disruption pressure and network role; circular ecosystem and match potential; and environmental and regulatory constraints. To complement the review with practice-based judgement, a hybrid expert-weighting survey combining the Analytic Hierarchy Process and budget allocation was conducted with seven experts from Croatia and Slovenia. The results indicate that supply readiness and remaining value received the highest priority, followed by network-related and ecosystem-related considerations. The proposed approach helps bridge the gap between stock-based circular assessments and component-level analysis by showing where further circular investigation is most justified using typical asset management and GIS data.

Keywords: Circular economy · Bridges · Asset management · Regional Screening · Component reuse

1 Introduction

Infrastructure asset managers are increasingly expected to deliver renewal pro-grammes that reduce embodied impacts and retain material value. As highlighted in the UNEP Annual Report 2023, circular economy strategies, which aim to do so through life extension, reuse, and high-quality recovery are gaining traction in infra-structure management [1]. Among circular strategies, component reuse is frequently framed as a high-value pathway because it preserves functional value rather than down-cycling materials, but it remains difficult to scale and prioritize within day-to-day asset management

because it requires earlier coordination and more evidence than conventional renewal or maintenance decisions [2].

A practical issue is that reuse is possible only when asset owners can anticipate feasible supply and plan early for harvesting, logistics, and compliance before project tenders are finalized. Chen et al. [3] shows that reverse logistics implementation is heavily constrained by operational barriers, such as collection, sorting, storage, and quality control, which are difficult to resolve once project delivery constraints are in place. El Hafiane et al. [4] similarly highlight persistent implementation barriers, including fragmented supply chains, uncertain reverse logistics capacity, and the lack of standards. For bridge assets, circular decisions also require detailed and costly information, including component inventories, structural conditions, connection and dismantling details, verification and testing, and documentation completeness. Cetin et al. [5] illustrate this challenge in the context of material passports, detailing the heavy data requirements and the practical constraints on data availability and validation across stakeholders at various lifecycle stages. As a result, reuse opportunities are often discovered late, after decisions about scope, timing, and traffic management have already narrowed the available option space [6].

At regional scale, circular planning often begins with material stocks and quantities, since these can be estimated across large territories using secondary data. Rajaratnam et al. [7] demonstrates how remote sensing enables scalable stock mining to help identify the locational dynamics of secondary materials. While stock mapping supports recovery and recycling planning, it does not prioritize reuse, because reuse depends on feasibility and value-retention conditions that cannot be inferred from quantity alone [8]. Scalable screening approaches are therefore needed to identify where follow-up reuse testing is most justified and cost-effective, without requiring passport-level detail for every asset in the region [9]. This study addresses the need by developing a screening-stage regional approach for bridge asset managers that translates reuse feasibility requirements into a compact set of indicators computable primarily from standard Asset Management System (AMS) data and GIS layers. This approach enables high-effort, component-level circular analyses to be targeted only where justifiable and ensures that circular options can be evaluated before delivery constraints are fixed.

2 Methodology: Factor Identification and Indicator Derivation

2.1 Literature Search Methodology

Although a growing body of research supports circular assessment in the built environment, its insights remain difficult to translate into a practical regional screening logic for bridge portfolios. Chang et al. [10] show that BIM- and GIS-based approaches can be used to estimate and map material stocks at scale, which is valuable for understanding resource distribution across space. Li et al. [11], however, show that circularity indicators remain highly fragmented and unevenly developed beyond the individual asset level, limiting their usefulness for systematic portfolio-level screening. To identify a more operational factor and indicator structure at the regional scale, a PRISMA-guided scoping review was conducted following the PRISMA 2020 reporting guidance [12]

Scopus and Web of Science using one broad core query and four targeted variants covering portfolio-scale screening, decision-support, transferable built-environment studies, and spatial or GIS-oriented circularity research. Following deduplication and staged screening, 52 studies were retained.

2.2 Hybrid Analytical Hierarchy Process/Budget Allocation Weighting

To complement the literature-derived factor structure with practice-based judgement, a hybrid weighting survey was conducted with seven experts involved in circular infrastructure projects. Experts were selected to reflect roles relevant to early bridge screening, including project and asset management, consultancy, and research. The respondents were based in Croatia and Slovenia, which was considered appropriate because the future empirical application of the approach will use Croatian motorway data. Ten experts were invited, and seven completed responses were obtained.

At the factor level, the Analytic Hierarchy Process (AHP) was used. AHP is a multi-criteria decision-making method in which respondents compare pairs of criteria to express their relative importance [13]. In this study, the five literature-derived factors identified in Sect. 2.1 were compared pairwise using a simplified verbal scale ranging from 'less important' to 'more important'. These judgements were converted into reciprocal numerical values using a reduced Saaty-type scale, where equal importance was coded as 1, slight preference as 3, and stronger preference as 5. For each respondent, the values were entered into a 5×5 reciprocal com-parison matrix, and factor weights were derived using the row geometric mean meth-od by normalising the geometric mean of each matrix row. Group-level weights were then obtained by aggregating corresponding pairwise judgements across respondents using the geometric mean. At the indicator level, respondents allocated a fixed total of fixed total of 100 points across criteria to indicate their relative importance [14]. For each factor, respondents allocated 100 points across the three embedded indicators. The final local indicator weights were then obtained by averaging these allocations across respondents and normalising them within each factor. This hybrid structure was adopted to preserve the comparative strength of AHP, while avoiding an unnecessarily burdensome number of pairwise comparisons at the indicator level.

3 Results and Discussion

3.1 Derived Factors and Indicators from Literature

The reviewed literature revealed a consistent set of shortcomings. Stock-based studies are effective at quantifying resource magnitude and locating future flows, but weak at aiding higher-level circular alternatives [15]. Documentation and material/component passports work help identify what reuse decisions depend on, while also exposing how fragmented and incomplete data remains in practice [16]. Spatial circularity studies further show that access, land use, resource proximity and storage determine whether circular flows are even feasible, whereas transport-agency work makes clear that circular projects in infrastructure must still prioritize functional safety and timely operational deliverability [17].

Together, these shortcomings point to five screening questions: candidate credibility, harvestability, operational disruption, regional uptake potential, and environmental or regulatory feasibility, which were the backbone behind factor development (Table 1).

Table 1. Derived factor structure and embedded indicators

Factor	Gap addressed in the literature
F1. Supply readiness and remaining value	Stock visibility does not show whether an asset is a credible reuse candidate
F2. Harvesting and reverse-logistics feasibility	Recoverability is often discussed without sufficient attention to mobilization and handling conditions
F3 Network disruption pressure and network role	Circular screening rarely integrates infrastructure service criticality and operations
F4 Circular ecosystem and match potential	Asset-level supply does not show whether regional uptake, storage and matching conditions exist
F5 Environmental and regulatory constraints	Circular options are overstated when land and environmental restrictions are not treated as feasibility limits

Supply readiness and remaining value (F1) address the central weakness of stock-based approaches: material quantity alone is a poor basis for prioritization. Francart et al. [14] make this point clear by arguing that municipal inventories based solely on aggregate estimates are insufficient for shifting to reuse decisions, whereas Honic et al. [17] show that digital models become more useful when quantities are linked to richer attribute-level information. The factor, therefore, combines three indicators designed to leverage existing AMS data and close this gap. Material stock magnitude captures whether the bridge represents a meaningful quantitative payoff as a supply source at the screening stage. Condition and restrictions then narrow that supply to bridges whose current state and restriction profile, such as defect flags or load limitations, indicate enough structural integrity to justify follow-up. Documentation readiness reflects whether the basic records needed to credibly assess reuse, including geometry, material specifications, and maintenance history, are available without intensive verification effort. Together, the factor captures whether value, technical plausibility, and informational confidence coexist strongly enough for a bridge to merit further attention.

Harvesting and reverse-logistics feasibility (F2) emerged because reuse fails not only when supply is absent, but also when recovery cannot be organized in space and time. Tsui et al. [18] identify accessibility, land availability, storage needs, and plot size as core spatial parameters for circular operations, while Verga and Khan [19] likewise show that space and land are recurrent barriers because circular activities impose greater temporal and spatial demands than traditional approaches. These insights support a factor centred on mobilization capacity. Distance to interchanges serves as an early accessibility proxy,

near-site staging space indicates whether suitable nearby space exists for temporary laydown and sorting, and typology-based disassemblability captures expected disassembly effort using structural characteristics as a screening substitute for connection-level detail. The factor, therefore, distinguishes conceptually attractive reuse from what can be realistically mobilized.

Network disruption pressure and network role (F3) address a gap that is less visible in building-led circularity research but unavoidable in bridge management. Lange et al. [20] indicate that bridge material flows are shaped by bridge-specific conditions, traffic load, and structural deficiencies, while Madden et al. [16] show that circularity in transport systems must remain aligned with the continued safety and technical function of the network. Even where material value, logistics, and recoverability appear favourable, interventions may still be unrealistic if a bridge is indispensable as a network link or if detours are absent. Demand level therefore approximates disruption pressure through traffic intensity; the functional importance class captures the route's strategic role as a network-criticality signal; and rerouting feasibility reflects whether operational measures such as closures, night work, or detours are realistically available. In this way, reuse potential is assessed not only at the asset level but also in relation to wider system effects.

Circular ecosystem and matching potential (F4) responds to the fact that reuse is not realised by a singular asset alone. GIS-supported territorialization can reveal resource-sharing opportunities by mapping resources and potential interactions. Verga and Khan [19] similarly show that circular activities rely on constellations of depots, warehouses, and collection nodes, and that sustained access to such spaces is itself an enabling condition. This supports a factor concerned with the regional context that can absorb and circulate recovered components. Typology clustering represents matching potential, where similar bridges in short distances increase compatibility and economies of scale; proximity to depots/storage yards captures handling and temporary storage capacity; and proximity to demand centres serves as a screening proxy for whether uptake and project matching are feasible within an acceptable radius. Together, these indicators estimate whether a bridge is embedded in a territorial configuration that can support reuse.

Environmental and regulatory constraints (F5) further function as a feasibility filter for the previous four. Tsui et al. [18] include land-use and environmental suitability among parameters for identifying viable hub locations, while Verga and Khan [19] show that circular ambitions compete with other spatial claims and that land scarcity can suppress otherwise promising practices. Opportunity maps are thus unreliable unless constraint layers are treated as constitutive rather than secondary. For bridge screening, protected area proximity indicates whether the asset lies within or near sites such as Natura 2000, national parks, nature reserves, etc. that can restrict methods and staging. Environmental constraints capture hydrological contexts such as floodplains, water protection areas, riparian buffer zones, etc. that may limit works and temporary storage. While other regulated zones represent additional planning and permitting constraints, including cultural heritage protection areas, designated landscapes, and archaeological zones. Thus, the factor intends to flag where circular action is likely to be delayed, narrowed, or blocked by siting and permitting conditions.

3.2 AHP/Budget Allocation Weights from Expert Surveys

Table 2 presents the final factor weights from group AHP and the local indicator weights from the budget-allocation exercise. Consistency was assessed using Saaty's consistency ratio (CR). For each matrix, the weighted-sum vector was calculated by multiplying the pairwise comparison matrix by the derived priority vector. This was divided element-wise by the priority vector to estimate λmax, after which the consistency index was calculated as $CI = (\lambda max - n)/(n - 1)$. The CR was then obtained by dividing CI by the random index; for a five-factor matrix, $n = 5$ and $RI = 1.12$. A CR below 0.10 is commonly treated as acceptable (Saaty, 1980). Respondent -level CR values ranged from 0.066 to 0.151, while the aggregated group matrix produced a low CR of 0.012. Although some individual responses slightly exceeded the conventional 0.10 benchmark [13], the low group-level CR suggests that the overall weighting pattern remained stable post-aggregation, which is consistent with applied AHP studies reporting somewhat higher inconsistency in individual self-administered survey formats [21].

Table 2. Factor and Indicator Weights

Factors (**AHP**)	Indicators (*Budget allocation*)
Supply readiness and remaining value (**0.276**)	Condition and restrictions (*0.464*); Material stock magnitude (*0.243*); Documentation readiness (*0.293*)
Harvesting and reverse-logistics feasibility (**0.166**)	Distance to interchanges (*0.314*); Near-site staging feasibility (*0.229*); System-level disassemblability (*0.457*)
Network role and disruption pressure (**0.220**)	Demand level (*0.357*); Functional importance class *(0.407)*; Workability/rerouting feasibility (*0.236*)
Circular ecosystem and match potential (**0.204**)	Typology-based matching potential (*0.386*); Proximity to depots/storage *(0.250)*; Proximity to demand centres (*0.364*)
Environmental and regulatory constraints (**0.134**)	Protected area proximity (*0.414*); Environmental constraints incl. water/flood (*0.343*); Other regulated zones overlap/proximity (*0.243*)

Respondent consistency ratios (CR): R1 = 0.147, R2 = 0.087, R3 = 0.066, R4 = 0.151, R5 = 0.106, R6 = 0.112, R7 = 0.129; aggregated group CR = 0.012

The experts placed the greatest overall emphasis on Supply readiness and remaining value (F1), followed by Network disruption pressure and network role (F3) and Circular ecosystem and match potential (F4). This suggests that early screening was understood primarily as a question of whether a bridge is a credible reuse candidate, whether intervention can be accommodated within the transport network, and whether the surrounding regional context is favorable to circular flows. Among factors, the highest local weights

were assigned to condition and restrictions in F1, system-level recoverability in F2, functional importance class in F3, typology clustering/matching potential in F4, and protected area overlap/proximity in F5. Overall, the results reinforce that promising circular candidates cannot be distinguished solely by material quantities, but require simultaneous consideration of asset readiness, recoverability, network role, and regional matching conditions.

4 Conclusion

This paper addressed the current gap between circular-economy ambition in infrastructure management and the limited availability of practical tools for early portfolio-scale decision support. While component reuse is widely recognised as a high-value circular strategy, its implementation in bridge management remains difficult because decisions are often made too late, relevant information is fragmented, and operational, logistical, and contextual constraints are rarely considered together at the screening stage. In response, this study developed an indicator-based regional screening approach that translates reuse-relevant considerations into a compact set of weighted factors and indicators, operationalised primarily using typical asset management and GIS data. The study combined a PRISMA-guided scoping review with an expert-weighting exercise using hybrid AHP and budget allocation. The resulting structure showed that experts prioritised supply readiness and remaining value most strongly, followed by network -related and ecosystem-related considerations, while harvesting feasibility and environmental or regulatory constraints were also retained as important parts of the screening logic. Taken together, the results suggest that promising circular candidates cannot be identified solely from material quantities, but require simultaneous attention to asset condition, recoverability, network role, and regional matching context. This combination will be applied and validated for a bridge stock dataset from the Motorway network of Croatia as a continuation of the study. Overall, the approach provides a practical first step toward moving circularity from a general ambition to a more operational, targetable decision problem in infrastructure planning.

Whole Life Carbon Assessment as a Tool for Urban Climate Action

Roberto Giordano(✉), Jacopo Andreotti, and Alice Masoero

Department of Architecture and Design, Politecnico di Torino, Turin, Italy
roberto.giordano@polito.it

Abstract. The mitigation of building-related greenhouse gas emissions (CO_2eq) is now recognised as a prerequisite for achieving long-term climate objectives. Several European countries and local communities are taking action to implement the Whole Life Carbon (WLC) vision and make it practical, enabling the assessment of building life-cycle emissions. The paper presents a simplified, standardised methodology for assessing WLC in building projects, developed as part of scientific research carried out for an Italian Municipality. The proposed framework aims to support the systematic accounting and reporting of CO_2eq emissions associated with new construction and renovations. The methodology is grounded in the Life Cycle Assessment standard and consistent with European standards and policy measures, including EN 15978, EN 15804, the Level(s) framework, and the Energy Performance of Buildings Directive recast (EPBD, EU 2024/1275). It focuses on selected life cycle modules: production (A1–A3), construction (A4–A5), use (B4, B6), and end-of-life (C2–C4). A twofold application is defined, encompassing a WLC evaluation at both the early design phase and the as-built report, utilising different data and quality levels (e.g., material generic data vs. product-specific data).

The paper outlines a simplified WLC framework to enhance comparability and decision-making in municipal contexts. Since the framework has not yet been validated through real case studies, the contribution describes the methodology underlying the simplified WLC assessment. This methodology represents the basis for a subsequent research phase focused on the application and validation of the framework in real case studies.

Keywords: Whole Life Carbon · Embodied Carbon · Operational Carbon · Life Cycle Assessment · Building standard

1 Introduction

The decarbonisation of the built environment is widely recognised as a critical component of global climate mitigation strategies. Buildings account for a substantial share of global greenhouse gas emissions, due to both operational energy use and embodied emissions associated with construction materials and processes [1, 2].

Historically, since Regulation 2018/1999, policies aimed at reducing the environmental impact of buildings have primarily focused on operational energy use [3]. However,

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 1186–1194, 2026.
https://doi.org/10.1007/978-3-032-34930-9_138

improvements in building energy efficiency are progressively increasing the relative importance of embodied emissions associated with materials, construction activities and end-of-life processes. Consequently, the concept of Whole Life Carbon (WLC) has emerged as a comprehensive framework for assessing the total greenhouse gas emissions associated with buildings throughout their life cycles [4, 5].

WLC assessment builds upon the methodological principles of Life Cycle Assessment (LCA) and is increasingly supported by international standards and European policy initiatives. In particular, the European standards UNI EN 15978 and UNI EN 15804 provide a consistent methodological basis for calculating the environmental impacts of buildings and construction products [6, 7]. From the policy standpoint, the Level(s) framework and the fourth recent recast of the Energy Performance of Buildings Directive (EPBD IV) require assessing the Global Warming Potential (GWP) across the entire building life cycle, accounting for CO_2-equivalent (CO2eq) emissions [8, 9].

Finally, some national and local initiatives have been introduced. In Italy, the Municipality of Milan adopted the "Piano Aria e Clima" (Air and Climate Plan) in 2021 to reach climate neutrality by 2050 [10]. At the same time, the recently introduced national standard UNI 11973:2025 highlights the relevance of decarbonising buildings. It sets out guidelines and procedures for WLC accounting [11].

In this context, there is a growing need for shared methodologies that enable designers to quantify carbon emissions effectively. This paper presents the development of "Operational Instructions" for a **simplified Whole Life Carbon** (WLC) **framework** intended for integration into urban planning and construction permitting processes. Aligned with the aforementioned standards and frameworks, as well as the national initiative *Tools for Decarbonisation* [12, 13], the proposed approach defines a practical and consistent tool for evaluating building-related emissions in accordance with international methodologies. Finally, the framework builds upon LCA principles while introducing methods that enable its application during different phases of the building process.

2 The Simplified Whole Life Carbon Framework

2.1 Definition and Indicators

The simplified WLC framework aims to quantify greenhouse gas emissions from buildings throughout their life cycles. According to UNI EN 15978 [8], the life cycle of a building can be divided into several modules covering the Production of construction materials, Construction processes, Use, and End-of-Life scenarios (see Fig. 1).

The simplified WLC framework is the sum of two main components:

- **Embodied Carbon (EC):** CO_2eq emissions from Production (A1–A3), Construction (A4–A5), Replacement (B4), and End-of-Life (C2–C4).
- **Operational Carbon (OC):** CO_2eq emissions related to energy needs during the Use of the buildings (B6) for heating, domestic hot water, cooling, lighting, and movement.

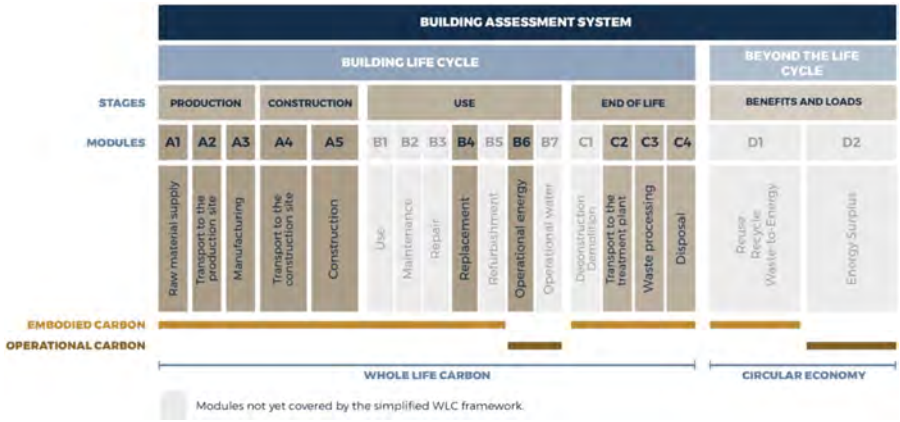

Fig. 1. Stages and modules covered by the WLC simplified framework.

2.2 Scope and Boundaries

The simplified WLC framework targets residential, office, school, healthcare, recreational, commercial, and sports buildings, excluding uses and typologies not covered by EPBD or the local building code.

The framework is designed for new buildings; however, with the appropriate selection of building elements and information on mechanical and electrical services, the method can also be used for buildings undergoing major retrofits.

The Functional Unit adopted is: $kgCO_2eq/(m^2$ HFA*year), where Heated Floor Area corresponds to the internal floor area of spaces served by the building's heating/cooling services.

The methodology also includes declared units, used in the accounting process for some modules. In this paper, a declared unit is represented by the Gross Floor Area (GFA), calculated in accordance with the EC for construction and installation processes (ECA5). The methodology is designed to support two main design and building processes:

- **Early Design.** The WLC framework provides a simplified approach to calculations, using generic datasets. This phase aims to support designers in comparing alternative design options and in identifying strategies to reduce embodied and operational carbon.
- **As-Built**. At this phase, calculations rely on more detailed information, including product-specific environmental data and updated quantities.

This two-step approach enables a progressive improvement of carbon estimates while ensuring consistency between design decisions and final reporting.

The reference period of the study (RSP) is set to align with the lifespan of buildings as defined in the main international standards, particularly Level(s) [8].

2.3 Modules and Calculation

The simplified WLC framework follows a structured procedure to ensure consistency across different building typologies:

- **Inventory Analysis:** material masses collection based on the "Design-as-Built (DaB)" project information.
- **Emissions Mapping:** assignment of emission factors (Generic or Specific/EPD) for each material to the accounted modules and stages.
- **Impact Calculation:** Application of the formulas across defined modules.

In the early design phase, emission factors are derived from generic datasets and literature-based values. In contrast, during the as-built phase, they are progressively replaced, where available, with product-specific data from Environmental Product Declarations (EPDs) to improve data quality and representativeness. Given the simplified nature of the framework, the results may be affected by uncertainty related to data quality and by assumptions concerning, among others, transport distances, replacement cycles, and end-of-life scenarios; these aspects will be examined through sensitivity analyses in the subsequent validation phase on real case studies."

The impact calculation refers to a defined number of life-cycle modules from UNI EN 15978, focusing on those assumed most relevant to municipal-level carbon accounting. Some modules were not considered because they were deemed difficult to account for. More specifically, priority was given to modules that can be accounted for using databases, certifications, and declarations (e.g., Environmental Product Declaration), or modules for which it is possible to establish assumptions compatible with local construction processes (e.g., average distances between the production site and the building construction site).

A1–A3 (Production): The modules account for raw material extraction and manufacturing. Calculations start from the DaB materials mass, adjusted by a production correction factor to account for site waste. If no specific information is available, a 9% value may be applied to all materials. For wood-based materials, the methodology accounts for biogenic carbon as a credit, provided it is not incinerated or landfilled at the End-of-Life (EoL).

Equation (1) defines the production $EC_{A1–A3}$:

$$EC_{A1-A3} = \sum_{J=1}^{n} \left[M_j \times f_{A1-A3,j} \times \left(1 + w_j\right) \right] \tag{1}$$

Where:

M_j = mass of the j-th material (kg)
$f_{A1–A3,\,j}$ = emission factor of the j-th material ($kgCO_2eq/kg$)
w_j = production factor of the j-th material (%)

A4 (Transport): The module uses standardised emission factors to estimate the impact of material transportation. Equation (2) defines the transport EC_{A4}:

$$EC_{A4} = \sum_{J=1}^{n} \left(M_j \times dj \times f_{trans,j} \right) \tag{2}$$

Where:

M_j = mass of the j-th material (kg)
dj = distance for transport from the factory gate to the construction site of the j-th material (km)
$f_{trans,\,j}$ = transport mode emission factor of the j-th material ($kgCO_2eq/km$)

A5 (Installation/Construction): The module accounts for emissions from on-site assembly and the management of construction waste. The installation is estimated via standardised factors based on the building's Gross Floor Area (GFA) or specific site equipment data. Equation (3) defines the Installation/Construction EC_{A5}:

$$EC_{A5} = GFA \times k_{A5} \tag{3}$$

Where:

GFA = Gross Floor Area (m^2)
k_{A5} = installation emission factor ($kgCO_2eq/GFA$)

B4 (Replacement): The module considers the estimated service life of components. Materials with a lifespan shorter than the RSP must be replaced, thereby increasing EC. "Roundup" is an operation that takes a number and rounds it to the nearest integer that is greater than or equal to that number. For instance, in the roundup, the result is 3, even though 2.5 is exactly in the middle; it always rounds up to the next whole number. Equation (4) defines the number of replacements and Eq. (5) the CO_2eq emissions released by the new materials installed EC_{B4}:

$$N_j = ROUNDUP\left(\frac{RSP}{SL_j} \right) \tag{4}$$

Where:

roundup = a function that increases a number to the nearest whole number
RSP = Reference Study Period (year)
$SL_{\,j}$ = Service Life of the j-th material (year)

$$EC_{B4} = \sum\nolimits_{J=1}^{n} \left[\left(EC_{A1-A3,j} + EC_{A4,j} \right) \times N_j \right] \tag{5}$$

Where:

$EC_{A1–A3,\,j}$ = emissions released from the j-th material's Production, see Eq. (1) ($kgCO_2eq$)
$EC_{A4,\,j}$ = emissions released from the j-th material's Transport to the construction site, see Eq. (2) ($kgCO_2eq$)
N_j = number of replacements of the j-th material within the RSP (number)

B6 (Operational Energy): The module is based on the energy performance certificates and predicted energy demand for the building's operation (e.g. Energy Performance Certificate). Equation (6) defines the Operational Carbon OC_{B6}:

$$OC_{B6} = \sum_{K=1}^{n} \left(Q_{B6,k} \times f_{B6,k}\right) \tag{6}$$

Where:

$OE_{B6,\,k}$ = energy needs of the building, including heating-cooling, ventilation, lightning (kWh/year)
$f_{B6,\,k}$ = emission factor of the k-th energy carrier ($kgCO_2eq/kWh$)

End-of-Life (C2–C4): These modules include waste transport (C2), waste treatment (C3), and final disposal (C4). The methodology requires determining $kgCO_2eq$ for modules C2–C4 by applying emissions factors to the waste mass. This mass is calculated by considering the volumes of waste produced by the Installation/Construction (A5), the Replacement (B4), and the building's EoL (C). Equation (7) defines the total waste mass:

$$M_{waste,j} = \sum_{J=1}^{n} \left[\left(M_j \times w_j\right) + \left(M_j \times N_j\right) + M_j\right] \tag{7}$$

Where:

M_j = mass of the j-th material (kg)
w_j = production factor of the j-th material (%), see Eq. (1)
N_j = number of replacements of the j-th material within the RSP (number), see Eq. (4)

Based on the waste mass, the transport to the treatment plant (C2) is calculated by assuming a fixed distance of 30 km. The CO_2eq emissions can be figured out by applying Eq. (2). At the same time, the waste processing (C3) and final disposal (C4) are performed together. It is based on a conservative EoL scenario of 30% disposal and 70% recycling, in line with EU waste policy and plans. Equation (8) defines the $EC_{C3–C4}$:

$$EC_{C3-C4} = \sum_{J=1}^{n} \left(M_{waste,j} \times 0,3\right) \times f_{C3-C4\ \mathrm{rec},j} + \left(M_{waste,j} \times 0,7\right) \times f_{C3-C4\ \mathrm{dis},j} \tag{8}$$

Where:

$M_{waste,\,j}$ = mass of the j-th waste (kg)
$f_{C3–C4\ rec,\,j}$ = emission factor of the j-th waste recycled ($kgCO_2eq/kg$)
$f_{C3–C4\ dis,\,j}$ = emission factor of the j-th waste landfilled ($kgCO_2eq/kg$)

2.4 The Total Whole Life Carbon

The total WLC building is the sum of EC and OC contributions, normalised to HFA and RSP. Equation (9) defines the WLC:

$$WLC = \frac{\sum(EC_{A1-A3} + EC_{A4} + EC_{A5} + EC_{B4} + OC_{B6} + EC_{C3-C4})}{HFA \times RSP} \quad (9)$$

Where:

$EC_{A1–A3}$ = emissions from Production ($kgCO_2eq$)
EC_{A4} = emissions from Transport of material to the construction site ($kgCO_2eq$)
EC_{A5} = emissions from Installation/Construction ($kgCO_2eq$)
EC_{B4} = emissions from Replacement ($kgCO_2eq$)
OC_{B6} = emissions from Operational Energy ($kgCO_2eq$)
EC_{C2} = emissions from Transport of waste to the treatment plant ($kgCO_2eq$)
$EC_{C3–C4}$ = emissions from the EoL scenario of waste ($kgCO_2eq$)
HFA = Total square meters of Heated Floor Area (m^2)
RSP = Reference Study Period (50 years)

A crucial step in the research is setting appropriate benchmarks for assessing the results achieved by the different buildings. Owing to ongoing testing of the methodology, a preliminary step involved setting an initial threshold value of 800 $kgCO_2eq/m^2$HFA*year for residential buildings, and 900 $kgCO_2eq/m^2$HFA*year for other uses (e.g. offices, schools, etc.) based on recent research conducted in Mediterranean EU countries [14, 15]. This value can be understood as an intermediate milestone in long-term carbon-reduction scenarios.

3 The Whole Life Carbon for Urban Climate Action

The simplified framework is designed to enable the integration of WLC assessment into urban climate action.

First and foremost, it is intended to provide a user-friendly, accessible framework for non-LCA experts, built on databases, certifications, and declarations available online, many of which are open source. The assumptions used to account for certain stages and modules are based on international standards and studies.

Second, by adopting a consistent calculation and reporting structure, the simplified framework is expected to improve the comparability of building projects by establishing a methodology for calculating and reporting emissions; the latter is particularly relevant for municipalities seeking to monitor the carbon performance of construction activities within their territories.

Third, the use of simplified data structures facilitates integrating WLC assessment into early design stages, enabling designers to evaluate the carbon implications of alternative materials and construction strategies.

Finally, the framework may support the future integration of EC and OC metrics into municipal climate policies and support the development of regulatory instruments to reduce building-related emissions.

4 Conclusion

The simplified WLC framework provides a pragmatic yet rigorous tool for urban climate assessments. Nevertheless, the practical application of LCA-based methods in design and policy contexts remains challenging due to their complexity and data requirements. Data availability and consistency remain critical issues, particularly for product-specific environmental data. In addition, future developments may benefit from integrating digital tools such as Building Information Modelling (BIM) and digital twins to enable automated data exchange.

The methodology has not yet been validated through applications to real buildings. At this stage, preliminary analyses have been conducted on representative building archetypes to test the internal consistency of the calculation structure and to support the definition of initial thresholds. The empirical validation of the framework through applications to real building cases constitutes the next phase of the research.

Future research targets include applying the WLC framework to a sample of different building types; this will enable the establishment of a benchmark and, subsequently, the development of a rating system comparable to the one currently used to assess energy performance.

Framework for Multi-Cycle Assessment in Circular Construction

John van Oorschot(✉), Joana Gonçalves, Francesca Vanoverberghe, and Wai Chung Lam

Vlaamse Instelling voor Technologische Onderzoek (VITO)/EnergyVille, Boeretang 200, 2400 Mol, Belgium

john.vanoorschot@vito.be

Abstract. Efforts to promote material reuse and selective deconstruction in the built environment increasingly rely on assessment tools to inform design, demolition, and policy decisions. However, current evaluation practices often fail to deliver coherent and decision-relevant insights across the building lifecycle. Circularity indicators tend to prioritize material cycling without adequately capturing environmental or value-retention impacts, while lifecycle assessment (LCA) remains rooted in single-cycle, linear logic. As a result, circularity and LCA frequently operate in parallel, producing fragmented or conflicting signals for decision-makers. Assessment outcomes are shaped by data availability, assumptions, and tool-specific structures. Data fragmentation, limited traceability of as-built conditions, and non-harmonised practices undermine comparability and confidence in results. These challenges are compounded by the fragmented construction value chain, where reuse only materialises when documentation aligns with market demand, regulatory conditions, and timing. This paper presents the development of a framework that addresses these limitations by linking environmental performance, circular strategies, and value retention across multiple lifecycles and building scales. Designed as a hierarchical structure, it ties together existing tools, indicators, and datasets within a shared logic. It integrates data from building inventories, circularity indicators, and LCA-based assessments, while remaining sensitive to decision contexts and stakeholder roles. By operationalising lifecycle thinking and coordinated decision-making, the framework clarifies actor involvement at distinct lifecycle phases and the basis of information use. Structuring assessment around purpose-driven, multi-cycle logic supports robust decision-making and provides a foundation for material catalogues and reuse marketplaces through transparent, scenario-based assessments linking environmental performance with value retention.

1 Introduction

The built environment is undergoing a pivotal transformation driven by the twin transition towards digitalization and sustainability. A key challenge within this transition is enabling multi-cycle management of building elements, components, and materials

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 1195–1202, 2026.
https://doi.org/10.1007/978-3-032-34930-9_139

to substantially reduce demolition waste, greenhouse gas emissions, and risks related to hazardous substances. Adopting a multi-cycle perspective enables the assessment of building elements and materials beyond a single linear life cycle, supporting cascading reuse, refurbishment, and recovery scenarios across successive use phases and preventing premature value loss [1, 2]. Improving access to reliable data across building life cycles is essential to unlock these benefits and to support the construction sector in delivering environmental gains, societal value, and economic opportunities.

Despite growing interest, significant methodological gaps persist. The sector is overwhelmed by a plethora of circularity tools which tend to be applied in isolation and without a clear stipulation about what and how they indicate circularity of buildings or its assets. Quantitative assessments remain largely carbon-centric, a phenomenon described as *carbon tunnel inertia* [3], where a narrow focus on CO_2 emissions obscures broader environmental impacts, resource depletion, and long-term value retention. Circularity assessments, in turn, are frequently disconnected from environmental and economic evaluation frameworks, limiting their practical applicability for end-of-life decision-making. This fragmentation presents a critical barrier for stakeholders, particularly demolition contractors and users of reclaimed construction elements, who must align circular ambitions with environmental performance and economic feasibility under real-world constraints.

To address these gaps, the paper asks: How can a multi-cycle perspective be operationalized within an integrated assessment framework that captures environmental and economic implications in alignment with real-world selective deconstruction processes? This paper presents the development of an integrated multi-cycle assessment framework designed to support evidence-based decision-making for building end-of-cycle scenarios. Rather than introducing a new aggregated sustainability scoring system, this framework provides a structured approach to define and evaluate multi-cycle scenarios, enabling consistent evaluation of circular strategies and positioning buildings as material banks for future use. In doing so, it addresses the disconnect between environmental assessment, economic valuation, and circularity assessment, contributing to a practical and scalable approach to advancing sustainable and circular management in practice.

2 Theoretical Background

Selective deconstruction refers to the act of taking a building apart and recovering the value embedded in its assets, i.e. building elements, components and materials, using different demolition strategies, methods, technologies and workflows [4–6]. The current landscape of circular deconstruction guidance frameworks provides an important foundation for moving beyond conventional demolition. Nonetheless, several gaps hinder their effectiveness and wider adoption. A key issue is the fragmentation and diversity of existing frameworks and indicators, resulting in inconsistencies and limited interoperability [7]. Furthermore, most frameworks lack a strategic decision-support structure that systematically integrates the full spectrum of circular economy strategies in accordance with the established priority ladder (R-strategies). This shortcoming is particularly evident in the absence of a clear methodology for decomposing construction objects from the building level down to elements, components, and materials. At the core of these

limitations lies the absence of a shared structuring logic that connects inventories, circularity indicators, economic valuation, and environmental assessment across scales. Addressing these limitations by harmonizing frameworks, embedding standardised criteria, and developing integrated decision-support systems, could significantly enhance the effectiveness and adoption of selective deconstruction.

Building inventories form the empirical backbone of selective deconstruction. A material inventory systematically documents the elements and materials present in an existing building and their associated characteristics. By identifying quantities, characteristics, and timing of availability, inventories enable matching supply and demand and support value retention. Without reliable and structured inventories, multi-cycle assessment remains theoretical rather than operational.

Multi-cycle lifecycle application of building assets starts from the premise of maintaining the value of materials, components, and buildings for as long as possible through circular strategies like reuse, repair, refurbishment, and recycling, contrasting the traditional linear "take-make-waste" model. However, circularity is often reduced to waste management and end-of-life considerations, lacking integration with environmental and economic assessment [8, 9]. In response, multi-cycle life cycle frameworks should adopt an explicit multi-cycle perspective, embedding circularity within structured environmental and economic assessments rather than treating it as a separate set of indicators.

While LCA remains the most accepted methodology for assessing environmental impacts, when circularity is introduced, it often remains external to LCA, addressed through separate indicator sets rather than being structurally embedded within the assessment logic. A multi-cycle perspective therefore requires embedding circularity within LCA through complementary indicators that capture cascading scenarios and the feasibility of higher R-strategies, for instance via disassembly [10, 11].

To operationalise this perspective, complexity must be reduced through structured and gradual analysis of circularity indicators. The following four hierarchical levels of analysis have been defined: building, building elements, building components, and building materials. These levels correspond to Brand's shearing layers, highlighting differentiated lifespans and replacement cycles, which are essential for multi-cycle value retention [12].

The hierarchy of R-strategies is fundamental to defining the multi-cycle circularity scenarios at each hierarchical level. The R-strategies are often presented in a sequential ladder from R0 (Refuse) to R9 (Recovery), prioritising actions that preserve embedded value and prevent downcycling. From a multi-cycle perspective, materials need to be kept in the circular loop by making them available again to use within a building, therefore maximizing value retention. Multi-cyclical application begins with determining whether a certain element, component or material is worth reclaiming based on its residual value. Residual value comprises residual technical (remaining functional capacity), economic (remaining monetary worth), and environmental value (avoidable embodied impact through reuse). Reclaim potential translates residual value into operational feasibility. End-of-life treatment depends not only on residual value but also on disassembly potential, defined as the ability to remove elements without compromising

surrounding objects [13]. Residual value and disassembly potential determine whether higher R-strategies can be realistically implemented.

Together, these concepts (hierarchical layers, R-strategy prioritisation, residual value assessment, disassembly potential, and structured inventories) establish the theoretical foundation for operationalising a multi-cycle assessment logic. They clarify how environmental and economic evaluation must be embedded within a layered and scenario-based decision structure that will be further detailed in the following sections.

3 Methodology

For the development of the multi-cycle life cycle framework, a design science approach (DSA) was followed [14, 15]. This approach focuses on the creation and evaluation of purposeful, innovative artifacts to solve complex, real-world problems. It emphasises both practical relevance and scientific rigour, bridging the gap between theory and application. This study followed five successive stages in developing the conceptual framework:

1. Relevant environmental and circularity concepts were identified based on literature on assessing sustainability and circularity in the built environment.
2. The decision context was identified and translated into the basic hierarchical structure of the framework.
3. To guide evidence-based decision-making on which R-strategy to pursue, key sustainability and circularity indicators were integrated in the framework in accordance with relevant standards and frameworks. Conditional indicators regarding value retention and reclaim potential were added.
4. The conceptual framework in the format of a flow diagram annex decision tree was designed.
5. For internal validation and refinement an expert meeting to validate and improve the conceptual design of the multi-cycle framework was conducted.

4 The Integrated Multi-Cycle Framework

Building on the previous theoretical context, the proposed framework is operationalised as a hierarchical, data-driven decision tree guiding selective deconstruction planning. Rather than providing a final sustainability score, the framework structures decision-making to define feasible multi-cycle scenarios and link them to appropriate selective deconstruction strategies. The framework constituents seven conceptual building blocks, positioning circularity indicators at the core and linking them to hierarchical levels, layers of Brand, R-strategies, reclaim potential, value retention, and inventory frameworks, within a unified decision logic. Through this structure, environmental assessment (LCA), life cycle costing (LCC), and circularity indicators are not treated as parallel tools but are embedded within a single decision logic aligned with established European standards and policy frameworks.

The multi-cycle framework is structured as a hierarchical decision logic across four levels: Building, Element, Component, and Material. As illustrated in Fig. 1, each hierarchical level follows a comparable decision sequence: (1) inventory and identification,

(2) assessment of physical condition, (3) evaluation of residual value, (4) analysis of disassembly potential, and (5) selection of an appropriate R-strategy. This recurring structure ensures consistency while allowing level-specific priorities to emerge.

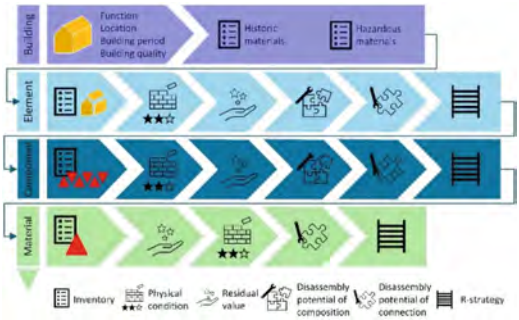

Fig. 1. The basic design of the Multi-Cycle Life Cycle Framework. For the detailed design: DISCOVER Decision Tree V2 - Miro

It begins by contextualising the building from which the material compositions and the building techniques can be deduced. The next step is to obtain an overview of which parts of the building are to be preserved for reasons of safety, heritage and/or community significance. Next, the framework challenges the necessity of demolishing the remaining. It explores whether a new project could be realised within the existing structure and therefore examines opportunities for waste reduction during design of the new project, targeting the highest R-strategies. Only when demolition is confirmed as unavoidable does the logic proceed to the lower hierarchical levels.

The element and component levels are structured identically. First, the tree questions whether the element or component in question is worth reclaiming, by assessing its residual technical (RTV), residual economic (REV) and embedded environmental (EEV) value. This tri-dimensional assessment determines whether higher R-strategies are technically and environmentally justifiable. If the analysis has a negative outcome, the tree transfers to a cascading level in the hierarchy. If the analysis has a positive outcome, the element's or component's DP is evaluated. If this component or element is fully integrated into the building or other elements or components, the tree proceeds to a cascading level. If it is modular, the tree continues to evaluate the DP of its connections, resulting in the appropriate EOL R-strategy.

Once it has been evaluated whether EOL treatment is possible on a higher hierarchical level, the material level comes into play. On the material level, the reclaim potential is first analysed using the REV and EEV of the material, instead of starting with an evaluation of its RTV, as in practice, the REV is the dominant factor to determine feasibility. If the material is evaluated as worth saving, the DP of the connections is assessed to determine the optimal EOL treatment based on the dismantling techniques required. At this level, economic feasibility, environmental benefit, and reclaim potential converge to refine the recommended recovery pathway.

Once completing the decision tree, as a key outcome, several evidence-based multicycle scenarios are being derived, indicating how a building and its subsequent assets

could be retained, which subsequently can be used to conduct LCA, LCC, circularity, sufficiency and/or sustainability assessments.

The operationalisation of the decision tree is subject to several boundary conditions related to data availability, valuation logic, market feasability, and technical constraints. The process of inventorying an existing building is time-consuming and costly. Currently, these inventories are often drafted manually and are therefore prone to errors and subjectivity. In addition, no standardised framework exists that dictates their format. To tackle this, different levels of inventories are introduced in the decision tree, namely: element inventory, component inventory and material inventory. The level of detail within these inventories intensifies with each hierarchical level. This tiered approach prevents excessive data collection at the outset and aligns the level of analysis with the decision context.

A second boundary condition concerns the evaluation of residual value. This is assessed as a balance between the residual technical, economic and embedded environmental value. Today, a demolition contractor starts with an economic evaluation to determine the reclaim pathway of DW, applying a lowest-cost approach. The costs related to environmental impacts, however, are currently not reflected in the economic value. This results in most materials being evaluated as waste, ignoring their reclaim potential. To counterbalance this bias, the framework treats embedded environmental value as equal to the economic value in determining feasible recovery pathways.

Finally, the application of disassembly potential requires careful interpretation. From an EOL perspective of a demolition contractor, an order of importance can be identified that differs for each hierarchical level. Accordingly, the framework adapts the weighting of disassembly criteria depending on the scale of analysis, ensuring that technical feasibility is assessed in relation to realistic deconstruction pathways.

5 Discussion and Conclusion

This paper explored the development of a guidance and assessment multi-cycle life cycle framework to support evidence-based decision-making for circular and sustainable end-of-life (EOL) strategies for buildings scheduled for decommissioning. The framework intends to guide the formulation of selective deconstruction plans that prioritise value retention of building systems, components, and materials thereby reducing potential environmental impacts. The framework establishes a structured approach to evaluating residual value, disassembly potential, and the applicability of different R-strategies across multiple life cycles, thereby bridging theoretical insights with practical requirements in selective deconstruction.

The developed framework provides a conceptual foundation for operationalising multi-cycle assessment in demolition practice. The current framework offers a replicable structure that guides evidence-based decision-making throughout the deconstruction process. In doing so, it lays the groundwork for a more systematic integration of circularity, life cycle thinking, and economic value assessment in the future of sustainable deconstruction. The multicycle scenarios derived from the framework can be used for quantitively and qualitative LCA, LCC, circularity, sufficiency and/or sustainability assessments. Because rooted in systematically derived scenarios avoiding narrowly set

boundary conditions these assessments are less susceptible to "burden shifting", one of the main methodological issues and critique associated with quantitative LCA and LCC studies [16, 17].

The decision tree is not free of limitations. First, the conceptual framework is not yet validated in its operational context. Specifically, greater clarity is needed regarding the timing of decisions in the deconstruction planning process, namely, which questions should be addressed at which stage, who is responsible for making these decisions, and who bears accountability for their outcomes. Second, the decision tree does not sufficiently differentiate between micro- and macro-economic effects [18, 19]. The framework is primarily designed around micro-economic considerations at the company or project level (e.g., contractors, architects, or individual construction projects). In contrast, macro-economic factors, such as market dynamics, sector-wide investment patterns, and regulatory influences, are largely outside its current scope. Future work could research the effect of market dynamics and public perception on the outcome of the decision tree. Taken together, testing the framework in real demonstrator projects will serve to assess the framework's robustness and effectiveness across a range of real-world scenarios, understanding what needs to be assessed, by whom, and when.

Abstract. Circular economy (CE) measures complement operational energy efficiency as a key strategy to reduce building and construction greenhouse gas (GHG) emissions, yet EU Member States' adoption capacities remain unclear. Using PULSE-EU, a building stock model representing the EU27, this study assesses Europe's uptake potential for six specific CE measures and their life cycle GHG mitigation impact considering both operational and embodied emissions. The assessed measures are: (i) reduction of average living area per person, (ii) building service-life extension through renovation, (iii) vacancy reduction, (iv) component/material reuse, (v) increased recycling, and (vi) increased on-site waste sorting. Socio-economic constraints are integrated to estimate realistic national CE uptake capacities. Under maximum diffusion, these measures collectively achieve 147 $MtCO_2e$ reductions by 2050, an 18% decrease from 2020 levels across EU27 embodied and operational emissions. Average living area per person and vacancy reduction emerge as primary mitigation levers, followed consistently by renovation-driven service-life extension, despite regional variations. Reuse, recycling, and waste sorting contribute modestly when assessed individually, but are important enhancers of secondary material flows. The assessment ranks CE measures by their national mitigation potential and highlights countries offering the greatest contributions. Findings emphasize the need for coordinated CE deployment that leverages CE measure's synergies while addressing local implementation barriers.

Keywords: building stock · circularity · renovation · GHG mitigation · life cycle assessment (LCA)

1 Introduction

European buildings and construction are among the world's most resource- and emission-intensive sectors, responsible for 37% of global energy-related CO_2 emissions, 50% of raw material consumption, 40% of waste generation, and 40% of material use through construction and demolition activities [1]. With the European Union (EU) targeting climate neutrality by 2050, transforming building lifecycles is urgent.

Climate mitigation policies have mainly focused on operational energy efficiency through better insulation, heating systems, and renewable energy integration, as seen in successive Energy Performance of Buildings Directive iterations [2]. These measures successfully reduced EU building GHG emissions by 43% between 2005–2023. However, embodied emissions remain largely unaddressed, comprising over 25% of 2022 building emissions and projected to grow without intervention [3].

Circular economy (CE) measures are increasingly recognized as essential complements to operational efficiency, moving beyond linear "take-make-dispose" models. CE strategies reduce primary material demand through three core principles: narrowing resource flows (efficiency improvements), slowing resource loops (extended service life and intensified use), and closing material cycles (recycling and reuse) [4]. Buildings offer the highest CE mitigation potential after agriculture and food systems, with global savings potential reaching 6.8 $GtCO_2e$ by 2050 through efficient design, space optimization, service-life extension, component reuse, and waste reduction [5].

While recent literature increasingly links CE strategies to climate mitigation, comprehensive EU-wide assessments remain scarce due to inconsistent modeling approaches [3]. Implementation capacity varies significantly across EU Member States, influenced by economic development, building stock characteristics, construction industry maturity, policy frameworks, and socio-cultural factors [6]. Previous studies typically examined single countries with limited CE measures and minimal socio-economic constraint integration [7].

This study addresses these gaps by systematically evaluating six key CE measures' GHG reduction potential across all EU27 Member States from 2020 to 2050, incorporating national adoption capacities for policy-relevant insights.

2 Methodology

2.1 Building Stock Model

PULSE-EU is an open-source building stock modeling framework designed to quantify the environmental impacts, particularly GHG emissions, of the EU27 building stock from 2020 to 2050 [8]. It enables exploration of prospective scenarios, including various Carbon Reduction and Removal Strategies (CRRS), by assessing mitigation potentials and national adoption rates over time [9, 10].

The model employs a bottom-up, archetype-based methodology that represents the heterogeneous EU building stock through 15,026 archetypes. These are defined by key parameters such as building types, construction periods, materials, technical installations, and energy performance levels [11]. Impacts are assessed through the upscaling of archetypes to the stock-level and incorporation of macro socio-economic limitations such as energy system transitions, manufacturing processes, policy interventions, population growth, demolition/renovation/new construction rates, and reuse practices [12].

PULSE-EU integrates two complementary components: material flow analysis (MFA) and prospective life cycle assessment (LCA). The MFA module dynamically tracks material flows through new construction, renovation and demolition, providing

the base for evaluating CE measures and their material loops influence. The LCA component, aligned with the EN 15804 + A2 and EN 15978 standards, uses the MMG-SLiCE LCA framework and Ecoinvent 3.6 database to calculate Global Warming Potential (GWP) across life cycle stages A1–A3 (product), A4–A5 (construction), B1–B7 (use), and C1–C4 (end of life), covering both embodied and operational emissions [13].

2.2 Circular Economy Strategies Assessed

CRRS have been assessed in PULSE-EU through groupings of individual measures [6]. For example, the strategy "Improve material efficiency" can be activated through the measures "Material use optimization in structural design" and "Offsite construction." Here we focus on understanding the impact of individual measures rather than already previously assessed groups of strategies. In between the diverse PULSE-EU measures, we identified and assessed 6 of them which are aligned with CE principles: (i) reduction of average living area per person, (ii) building service-life extension through renovation, (iii) reduction of building vacancy, (iv) reuse of existing building components and materials, (v) increased material recycling and (vi) increased on-site waste sorting. Derived from Alaux et al. [6], Table 1 gives an overview of assessed CE measures, their level of implementation in the model and the PULSE-EU strategies they relate to.

The direct effects of these measures are linked to either the archetype or stock-levels, influencing operational and/or embodied emissions. Measures such as (ii) Building service-life extension through renovation depend on and immediately impact the number of buildings on stock-level. These are therefore directly implemented in the PULSE-EU model. However, the effects of archetype-related measures, such as reducing operational emissions, are captured by adjusting individual archetype's LCA results.

Measures have different uptake levels for 2030, 2040 and 2050, which are influenced by two parameters: capacities and diffusion rates. Capacities differ per country and refer to how intensely and quickly each EU Member State is able to implement a certain measure. Diffusion rates vary by measure and define the percentage of implementation for each, thereby determining the related material flows into the model. Both these parameters are based on local macro socio-economic constraints such as technical feasibility, economic viability, policy support, industry readiness, and social acceptance. Capacities and diffusion rates were determined by following extensive desk research on literature and complemented by interviews with selected stakeholders from the industry and representative institutions. Further information on how capacities and diffusion rates are quantified and validated is available in Alaux et al. (2024) [6] and in the "Strategies" file under the associated GitHub repository in Alaux et al. (2026a) [8]

The PULSE-EU modeling approach for each CE measure is described below:

(i) **Reduction of average living area per person:** average living area per capita is a key determinant of building stock expansion. Under business-as-usual (BAU) conditions in Europe, this indicator is expected to rise due to economic and societal trends. In PULSE-EU, this parameter moderates the BAU growth trajectory by a defined percentage. For instance, if BAU projections indicate a 10% annual increase, a 1% diffusion of this measure would limit the realized increase to 9%. This measure reduces future floor area demand, thereby proportionally decreasing new construction needs, material consumption, and embodied emissions.

Table 1. Overview of assessed CE measures, their implementation levels in the building stock model and related PULSE-EU strategies.

PULSE-EU Strategies	Assessed CE measures	Implementation
Reduce per capita space demand	(i) Reduction of average living area per person	Stock-level
Prioritise better use, renovation and repair over demolition and new construction	(ii) Building service-life extension through renovation	Stock-level
	(iii) Reduction of building vacancy	Stock-level
Increase circular material use	(iv) Re-use of existing building components and materials.	Archetype-level
	(v) Increased material recycling	Archetype-level
Reduce construction and demolition waste	(vi) On-site waste sorting	Archetype-level

Adapted from Alaux et al. (2024) [6].

(ii) **Building service-life extension through renovation:** building demolition rates are modeled using probabilistic service-life distributions depending on building typologies and construction periods. This measure adjusts rates by keeping a share of buildings that would otherwise be demolished. Eligibility is limited to buildings identified for potential deep renovation (comprehensive envelope improvements and system replacements). At a 10% diffusion rate, 10% of buildings reaching end-of-life under BAU conditions are instead deep renovated and retained. This measure reduces demolition and embodied emissions from replacement construction while increasing renovation material flows and enhancing operational energy performance.

(iii) **Reduction of building vacancy:** vacancy rates are calibrated based on national statistics [14]. The vacancy reduction measure activates a share of vacant dwellings via deep renovation, shifting them to occupied status. At 10% annual diffusion, 10% of the vacant stock undergoes deep renovation each year. This offsets equivalent new construction demand, incorporating renovation material flows and embodied emissions while avoiding substantially higher emissions from new construction.

(iv) **Reuse of existing building components and materials:** material reuse substitutes a percentage of raw material inputs with recovered products, materials, or components from demolition and renovation waste streams, focusing on steel, bricks, and concrete. A 2% diffusion rate meets 2% of material demand via reuse. Reused materials carry lower environmental impacts (avoiding primary production) while accounting for recovery, processing, transport, and quality control.

(v) **Increased material recycling:** this measure is modelled through reductions in archetype-related LCA results due to increased recycled content for primary materials (steel, plastic, brick, aluminium, copper, wood, glass, concrete, insulation, gypsum). Diffusion rates represent average recycled content shares, reducing energy

demand and GHG emissions from production. Unlike (iv) reuse (direct component application), recycling involves industrial reprocessing into new products.

(vi) **On-site waste sorting:** this measure redirects a higher share of construction and demolition waste from landfill to recycling and recovery pathways. The diffusion parameter represents the percentage of waste diverted to recycling/reuse, reducing GHG emissions via lower volume sent to landfill, avoided transportation distances and raw material production. It synergizes with reuse/recycling measures by enhancing secondary material quantity and quality.

3 Results and Discussion

Collectively and under maximum diffusion, the assessed CE measures represent a total reduction of 147 $MtCO_2e$ in 2050, corresponding to an 18% decrease from 2020 levels in combined embodied and operational emissions of the EU27 building stock. The results show a sharp increase in mitigation potential through 2030, followed by a more gradual rise up to 2050. As CE measures interact dynamically, synergies arise when complementary measures show higher potential emissions once combined, for example the reinforcement of recycling through on-site waste sorting. Trade-offs also appear, such as reuse and recycling competing for the same demolition waste, or lack of timeline alignment for material loops.

Among the assessed CE measures, (i) reducing living area per capita provides the highest mitigation potential, ranking first in 22 of 27 countries and consistently within the top two overall, except in Spain, where (iii) reducing vacancy ranks first. Vacancy reduction also performs strongly, ranking second in 14 countries and within the top three in all cases. (ii) Extending building service-life through renovation achieves the third-highest potential on average, though it ranks lowest in Finland, Luxembourg, Malta, and Poland. (v) Increased material recycling and (iv) re-use of existing components follow, with recycling ranking fourth in 21 countries. (vi) On-site waste sorting shows the least impact, ranking sixth in 14 countries and fifth in the remaining 12.

Material-side measures (recycling, reuse, waste sorting) mainly target embodied emissions and have therefore relatively low individual impact compared to measures achieving greater reductions in operational emissions. However, they play an important supportive role by improving quantity and quality of secondary material flows. An observed modelling limitation for living area reduction is the neglect of potential trade-offs from additional materials required for delivering denser livable spaces. Table 2 lists the EU countries from highest to lowest absolute GHG reduction potential through the combined implementation of CE measures by 2050. These measures are individually ranked in terms of national capacities for mitigation.

Figure 1 illustrates the total potential GHG emissions reductions in 2050 from each individual CE measure assessed in the study. Emissions are expressed relative to the 2020 baseline (808 $MtCO_2e$) across the EU27. The individual results are non-additive to other measures due to synergies and trade-offs between them.

Table 2. EU countries from highest to lowest absolute GHG reduction potential (2050) along with ranked national CE measures' mitigation potential.

13	Denmark	i	iii	ii	v	iv	vi	27	Estonia	i	iii	ii	v	iv	vi
14	Bulgaria	iii	i	ii	v	vi	iv								

Assessed measures are (i) average living area reduction per person, (ii) service-life extension through renovation, (iii) vacancy reduction, (iv) component/material reuse, (v) increased recycling, and (vi) on-site waste sorting.

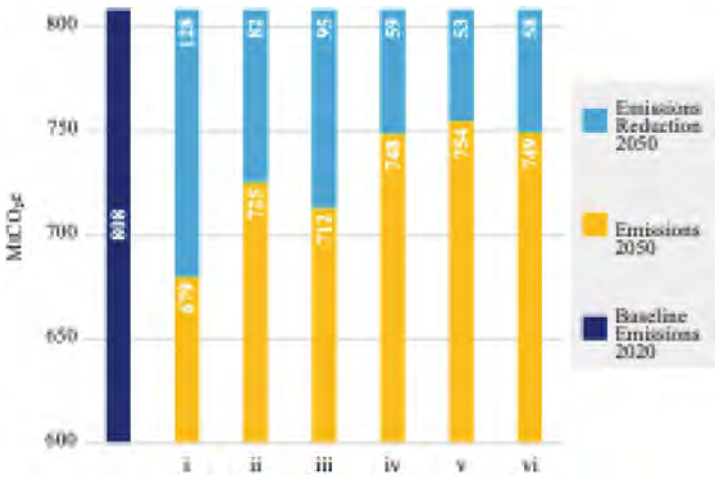

Fig. 1. Total potential GHG emissions reductions in 2050 from each individual CE measure relative to 2020 baseline emissions across the EU27.

4 Conclusion

The analysis demonstrates that CE measures offer substantial, differentiated GHG mitigation across the EU27, with a collective potential of 147 $MtCO_2e$ by 2050, equivalent to 18% of 2020 building emissions, primarily through reduced new construction and optimized material loops. Living area and vacancy reduction emerge as main levers of emission reduction, using basic economic and social factors as potentials to cut embodied emissions. However, future development of the modelling should account for possible trade-offs, such as additional materials needed to transform existing buildings into denser, livable spaces. Renovation-driven service-life extension provides consistent third-place gains despite regional differences. Material-side measures (reuse, recycling, waste sorting) contribute modestly when assessed individually, but are an important enhancer of secondary flows, underscoring the need for integrated deployment of CE measures. Further research is recommended for critical assessment of social, political and market barriers for CE measure adoption to better capture their actual implementation constraints and opportunities.

Abstract. Whole-building life cycle assessment (WLCA) is increasingly required by European regulations and international standards. However, the development and evaluation of alternative LCA scenarios remain complex due to the large amount of data involved, the influence of context-specific variables, and the constraints affecting design decisions. Recent developments in Green Public Procurement (GPP) introduce performance-based criteria aimed at improving the environmental quality of public works, requiring the assessment of design alternatives against a defined baseline. In this context, the production of environmental improvements becomes a critical and resource-intensive task. This paper suggests a framework for supporting the assessment of alternative LCA scenarios in public procurement processes. The approach is based on a proof-of-concept LLM-orchestrated workflow that integrates project data with external sources, such as Environmental Product Declarations (EPDs), to explore potential design improvements. The workflow is implemented through a Retrieval-Augmented Generation (RAG) architecture, enabling the semi-automated identification and evaluation of alternative materials. The method was showcased on a real case study involving a mixed-use residential building with social functions, demonstrating how the proposed approach can support the identification of lower-impact solutions and the estimation of potential environmental improvements. The results highlight the potential of LLM-orchestrated workflows to facilitate the exploration of design alternatives, while also outlining current limitations and areas for further development.

1 Introduction

Whole Life Carbon Assessment (WLCA), which accounts for both embodied and operational greenhouse gas emissions over the entire building life cycle, is increasingly recognised as a key approach to support decarbonisation strategies in the construction

sector. Recent European policy developments, including the revised Energy Performance of Buildings Directive (EPBD IV) [2] and the EU Taxonomy framework, emphasise the need to address both components, highlighting the growing importance of reducing embodied impacts alongside operational energy demand [3].

In this context, Life Cycle Assessment (LCA) represents the reference methodology for quantifying environmental impacts, particularly Global Warming Potential (GWP). Several European countries have already integrated LCA into their regulatory frameworks, while others are progressively introducing harmonised methodologies and reporting requirements.

In Italy, a standardised national LCA methodology is still lacking. The main reference is represented by the "Criteri Ambientali Minimi" (CAM) for buildings, developed within the Green Public Procurement (GPP) framework and mandatory for public procurement procedures [4]. The recent 2026 update introduces a simplified LCA methodology, inspired by the European Level(s) framework, focusing on selected life cycle stages and technical elements. Although simplified, this approach ensures comparability of results, which is essential in procurement processes.

Beyond methodological aspects, CAM introduce performance-based award criteria aimed at promoting environmental improvements. Within this framework, LCA is used as a comparative tool to evaluate design alternatives against a baseline scenario defined at the feasibility stage. Design proposals are required to demonstrate measurable reductions in environmental impacts, typically through material substitutions supported by Environmental Product Declarations (EPDs).

However, the development and verification of alternative LCA scenarios remain complex and resource-intensive, particularly in early design stages, where data availability is limited and uncertainty is high. This creates a significant barrier to the effective implementation of performance-based procurement criteria.

This study addresses this challenge by proposing a preliminary AI-assisted workflow to support the identification and evaluation of alternative LCA scenarios within GPP procedures. The approach integrates, into a unified workflow, tools that had previously been tested singularly, working out a Large Language Models (LLM) [5] and Retrieval-Augmented Generation (RAG) architecture [6] that matches project data with EPD databases, to enable the semi-automated exploration of lower-impact design solutions. The objective is to support designers in assessing potential improvements starting from a baseline LCA defined at the Technical-Economic Feasibility Project stage.

2 Performance-Based LCA Criteria in Italian GPP

The CAM for buildings include technical specifications, contractual clauses, and award criteria. While the first two are mandatory, award criteria apply when the Most Economically Advantageous Tender (MEAT) criterion is adopted, promoting performance beyond minimum requirements.

Within this framework, LCA is used as a comparative tool based on a baseline scenario and a set of reference indicators. The LCA report must include all mandatory indicators defined by the relevant standards, while the designer selects three key indicators for comparative assessment, including at least total GWP.

During the design phase, proposals are rewarded when they achieve a minimum improvement of 10% compared to the baseline defined at the feasibility stage. During the construction phase, alternative technical solutions proposed by contractors are evaluated against the reference design, requiring at least a 5% reduction for each selected indicator.

Such improvements are typically achieved through the substitution of building elements with alternatives of equivalent technical performance but lower environmental impact, as documented by environmental product declarations. Scoring is based both on the magnitude of the improvement and on the use of products supported by such documentation.

In this context, the verification of LCA results against the proposed improvements becomes a key element for both the evaluation and award of bids, ensuring compliance with the defined environmental performance targets.

3 Methodology

Building on the framework described above, this study explores how artificial intelligence can support the assessment of environmental improvements in public procurement processes, starting from a baseline design defined at the Technical-Economic Feasibility Project (TEFP) stage.

At this stage, the baseline LCA is typically based on generic data, due to the limited availability of product-specific EPDs. The proposed approach uses this baseline as input for an AI-assisted process aimed at identifying alternative materials characterised by lower environmental impacts and supported by EPDs, and recalculating the LCA accordingly.

The assessment considers the life cycle stages A1–A3, A4–A5, B2–B4, and C1–C4, in line with CAM requirements. The operational energy use stage (B6) is excluded, as it is not affected by material substitution.

Environmental performance is evaluated using the Global Warming Potential (GWP), expressed in $kgCO_2eq/m^2$.

3.1 Case Study and Baseline Results

The proposed approach was applied to a real case study (Fig. 1), consisting of a mixed-use residential building with social functions located in Italy, in seismic zone 3 and climatic zone D. The case study is derived from a previously developed WLC benchmark for the Italian building sector [7].

The building has two above-ground floors: the ground floor hosts a public-social facility, while the upper floor includes eight social housing units.

The structural system consists of a braced steel frame combined with reinforced concrete elements, designed to meet seismic requirements. The foundations are shallow reinforced concrete systems, and the intermediate floors are composite slabs. The main characteristics of the case study are summarised in Table 1.

The baseline LCA was developed at the TEFP stage using generic data, in line with CAM requirements. Results are expressed in terms of Global Warming Potential (GWP), in $kgCO_2eq/m^2$, considering the life cycle stages A1–A3, A4–A5, B2–B4, and C1–C4.

Table 1. Key characteristics of baseline case study

Parameter	Value
Climate zone	D
Seismic zone	3
Year of intervention	2025
Useful Floor Area (UFA)	1088.77 m^2
N° floors	2
N° apartments (N° occupants)	8 (20)
Construction type	Braced steel frame structure with reinforced concrete

The results show that the product stage (A1–A3) represents the dominant contribution, accounting for approximately 58% of the total GWP. This highlights the significant impact of material production on the overall environmental performance of the building.

The analysis by building element confirms that structural components are the main contributors to total emissions. In particular, the load-bearing structure and vertical elements account for approximately 33.9% and 25.7% of total GWP, respectively (Figs. 2 and 3).

Fig. 1. Simplified archetype building geometry adopted for the study

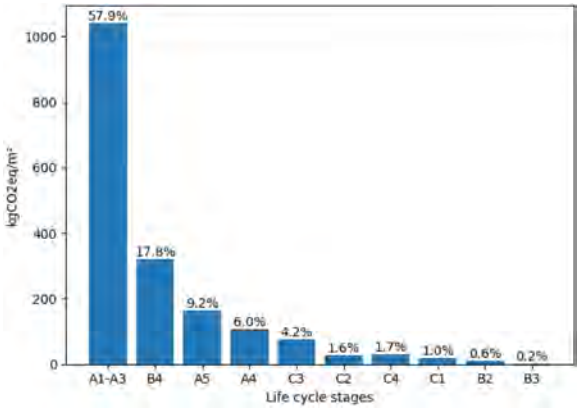

Fig. 2. Distribution of total GWP by building element across the considered life cycle stages ($kgCO_2eq/m^2$)

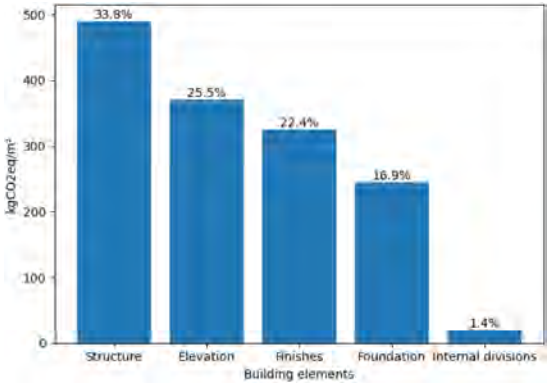

Fig. 3. Breakdown of total GWP by building element ($kgCO_2eq/m^2$ UFA)

4 LLM-Orchestrated Workflow to Assess Alternative Scenarios

4.1 Conceptual Framework

The proposed framework implements an AI-assisted workflow for the analysis and verification of CAM requirements, based on a combined LLM and RAG- based architecture (Fig. 4). The approach enables the integration of project data with external sources, such as EPD and cost databases, to support the identification of alternative design solutions.

Unlike traditional LCA workflows, which rely on manual data processing and limited datasets in early design stages, the proposed approach allows a semi-automated exploration of alternative materials starting from incomplete baseline information.

The workflow is structured into four phases: data input, AI processing, evaluation of alternatives, and decision support.

In the data input phase, project documentation (i.e. LCA reports and bill of quantities) is provided and processed to extract relevant variables for environmental assessment.

In the AI processing phase, an LLM-orchestrated system links project data with external databases, enabling data retrieval and the identification of alternative materials based on environmental and economic parameters.

The evaluation phase supports the comparison between baseline and alternative scenarios, including both environmental impacts and cost aspects.

Finally, the system generates an optimised design alternative, which is validated by the designer. The approach does not replace the design process but enhances its analytical and comparative capabilities.

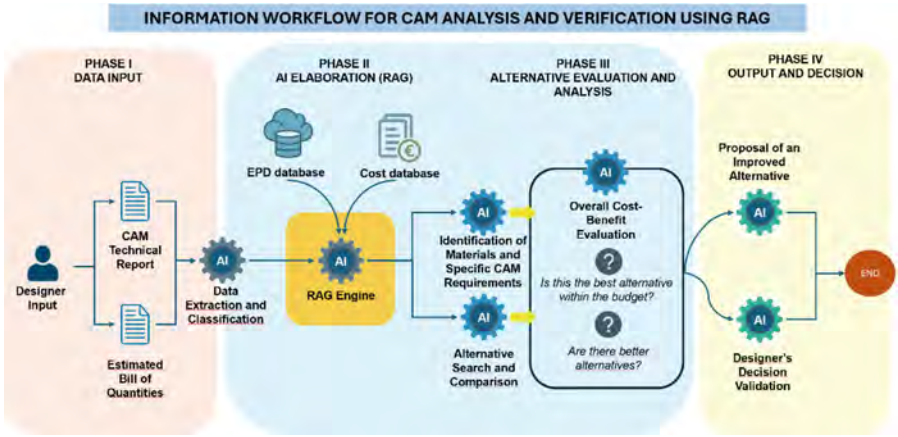

Fig. 4. Proposed RAG-based workflow for CAM analysis, alternative evaluation, and decision support.

4.2 Proof of Concept and Results

In order to preliminarily showcase the potential of the proposed framework, a proof of concept (PoC) based on LLM-orchestrated workflows was developed. The PoC performs three main tasks: (i) extraction of GWP contributions from the baseline LCA report, (ii) retrieval of LCA impact indicators from EPD documents, and (iii) estimation of the environmental impact resulting from material substitution.

The workflows are structured into three main components (Fig. 5).

The first workflow processes context-specific information from the LCA technical report to extract the breakdown of GWP contributions by building elements and life cycle stages. The second workflow retrieves GWP data from EPD documents, enabling the definition of alternative LCA scenarios. The third workflow consists of an agent that evaluates the environmental impact resulting from the replacement of materials, combining the information extracted in the previous steps.

The workflows were implemented using the open-source automation platform N8N™, a visual programming environment that enables low-code integration of components such as vector stores, embedding tools, agents, and external databases. Due to the

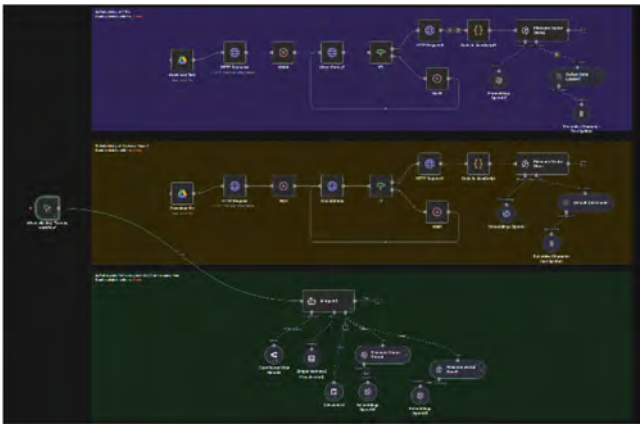

Fig. 5. LLM-orchestrated workflows to assess the GWP total figure of a building material.

heterogeneous nature of the data, a Retrieval-Augmented Generation (RAG) architecture was adopted.

The LCA technical report and the EPD datasets were embedded in a Pinecone vector store, with a chunk size of 2000 tokens and an overlap of 100, after preprocessing within LlamaIndex (v.1). This setup enabled semantic search and structured data retrieval across both contextual and technical information sources.

The analysis focused on the replacement of a concrete type used in the baseline scenario. The agent was instructed to identify the total quantity of "concrete type C35/45" from the bill of quantities, aggregating contributions from different subsystems, and to calculate the associated GWP. Subsequently, it retrieved the GWP values of an alternative concrete ("C35/45 a/c max 0.60 S5 D22.4 XC1 CAM5") from the corresponding EPD and estimated the updated environmental impact.

The results confirm the correctness of the workflow. The total quantity of concrete in the baseline scenario is 1,691,338 kg, corresponding to a GWP of 219,468.70 $kgCO_2eq$. The system calculated the GWP for the required life cycle stages, resulting in a value of 240.01 $kgCO_2eq/m^3$. Based on the alternative material, the total GWP was estimated at 169,140.85 $kgCO_2eq$.

This corresponds to a reduction of approximately 22.9% in the GWP associated with the analysed material. These results demonstrate the effectiveness of the proposed approach in supporting the quantitative assessment of alternative design solutions, enabling a structured and data-driven comparison of scenarios.

5 Conclusions

This study presents a preliminary AI-assisted approach to support the evaluation of alternative LCA scenarios within GPP procedures. Starting from a baseline LCA defined at the TEFP stage, the workflow integrates project data with external LCA datasets to identify and assess lower-impact design options.

The case study confirms that structural components are the main contributors to total GWP, highlighting them as key targets for improvement. The workflow enables the retrieval of impact data, recalculation of results, and comparison between baseline and alternative scenarios. In the analysed case, replacing a concrete type reduced the associated GWP by about 22.9%.

While promising for decision support, the approach is still limited by data availability, EPD consistency, and partial automation. Future work will expand datasets, improve environmental-economic integration, and test additional case studies.

Tracing Resource Dependencies in Construction: Supply Chain Sufficiency as a Circularity Metric

Alejandro de Castro Mazarro(✉) and Lamiaa Ghoz

Leibniz Institute of Ecological Urban and Regional Development, Dresden, Germany
a.decastro@ioer.de

Abstract. Narrowing, slowing, and closing loops can increase the circularity of the built environment; however, they do not account for the dependence of supply chains on resource sinks from which raw construction materials are sourced. This is particularly important in the case of structural dependencies between countries for materials such as iron and wood, which are critical for urban development activities. This paper aims to conceptually address this gap by identifying supply chain sufficiency as an overlooked dimension of circularity assessment in the construction sector. To do so, we first describe existing methods that could potentially contribute to the overlooked metric, and then explore the use of the supply chain network analysis methodology in the case of iron used within Germany's construction sector to illustrate Germany's dependencies on other countries for sourcing iron and steel for construction. Our tentative results, based on 2019 international trade data, show a significant dependence of Germany on Kazakhstan and the Russian Federation for the supply of iron ore used throughout the construction supply chain for the production of construction steel. While these results still need to be depurated to incorporate domestic iron and steel production, as well as the iron intensity of construction products, they suggest the value of a potential metric that could enable countries to better assess their interdependencies regarding the production of their built environment.

Keywords: Circularity · Supply chain sufficiency · Supply chain network analysis · Material flow analysis · Construction sector · Resource dependencies

1 Introduction

To develop a circular economy for the built environment, the construction industry is currently aiming to narrow, slow, and close its resource flows. As a consequence, a number of strategies aimed at reducing waste to an ideal point of self-sustenance, from efficient material use to design for longevity, to recycling and urban mining, have gained prominence. To achieve these strategies, a large number of material circularity indicators in the built environment at micro, meso and macro levels have been created [1]. Such indicators largely focus on the efficiency of internal industrial processes, or on the productivity of materials as a share of their weight. For instance, the Material Circularity Indicator (MCI) measures how much a product's material is made from recycled

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 1219–1225, 2026.
https://doi.org/10.1007/978-3-032-34930-9_142

or reused sources – in the building sector, from recovered building and infrastructure materials. Other widely accepted metrics include the Life Cycle Assessment (LCA), which quantifies the environmental impacts in terms of water, energy, or greenhouse emissions from the cradle to the grave of resource use.

Yet, as highlighted recently by the Ellen MacArthur Foundation [2], circularity is constrained by complex and globally fragmented supply chains that reduce the transparency and traceability of material flows. As circularity indicators largely focus on the reduction of waste output, a significant "blind spot" in contemporary circularity metrics lies in overlooking the primary resource sinks that commonly initiate secondary material loops in a circular system. A brief analysis of MCI may offer an insightful example of this problem. As MCI focuses on the impact of material recycling to increase circularity, it overlooks the ability for a reduction in primary resource consumption to increase the overall circularity of a supply chain. In a spatial sense, additionally, it does not distinguish whether a ton of primary raw material originates from the same country as its corresponding secondary raw material, or whether it originates from a distant region. Such bias, extended in existing circularity strategies, limits the ability to address the sufficiency of a supply chain, as well as the landscape degradation and environmental injustice derived from resource extraction in an international environmental policy context.

Construction activities, indeed, are fundamentally dependent on primary resources; recent research on the historical accumulation of anthropogenic mass demonstrates not only that the construction sector is the largest contributor to human-made mass, but also that since the "Great Acceleration" observed after 1950, the proliferation of concrete and aggregates in Europe and the United States has become the primary driver of resource extraction [3]. This "blind spot" in circularity metrics, thus, lies in overlooking the spatial politics of supply chains that, otherwise, are subject of current sustainability and spatial research [4]. The assumption that recycling can create closed domestic loops and self-sufficiency overlooks the reality that, even with a full material recycling rate, highly industrialised economies and their construction sectors substantially require the extraction of primary materials and energy from distant resource sinks, whose inflows from foreign locations are required to maintain loops [5].

The degree of sufficiency of a supply chain can be operationalised as a domestic-share metric that would measure the proportion of a resource originating within a country's own borders, compared to the total consumption of such a resource within the country. Such a metric would indicate the degree to which the supply chain is sufficient, ranging between a value of 0 (all primary resources originate abroad) to 1 (all primary resources originate domestically), according to the following formula:

Resource Sufficiency = Domestic Resource Consumption/Total Resource Consumption

We consider that "resource sufficiency" should be considered a fundamental metric of circularity integrated into the narrowing, slowing and closing of material flows within the circular economy framework. A tentative definition of resource sufficiency, in this context, would be the ability of a system to mainly rely on domestic and near resources. A sufficient supply chain would not rely on a single foreign source or primary resources, nor be dependent on risky, long-range logistics.

Given that the mapping of material flows within supply chains is a precondition for identifying sufficient supply chains, this paper follows an exploratory approach to identify existing methodologies that could map such flows. Based on this, we illustrate below the potential application of such methodologies through the brief analysis of a case study under development. Finally, the paper concludes with future research directions and limitations of this study. With these, we aim to critically evaluate current circularity metrics and identify approaches to shape a tool that explicitly incorporates supply chain dependencies into a resource sufficiency indicator.

2 Measuring Resource Sufficiency

To address the gap identified above—the absence of circularity metrics addressing supply chain dependencies—this paper explores the validity of two available methods for tracing international dependencies in supply chain networks: Material Flow Analysis (MFA) and Supply Chain Network Analysis (SCNA).

Supply chain network analysis (SCNA), used in the fields of resource security and ecosystem ecology, is a methodology that traces and measures the structural dependencies of traded products and identifies their resource origin. SCNA calculates graph traversals, namely a systematic process of algorithmic analysis exploring the relationships between nodes within a graph to extract insights. In a supply chain, Breadth-First Search (BFS) algorithms identify all Tier-1 suppliers, then all Tier-2 suppliers, gradually expanding outward to map the "breadth" of the supply network. In opposition, Depth-First Search (DFS) algorithms dive as deep as possible along a branch before backtracking. With a combination of both, SCNA can trace the journey of a material through multiple tiers of processing—for example, from a mine in Brazil to a pelletizer in the Netherlands, and a blast furnace in Germany.

An additional methodology that may assess the sufficiency of a supply chain, used within industrial ecology, is trade-linked Material flow analysis (MFA). Traditional MFA tracks the stocks and flows of materials within a defined system (like a city or a nation). Trade-linked MFA expands this by attaching "origin tags" to those flows. Trade-linked MFA incorporates material content and production yields, and at each process level, this way offering a mass-balanced account of flows - namely a closed system where the sum of inputs and outputs in the supply chain is constant.

While both types of analysis trace the location of resource flows through supply chains, they operate at different levels of analysis. Both trade-linked MFA and SCNA rely on a supply chain model that helps to structure the flows of raw and semi-finished goods in the supply chains according to trade data, namely import and export records for raw materials, semi-finished and manufactured goods. In a practical sense, they allow for mapping hidden vulnerabilities in the supply chain. They may, for example, identify deep-tier "diamond-shaped" risks, by which a diversified supply chain of semi-manufactured products relies on single raw resource sinks. These methods, also, may identify single points of failure that are invisible in traditional supply chain reporting. Additionally, they can help to identify bottlenecks for regions that are critical by their structural position in the global network. Finally, these methods help to assess the true environmental impacts of resource use. By traversing every process in the supply chain,

we can calculate the "true" carbon footprint, accounting for the energy intensity of every node from extraction to assembly. Each of these methods, however, provides a different level of consistency: SCNA can be upgraded to trade-linked MFA if it provides a mass-balanced account of material flows, for which it requires, among others, domestic production data and production yields of each process. Otherwise said, SCNA may not necessarily address the share of products distributed within each supply chain node, while the trade-linked MFA does provide such level of detail – at the expense of a higher data intensity.

3 A Case Study Snapshot: The German Construction Steel Supply Chain

To test the value of these methodologies to provide a measure of supply chain sufficiency empirically, we explore the application of a SCNA for construction steel imported in Germany in 2019—a year of significant urban development, before the global supply chain shock created by the global pandemic of 2020.

Even when in 2019, Germany was the world's 7th largest producer of pig iron, the country was heavily dependent on imported raw materials for metals and had no raw iron extracted from mines [6]. Germany's construction sector remains, in fact, a massive consumer of virgin iron and steel, as its construction industry accounts for approximately 33% of its steel consumption [7]. Iron is, on its own, the world's second most traded commodity by economic volume and a cornerstone of modern construction, with steel accounting for approximately half of all iron produced [8]. While iron mining is known to be associated with environmental catastrophes and social harms in developing regions, such as Minas Gerais and Pará in Brazil [9], these regions are decoupled from the sectors driving the demand for iron. In doing so, sectoral, national and international institutions are limited in addressing the environmental and social issues derived from mining.

To re-territorialise the iron consumed by the German construction sector into the landscapes and regions most affected by iron extraction, we present a supply chain network analysis, currently in development, from the global iron mines to the crude and conformed steel production in Europe and Germany, and to the end-use products for the construction industry in Germany. To do this, we use export data for products that are mainly used for the construction supply chain, from the UN Comtrade database according to its Harmonised System [10]. The trade data is assigned to one of the four generally agreed-upon phases: iron mining (Phase 1), iron reduction (Phase 2), steel casting (Phase 3), and production of steel goods (Phase 4). Starting with the supply chain Phase 4 and until Phase 1, we use a Breadth-First Search to find all exporting countries that have a negative weight balance with their corresponding importer countries. This means that we first analyse which countries have a negative net trade balance with Germany (namely, which countries export more steel goods than they import to Germany) (Fig. 1, right side); we then analyse which countries have a negative net trade balance with the previous exporting countries for steel casted products; and so forth for the supply chain phases 2 and 1. As products cannot travel "backwards" through the supply chain, the analysis hypothesises that all surplus weight accumulated by Germany can be found, through the supply chain, in the countries exporting iron ore.

Our model carries a number of assumptions that need to be clarified to restate its ongoing, exploratory nature. As mentioned earlier, in our analysis we have not yet assigned sector coefficients to the products of Phase 4, meaning that we carry the assumption that 100 % of the harmonized system products are used in the construction industry. On the other hand, we do not calculate the domestic production of iron ore, which limits the ability to have a mass-balanced account of resource use; this limitation, also, can be overcome in a further development of the SCNA into a full, trade-linked MFA. Last but not least, the iron/steel supply chain model can be improved to avoid data distortion from re-trade and double counting.

Our analysis revealed a high concentration of dependency in the original suppliers of iron, even when steel for construction is largely manufactured in Europe. The tentative results of our analysis, portrayed as a Sankey Diagram flow chart in Fig. 1, display the flows of iron across supply chain phases and countries, as proportional in quantity to line widths. Despite Germany's robust domestic steel industry, the diagram shows that primary iron used for construction steel was heavily reliant on two specific resource sinks: Kazakhstan and the Russian Federation, which are not the largest global iron ore producers. It should be noted that the absolute value of these flows is not as relevant as their relative value, as the values of the Sankey diagram are not mass balanced.

By mapping these flows, this paper highlights that concentrated urbanisation entails environmental and social impacts on specific extraction regions tied to construction materials, regardless of their efficient manufacturing. It also aims to address accountability gaps within the governance of trade regimes, which may foster more equitable and sustainable practices in the global iron trade. Within the context of Industrial Ecological research, the paper aims to contribute to the investigation of global resource use of cities through the identification of regional hotspots of resource extraction, which

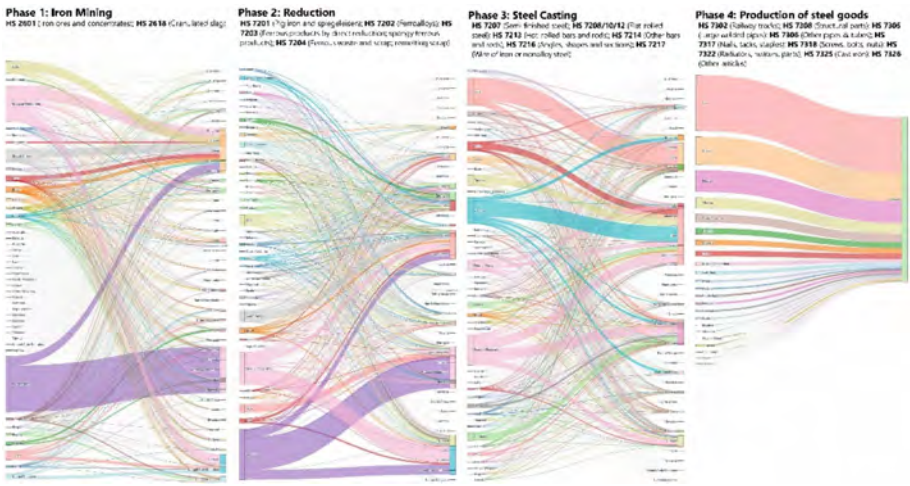

Fig. 1. Sankey diagram representing a tentative supply chain network analysis of German construction steel in 2019, across four supply chain phases: iron mining, iron reduction, steel casting, and production of steel goods.

may indicate where policy priorities need to take the lead. These results may be seen to represent a "circularity leak" by which the ability to "slow" or "narrow" loops is constrained by the external pricing and availability set by the geopolitical blocs where the steel originates.

4 Results and Recommendations

While the construction sector remains the world's largest consumer of raw materials, true circularity within cannot only be centred around the metabolisation of waste, but also around the preservation of resource sinks, which provide the materials that compose our cities. To ignore the source of primary resources implies not only a flawed imaginary of the circular economy, but also a pretext for unequal trade relations among countries to persist. We must move toward a system that is not only resource-efficient but also resource-sufficient – this means, profoundly sustainable and geopolitically secure.

Our brief analysis of Germany's iron dependencies suggests a stark geopolitical reality: the physical urban infrastructures of countries like Germany may strongly rely on the earth, mines and regions of other countries. This may serve as a cautionary for the transition of the built environment towards sufficiency: While iron may be the most visible example of these vulnerabilities, the exploration of the methods here presented for other materials involved in urbanization - like wood, copper, or rare earths - may help to describe the relative unavailability of some construction resources within some nations' borders.

If resource sufficiency could be considered a "score" to disclose in new infrastructure or building projects, then SCNA and trade-linked MFA may become potential methods to assess circularity has the potential to improve circularity reporting in the construction sector. In the context of political ecological, and postcolonial research studies, the historical tracking of sufficiency metrics may, additionally, allow to observe resource dependencies across nations over decades, and help identify unequal trade dynamics built over time.

This paper's exploratory approach provides a roadmap towards a construction sector that is just and ecological. Our approach, however, carries inherent limitations: we have reviewed existing methods but not fully tested them. Consequently, we cannot prescribe a concrete tool for integrating supply chain resilience into circularity metrics. Such methods require further validation across case studies and with robust dataset analyses. Furthermore, our empirical illustration is limited to one material (iron/steel), one country (Germany), and 1 year, which restricts generalizability. Our contribution, therefore, ends at exploration, leaving future research to empirically test our findings and develop a testable methodology.

Circularity Indices for Buildings: A Conceptual Categorization and Comparative Analysis

Andrea Skaaland Larsen, Alvilde Bergh Wold, Rolf André Bohne, and Freja Nygaard Rasmussen(✉)

Norwegian University of Science and Technology, Trondheim, Norway
freja.n.rasmussen@ntnu.no

Abstract. Despite a widely accepted need for increased circularity in the built environment, progress is still slow. One source of confusion is the multitude of circularity indices measuring circularity performance at the building scale. Several systems exist in parallel, with profound differences in goal, scope and transparency. The aim of this article is to contribute to a more coherent and transparent knowledge base for quantifying circular resource use. The analysis includes Level(s) indicators 2.3 and 2.4, the FutureBuilt Sirkulær, DGNB Circularity Index, One Click Building Circularity tool, Madaster Circularity Indicator, the Ellen McArthur Material Circularity Indicator and the Whole Building Circularity Indicator. The work provides a structured overview of CI typologies, scope, weighting factors and levels of granularity that can support both researchers and practitioners in understanding, selecting, and combining circularity indices in the assessment of buildings. The study also identifies overlaps, gaps, and potential synergies between the indices.

Keywords: Circularity indices/indices · Building-level assessment · Material reuse · Comparative analysis · Circularity tools

1 Introduction and Theoretical Framework

The construction and real estate sector is among the most resource-intensive sectors globally, accounting for substantial material extraction, waste generation and greenhouse gas emissions. Despite growing policy and industry commitment to circular economy principles, current practice remains largely grounded in a linear extract–produce–use–dispose model. The circular economy proposes a systemic transition aimed at reducing resource extraction and environmental impacts by maintaining the value of materials, products and buildings for as long as possible while minimising waste and pollution [1].

To operationalise circular economy principles in the built environment, circularity is increasingly translated into measurable indices. An indicator represents a measurable variable describing a specific aspect of a system, whereas an index aggregates multiple indicators into a composite score. For buildings, numerous circularity assessment methods have emerged, ranging from material-based metrics such as the Material Circularity Indicator (MCI) to building-level frameworks such as Level(s). These approaches differ

in system boundaries, data requirements, aggregation logic and weighting procedures, as well as in whether they assess current material flows or future circularity potential embedded in design strategies such as adaptability and disassembly.

As a consequence, circularity indices do not merely measure performance; they operationalise circularity through distinct methodological choices. The same building may therefore receive substantially different circularity scores depending on the selected assessment framework. This raises fundamental questions regarding comparability, transparency and the normative implications of aggregation logic within circularity metrics.

Against this background, this article addresses the following research question:

How do different circularity indices operationalise circularity in buildings, and which methodological and conceptual differences influence the assessment outcomes?

By systematically comparing selected circularity indices, the study identifies underlying assumptions, system boundaries, aggregation structures and weighting logics. In doing so, it contributes to a more transparent and critically informed understanding of circularity metrics in the built environment.

2 Methodology

This study combines a structured literature review with document analysis to identify, select, and analyse circularity indices relevant to the construction and real estate sector and to establish a systematic basis for comparison.

2.1 Circularity Indices Selection

A structured literature review was conducted to identify academic contributions on circularity indices. Snowballing of reference lists was applied to identify additional sources, and policy documents and industry frameworks were included to capture regulatory and practice-oriented perspectives beyond academic databases.

The initial pool of circularity indices was based on the review by Khadim et al. [2], supplemented by additional indices identified through the literature search. Selection was limited to indices providing quantifiable circularity assessments, i.e., those producing an overall circularity score. These scores reflect aggregated performances at building level, underpinned by embedded weightings or dynamic relationships across material, element and/or building scales. Such weighting structures and aggregation logics were given particular attention in the comparative analysis.

2.2 Comparative Analysis and Harmonisation

Each circularity index was first mapped individually according to its defined circularity concepts. Cross-cutting umbrella categories were then established to enable systematic comparison across indices with similar intent.

The indices were analysed according to their coverage of three life-cycle phases: current/pre-use, use, and future/post-use. The current/pre-use phase refers to material origin and composition prior to operation, broadly corresponding to stages A1–A5 in

CEN/TC 350 standards. The use phase captures functional performance over time, including adaptability, flexibility and durability (stage B). The future/post-use phase addresses end-of-life considerations (stage C).

In addition, the indices were mapped across three aggregation levels defined in this study: material, element and building. The material level concerns individual material inputs and their recovery potential. The element level refers to assemblies composed of multiple materials and their reuse or disassembly potential. The building level captures system-wide design attributes such as flexibility and adaptability.

Circularity concepts were consolidated into eight overarching categories to cover the range of material flows while preserving conceptual intent. A similar harmonisation was applied to circular strategies for material origin and return, resulting in four common categories: reuse, recycling, energy recovery and disposal/landfill, with qualitative distinctions such as closed- versus open-loop recycling retained where possible.

3 Results

Table 1 shows a general overview of the identified quantifiable circularity indices and their inclusion of life-cycle phases, aggregation levels and circularity concepts. The analysed tools include DGNB [3], FutureBuilt Circular (FB) [4], OneClick Building Circularity (OC) [5], Level(s) indicators L2.3 [6] and L2.4 [7], Material Circularity Indicator (MCI) [8], Madaster (Mad) [9], and the Whole-Building Circularity Indicator (WBCI) [10].

Table 1. Mapping of main circularity concepts, life-cycle phases and aggregation levels.

LC-phase	Aggregation level	Circularity concept	DGNB		FB	OC	L2.3	L2.4	MCI	Mad	WBCI
			<20a	>20a							
Pre-use	Material + Element	Material /element origin	0.45	0.60	0.60+ 0.10*	0.50			x	x	x
	Material +Element	Construction demolition waste	0.05						x	x	x
Use	Building	Flexibility / DfA	(x)				1,00				x
Post-use	Element	Detachability/ dis-sasembly element /DfD	0.10	0.05				(x)		(x)	x
	Material +Element	Material Separability	0.10	0.05				(x)			
	Material +Element	Material /element Return	0.20	0.15	0.30	0.50		1.00	x	x	x
	Material	Material compatibility	0.10	0.10							
All	Building	Aggregated calculation	(x)							x	x

*: indicates that FB splits weighting of material/ element origin into building (0.6) and backfilling (0.1).
numbers: indicate weighting factors used within each circularity index
x: marks aspects that are included in the assessment but cannot be quantified as a weighting value
(x): marks aspects that are considered as background requirements without directly influencing the score
DGNB is shown in two columns (<20a and >20a), representing buildings with a service life below and above 20 years.

3.1 Life-Cycle Phases and Aggregation Levels

As seen in Table 1, the analysed indices differ in how circularity is represented across life-cycle phases. Current/pre-use and future/post-use phases are more consistently addressed, while the use phase appears less frequently. DGNB incorporates use-phase aspects through flexibility-related criteria, though without explicit weighting. MCI and Madaster integrate the use phase indirectly through lifetime assumptions for building elements, while Level(s) indicator L2.3 emphasises adaptability at building level. In contrast, L2.4 focuses primarily on post-use recovery potential. OC concentrates largely on pre-use material assessments, whereas integrative indices such as MCI, Madaster and WBCI combine multiple life-cycle phases within a unified calculation framework.

Beyond life-cycle phases, the indices differ in their aggregation scales. Most operate primarily at material and element levels, where circularity is defined through aspects such as origin, return and separability. OC and L2.3 are particularly concentrated at these lower aggregation levels, while more comprehensive systems integrate several levels simultaneously. In DGNB, the building category is conceptually included but not explicitly weighted, which explains its marking as (x) for aggregated calculation.

WBCI stands out by explicitly introducing an intermediate system level between element and building. Circularity is calculated across material, element, system and building scales within a single aggregated equation presented by [10]

$$\mathrm{WBCI} = \frac{\mathrm{BFS}}{\mathrm{LK}} \sum \mathrm{SCI_i} * \mathrm{LK_i} \tag{1}$$

In Eq. (1) BFS denotes building-level flexibility, $\mathrm{SCI_i}$ represents the circularity score of each system derived from lower aggregation levels, and $\mathrm{LK_i}$ expresses the relative importance of each system layer, reflecting aspects such as service life and disassembly potential.

Some indices also incorporate benchmarking mechanisms. Madaster evaluates circularity relative to a reference dataset using weighted averages, enabling comparative performance assessment. In DGNB and FB, the circularity index forms part of a broader certification framework rather than functioning as a stand-alone metric.

3.2 Aggregation Logics and Circular Strategies

A central observation emerging from Table 1 is the presence of two fundamentally different aggregation logics across the analysed indices. The first group comprises DGNB, FB, OC and the Level(s) indicators L2.3 and L2.4. These systems operationalise circularity through predefined categories, typically based on mass calculations combined with explicit weighting factors. Circularity is therefore structured as a sum of weighted subscores, resulting in relatively static scoring frameworks where the relative importance of each category is predetermined.

Across the indices in this group, circularity is operationalised through strategies such as design for disassembly, adaptability, and prioritisation of material origin and return. FB, OC and DGNB rely on quantified mass-based contributions combined with explicit weighting between main and sub-categories. Within this group, DGNB applies the most differentiated weighting structure. For buildings with a service life exceeding 20 years,

DGNB and FB prioritise material or element origin in the pre-use phase over post-use return, assigning weightings of 0.6 to building material origin-related aspects. In contrast, OC distributes weight evenly between parameters, resulting in a 50/50 balance between origin-related and return-related contributions.

Level(s) differs structurally from the other indices in this group by operating as stand-alone indicators rather than a combined weighted framework. Indicator L2.3 centres on adaptability and flexibility at building level, effectively assigning full weight to design strategies within a single indicator. Indicator L2.4 treats detachability and separability primarily as enabling conditions and focuses on quantifiable post-use material return, making end-of-life recovery the dominant scored dimension.

The second group consists of MCI-based approaches, including MCI, Mad and WBCI. Rather than relying on predefined weights, these indices apply ratio-based formulas derived from the Linear Flow Index combined with lifetime or utility parameters. Material inputs, outputs and service life are integrated within a single equation, meaning that category contributions emerge dynamically from the mathematical relationships between variables rather than from externally assigned weights. Instead of allocating predefined weights to circular strategies, circularity is calculated through a composite formula in which strategic prioritisation is embedded implicitly within the mathematical structure.

Table 1 also maps the circularity concepts addressed by each indicator. Among the weighted category-based indicators, DGNB covers the broadest range of concepts, while FB and OC address a more limited subset. The MCI-based approaches incorporate several of the same concepts but to varying extents: MCI focuses primarily on material flows and lifetime, Mad expands this scope by including aspects such as detachability, and WBCI represents the broadest interpretation by also incorporating building-level strategies such as flexibility.

3.3 Material/Element Origin and Return

Material and element origin and return constitute a central dimension in several of the indices assessed in Table 1. To further clarify how circular strategies are operationalized within this dimension, Tables 2 and 3 provide a more detailed breakdown on the origin of materials and elements.

Table 2 focuses on material and element origin and illustrates the level of granularity with which the different indices differentiate between sources of material input. The aim is to show how each tool subdivides origin-related categories and how these distinctions are reflected through weighting factors where applicable. For the MCI-based approaches, such explicit category weightings are not defined. Instead, the table indicates how the variables used in the underlying formula are distributed across the mapped origin categories.

Table 2. Mapping of material/element origin across indices

			DGNB	FB	OC	MCI	Mad	WBCI
Reused/ Repurposed material		Reused	1.00	1.00	1.00	F_U	F_U	F_u
		Repurposed/remanufactured	1.00	1.00		F_U		
		Surplus from construction sites and leftover inventories		0.35				
Recycled materail		Closed loops	0.75	0.50	1.00	F_R	F_R	F_r
		Open loops	0.50					
Primary raw material / Virgin material	Renewable	Certified (high-quality, with reforestation) or comparable (rapidly renewable)** or biobased	0.75	0.00	1.00	F_S	F_{RR}	F_b **
		Primary raw material, renewable, not certified (high-quality, with reforestation) or not comparable (rapidly renewable)** or not biobased	0.50					
	Non-renewable		0.00		0.00	$\frac{V}{M}$	$\frac{V}{M}$	$\frac{V}{M'}$

As shown in Table 2, the MCI-based tools and the original MCI apply comparable categorisations of material origin. All operate with the same primary distinctions: reuse, recycled material, renewable virgin material and non-renewable virgin material. While this structure broadly reflects the waste hierarchy, it offers limited differentiation regarding qualitative material characteristics.

A methodological nuance is introduced in the 2024 update of the MCI Excel tool. Whereas earlier versions did not formally distinguish between reuse and remanufacture, the updated version specifies this distinction. However, the mathematical structure remains unchanged, as both strategies are incorporated through the same utility-related term (F_U) in the final equation. Remanufacturing is operationalised as reuse with an assumed addition of 5% virgin material input. This modification increases categorical resolution while preserving the underlying computational logic.

However, Table 2 also reveals clear differences in how virgin and renewable materials are weighted. FB assigns no positive value to virgin materials, regardless of whether they are renewable or not. OC goes one step further by awarding credit for renewable materials, but without distinguishing between certified and non-certified origin. DGNB has the most detailed approach and explicitly differentiates between certified and non-certified renewable virgin materials. Thus, not only the renewability of the material, but also documented sustainability quality is taken into account. At the same time, OC appears to be the simplest method, with default weighting given as 0 or 1, whereas DGNB and FB follow a more stepwise logic that reflects the priorities of the waste hierarchy.

The same mapping where done for material and element return. Where Table 3, representing the potential pathways for future use once materials reach the end of their service life. Similar to Table 2, the table highlights the degree of granularity across the indices, showing how return strategies are differentiated and weighted where such values are explicitly defined.

Table 3. Mapping of material/element return across indices

			DGNB	FB	OC	L2.4	MCI	Mad	WBCI
Reuse		Direct	1.00	0.67	1	1	C_U	C_U	C_u
		Preparing for reuse / remanufacture				0.9	C_U		
Recycling	High-quality closed loop recycling / Recycling pure stream		0.80	0.33	1	0.75	C_R	C_R	C_r
	Material recycling	Without effort /closed-loop with effort	0.70			0.5			
		With processing effort /open-loop recycling / mixed stream	0.60		0.5				
		Reprocessing with inferior quality / other material recycling / Recovery material	0.40			0.25			
Energy recovery	Energy recovery renewable/ biogenically certified and demonstrably low in pollutants /compost /bio decomposition		0.40	0	0.5	0.15	C_C	$\frac{W_0}{M}$	C_b
	Energy recovery non-renewable	Non-renewable/biogenic, renewable/not biogenically certified	0.20				C_E		$\frac{W_O}{M}$
		Energy disposal	0				$\frac{W_0}{M}$		
Disposal/ landfill	Disposal	Backfilling	0.20		0	0.01			
		Disposal Non-hazardous waste (LC 0-II), incl.	0.20						
		Disposal Hazardous waste (LC III-IV), disposal	0			0			

As illustrated in Table 3, the differences between the indices become more pronounced in return flows, where MCI, Mad and WBCI show greater variation in granularity at the lower levels of the waste hierarchy, i.e. energy recovery and disposal.

Table 3 further shows that DGNB stands out with the highest level of detail, operating with 11 weighting categories. The index differentiates between direct reuse and preparation for reuse, between different quality levels of recycling, as well as between different forms of energy recovery and disposal. In contrast, FB operates with only three main categories for return flows, resulting in a more aggregated assessment. OC and L2.4 lie between these extremes, with explicit weights that largely follow the ranking of the waste hierarchy.

4 Discussion

The results demonstrate substantial variation in how circularity indices define system boundaries, select reference metrics and structure aggregation. While some methods primarily quantify current material flows through mass-based balances, others emphasise future circularity potential embedded in design attributes such as adaptability and disassembly. Consequently, circularity scores are not solely reflections of material performance, but outcomes shaped by methodological design choices.

Importantly, variation occurs not only at the level of overarching assessment logic but also within comparable circularity concepts. Indices addressing material origin and return assign different weights and levels of differentiation to similar strategies. Such internal weighting structures influence how strongly recycled content, reuse potential or end-of-life scenarios contribute to the final score, thereby embedding implicit priorities within the assessment outcome.

For industry practitioners, this variation has practical consequences. When assessment outcomes depend heavily on methodological design and weighting logic, circularity becomes difficult to compare across projects and frameworks. This may create uncertainty in decision-making and benchmarking, particularly as several of these circularity indices are being integrated into policy instruments and certification schemes. Greater transparency and methodological alignment are therefore essential to ensure that circularity metrics support meaningful transformation rather than merely procedural compliance.

At the same time, the findings should be interpreted in light of certain limitations. While several widely used circularity indices were included, additional tools exist within national certification systems and emerging assessment frameworks that were not part of this study. Furthermore, the comparison primarily focuses on material input and output metrics.

5 Conclusion

This study provides a structured comparative overview of circularity index typologies, scope, weighting structures and aggregation levels, supporting researchers and practitioners in selecting and applying circularity assessment tools for buildings. The findings show that circularity indices operationalise circularity through fundamentally different methodological logics. Differences in system boundaries, reference metrics, aggregation methods and internal weighting, particularly within material origin and return, lead to divergent assessment outcomes for the same building.

Circularity indices are therefore not neutral measurements of performance, but outcomes shaped by methodological choices. This highlights the need for transparency and critical awareness when such indices are used in practice and policy. A clearer understanding of underlying assumptions is essential to ensure that circularity assessment supports consistent and meaningful transformation in the built environment.

Future research should therefore expand the scope to include additional indices, further investigate how circular design strategies and building-level performance indicators are integrated into circularity assessment, and test the indices on case studies to examine how methodological differences influence assessment outcomes.

Abstract. The built environment is often treated as a driver of resource depletion, waste generation, and environmental harm. Yet this view is incomplete if it overlooks that the built environment is also shaped by engineering, design, and technological choice, and may therefore function not only as a source of pressure but also as a potential site of mitigation. This study examines that tension by asking whether the built environment operates mainly as a channel through which development-related pressures intensify environmental damage, or whether its links with circularity- and efficiency-related mechanisms also reveal mitigating pathways. To address this question, the paper employs a Bayesian Network framework using Eurostat data for the 27 European Union member states over the period 2014–2023. Based on pooled country-year observations, the analysis investigates the probabilistic dependency structure among indicators representing built environment activity, circular economy processes, and environmental pressure. In doing so, it provides an integrated and interpretable view of this nexus and illustrates the value of Bayesian Networks for analyzing interdependent sustainability indicators.

Keywords: Bayesian network · Built environment · Circular economy · Environmental pressure · Sustainability

1 Introduction

The built environment is often discussed as a major driver of resource depletion, waste generation, and environmental degradation. Yet this view is incomplete if the built environment is treated as an autonomous starting point. Its expansion is shaped by broader demographic and socioeconomic pressures. Rising population, increasing density, and higher levels of economic activity create demand for housing, infrastructure, and related services, thereby stimulating construction and intensifying the use of materials, energy, and land. The built environment is therefore not simply an exogenous force acting on the environment, but also a material outcome of development pressures that influences how those pressures are translated into environmental consequences.

Accordingly, the environmental role of the built environment depends on how development pressures are materialized through construction, design, infrastructure, and resource-use patterns. When these patterns remain linear and resource-intensive, they may aggravate environmental pollution (Liang et al., 2019), increase pressure on urban water systems (Ganguly and Cahill, 2020), and contribute to rising CO_2 emissions (Wang and Zhao, 2018). However, as a domain shaped by engineering, design, planning, and technological choices, the built environment may also support mitigation when resilience and sustainability are embedded in infrastructure design and operation. Sánchez-Silva et al. (2025) emphasize that resilience and sustainability are central to the safe and responsible evolution of the built environment, including lifelines, road networks, energy supply, and housing. This mitigation potential is reflected in energy-efficient buildings, renewable energy integration, lower material intensity, improved resource productivity, circular construction practices, and reduced water demand.

The key issue, therefore, is not whether the built environment is inherently harmful or beneficial, but how its interaction with circular economy processes and environmental outcomes can be understood within a broader system perspective. This interaction is inherently multidimensional. Environmental implications arise through construction-related waste, domestic material consumption, material footprint, greenhouse gas emissions, and water stress, while mitigation may depend on resource productivity, renewable energy use, circular material use, recycling, and recovery mechanisms. Existing studies often approach these dimensions through composite indicators, urban quality-of-life frameworks, or building-level circularity assessment tools (Psatha, 2025; Khadim et al., 2025). Although these approaches are valuable, they generally focus on aggregated scores, individual dimensions, or isolated assessment structures. They therefore provide limited insight into how built environment activity, circularity-related mechanisms, and environmental pressures interact probabilistically within a broader system.

Given this multidimensional and interdependent structure, this study employs a Bayesian Network framework to examine the built environment–circular economy–environmental pressure nexus in the European Union. The analysis is based on 18 Eurostat variables covering demographic and macroeconomic conditions, construction activity, material and waste pressures, circularity mechanisms, mitigation-related factors, and environmental outcomes. Annual observations for 27 EU countries over 2014–2023 are pooled to identify the EU-level probabilistic dependency structure among these variables, rather than to conduct a country-by-country comparison. The purpose is to investigate how built environment activity is probabilistically positioned within this system and whether it is associated mainly with environmental pressure or also with circularity- and efficiency-related mitigation pathways. The remainder of the paper presents the methodology and dataset, the learned network and analyses, and the main findings and conclusions.

2 Methodology and Data

Bayesian Networks (BNs) are directed acyclic probabilistic graphical models in which nodes represent variables and directed arcs represent probabilistic dependencies. Each node is associated with a local probability distribution, marginal if it has no parents and

conditional if it does. Under the conditional independence assumptions encoded in the graph, the joint probability distribution can be factorized into the product of these local distributions, as shown in Eq. (1)

$$P(X_1, \ldots, X_N) = \prod_{i=1}^{N} P(X_i | Pa(X_i)) \tag{1}$$

BNs are well suited to complex multivariate systems because they allow dependency structures, indirect effects, and uncertainty propagation to be examined within a unified probabilistic framework. Their data-driven and interpretable structure has supported applications in civil and reliability engineering (Wang et al., 2025; Zwirglmaier et al., 2024), risk analysis (Arabi et al., 2022), economics and finance (Cinicioglu et al., 2024), and medicine (Bhardwaj et al., 2022). They have also been used to examine broader sustainability nexuses, such as the Water–Energy–Food–Economy–Society–Environment nexus (Chai et al., 2020), and EU circular economy indicator dependencies (Cinicioglu, 2025). However, their application to the built environment–circular economy–environmental pressure nexus remains limited. The empirical dataset was obtained from the Eurostat database (European Commission, 2026) and covered the period 2014–2023. The Bayesian Network was constructed using 18 variables grouped into six analytical dimensions: contextual drivers (population density, real GDP per capita); built environment activity (construction investment, construction employment, construction GVA); resource and waste pressures (domestic material consumption, construction waste generation, municipal waste generation per capita); circularity (CDW treatment recovery rate, trade in recyclable raw materials, recycling rate of municipal waste, circular material use rate); mitigation (resource productivity, renewable energy share, energy productivity); and environmental pressure/harm (material footprint, water exploitation index, greenhouse gas emissions). These dimensions capture the broader demographic and macroeconomic context, construction-related activity, material and waste pressures, circularity mechanisms, mitigation capacity, and environmental outcomes associated with the system under study. The analysis covered the 27 EU countries for which continuous annual data were available over the full period. Each country-year was treated as one observation, yielding 270 observations per variable. The purpose was therefore not to conduct a country-by-country comparison, but to identify the EU-level probabilistic dependency structure among the selected variables and explore the relationships within the built environment–circular economy–environmental pressure nexus. The few missing observations were completed through simple within-country imputation using neighboring observations from the same country series.

Before model estimation, all variables were discretized into four ordinal states using hierarchical discretization, with thresholds determined separately for each variable according to its empirical distribution. Four states were preferred to balance interpretability and distributional differentiation. Hierarchical discretization was used because it allows state boundaries to emerge from each variable's empirical structure rather than from arbitrary cut-off values, thereby preserving variable-specific distributional characteristics. The structure of the Bayesian Network was then learned from the data using the Bayesian Search algorithm, a score-based method employing hill-climbing optimization with random restarts to identify the network structure maximizing the log-likelihood score (Bouckaert, 1995; Cooper and Herskovits, 1992). The associated

conditional probability distributions were subsequently estimated using the Expectation–Maximization (EM) algorithm, which iteratively estimates the conditional probability tables by maximizing the likelihood of the observed data given the learned network structure (Dempster et al., 1977; Lauritzen, 1995). All procedures were carried out in GeNIe 5.0 (BayesFusion, 2025).

3 Analysis and Results

Figure 1 presents the Bayesian Network obtained from the procedure described in the previous section. It represents the data-driven dependency structure of the built environment–circular economy–environmental pressure nexus. Variables are color-coded according to the six analytical dimensions to facilitate interpretation: yellow for contextual drivers, blue for built environment activity, purple for resource and waste pressures, green for circularity, orange for mitigation, and red for environmental pressure/harm. Each node displays its marginal probability distribution across the four discretized states, where $s1$ denotes the lowest value interval and $s4$ the highest. The interval labels preserve interpretability with respect to the original variable scales. The resulting network contains 44 arcs, representing direct probabilistic dependencies among the variables; however, these dependencies differ in strength.

Arc thickness in Figure 1 represents the strength of the corresponding parent–child relationship. In this study, arc strength was quantified by the average Euclidean distance between the child node's conditional probability distributions across the states of its parent. Let X and Y denote two variables in the BN, where X is the parent node and Y is the child node. For each parent state x_i, let $P(Y \mid X = x_i)$ denote the conditional probability vector of Y. The Euclidean distance between two conditional distributions of Y, corresponding to two different parent states x_i and x_j, is computed as in (2) where k denotes number of discrete states of the child variable Y. The arc strength is then obtained by averaging this distance over all pairs of parent states. Larger values indicate stronger changes in the child node's conditional distribution as the parent node moves across its states. Table 1 reports the five strongest relationships based on average arc strength.

$$d\left(x_i, x_j\right) = \sqrt{\sum_{m=1}^{k} \left[p(y_m|X = x_i) - p\left(y_m|X = x_j\right)\right]^2} \tag{2}$$

The strongest average arc strengths are observed between Material Footprint and Domestic Material Consumption (0.4964), Real GDP per capita and Domestic Material Consumption (0.4437), and Water Exploitation Index and Population Density (0.3765). These relationships indicate that the strongest probabilistic dependencies in the network are associated with broader patterns of material consumption, economic activity, and population-related pressure rather than directly with built environment activity variables. In particular, the strong dependency between Material Footprint and Domestic Material Consumption highlights the central role of consumption intensity within the nexus.

The arc structure also provides important insights into the role of built environment activity. The three built environment activity variables, namely Construction Investment, Construction Employment, and Construction Gross Value Added, do not exhibit

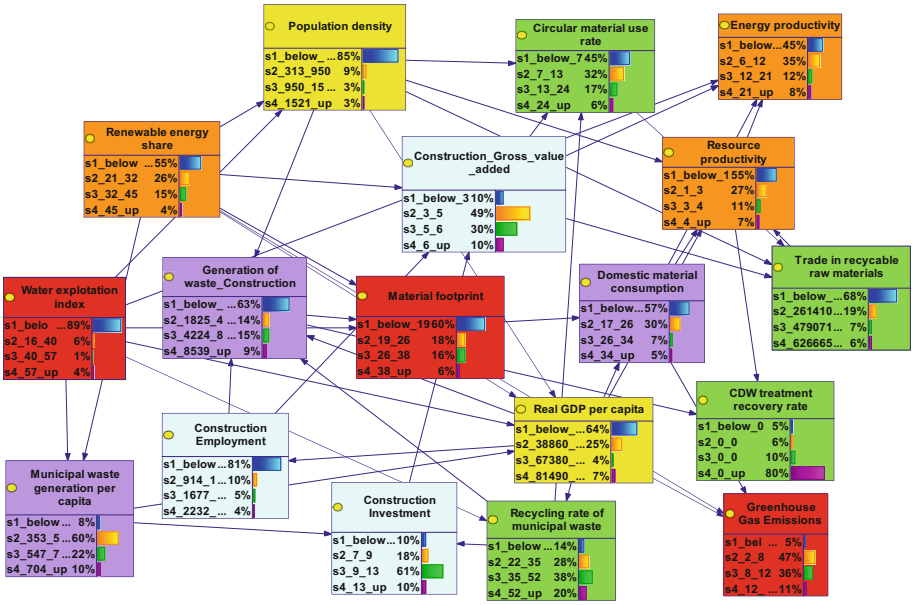

Fig. 1. Learned Bayesian Network with arc thickness indicating arc strength

Table 1. Top five parent–child relationships by average arc strength

Parent node	Child node	Average arc strength
Material footprint	Domestic material consumption	0.496399
Real GDP per capita	Domestic material consumption	0.4437
Water exploitation index	Population density	0.376494
Recycling rate of municipal waste	Construction Investment	0.350131
Renewable energy share	Municipal waste generation per capita	0.332998

direct probabilistic dependencies with the environmental pressure/harm variables. On the contrary, their direct dependencies are observed with construction-related, circularity-related, and mitigation-related variables. Construction Employment is directly connected to Construction Gross Value Added (0.2007) and Generation of Waste–Construction (0.0589). Construction Investment is directly connected to Construction Gross Value Added (0.2006), while it is also linked with Recycling Rate of Municipal Waste (0.3501) and Municipal Waste Generation per capita (0.3203). Construction Gross Value Added is directly connected to Trade in Recyclable Raw Materials (0.1344), Circular Material Use Rate (0.1167), and Energy Productivity (0.0778). This pattern is important because, rather than positioning built environment activity directly as a probabilistic driver of environmental harm, the learned network associates it with construction dynamics,

circularity-related mechanisms, and mitigation-oriented variables. The direct dependency between Construction Gross Value Added and Energy Productivity is particularly noteworthy because Energy Productivity is included as a mitigation variable. This suggests that built environment activity may also be linked to efficiency-oriented processes rather than only to resource-intensive pressures. Likewise, its direct connection with Trade in Recyclable Raw Materials may indicate that material recovery and recirculation mechanisms are becoming integrated into construction-related economic activity. Taken together, these findings support the view that the role of the built environment within the nexus is multidimensional rather than unidirectional.

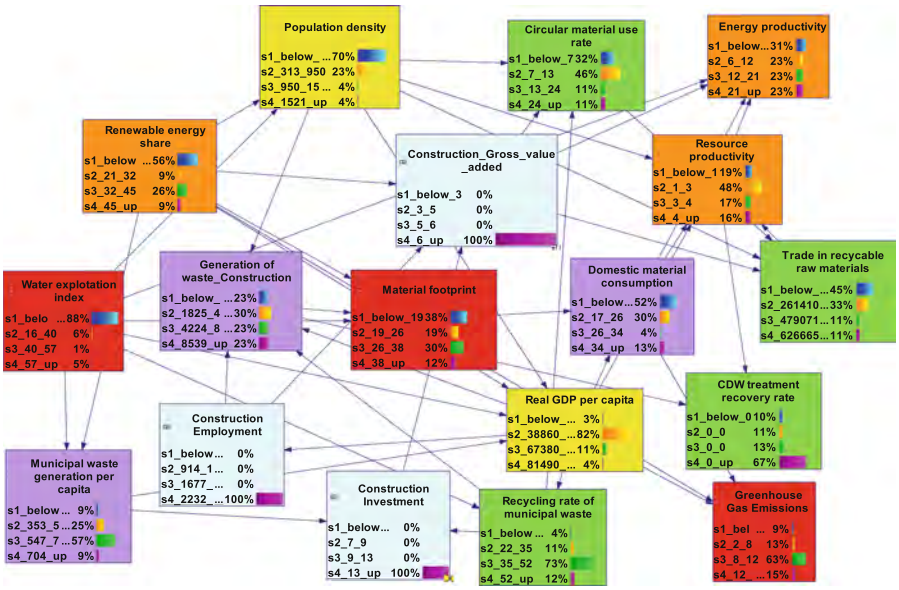

Fig. 2. Posterior probabilities of the Bayesian Network under high built environment activity, conditional on the evidence configuration Construction Gross Value Added = $s4$, Construction Investment = $s4$, and Construction Employment = $s4$

As the next step of the analysis, evidence observation was used to examine how the probability distribution of the remaining variables changes when a specific node or set of nodes is fixed to a given state. In probabilistic terms, this corresponds to conditioning the network on an entered evidence configuration, so that the posterior probability of a target variable is updated as $P(Y|E = e) = P(Y, E = e)\,/P(E = e)$. In the present analysis, the three built environment activity variables, namely Construction Gross Value Added, Construction Investment, and Construction Employment, were fixed at their highest state ($s4$). This evidence configuration is particularly informative because the learned network does not include direct arcs from built environment activity variables to the environmental pressure/harm variables. However, the absence of direct arcs does not imply that changes in the distributions of built environment activity variables are irrelevant for environmental pressure outcomes. In a Bayesian Network, probabilistic

influence may propagate through indirect paths, so conditioning one part of the network can update the posterior distributions of variables that are not directly adjacent to the evidence nodes. As shown in Fig. 2, the posterior distributions shift toward higher environmental pressure states. The most notable change is observed for Greenhouse Gas Emissions, where the probability of $s3$ increases from 36% to 63% and that of $s4$ increases from 11% to 15%. Material Footprint also shifts upward, with its distribution changing from 60%, 18%, 16%, and 6% to 38%, 19%, 30%, and 12% across states $s1$–$s4$. These findings indicate that, even in the absence of direct probabilistic dependencies, high built environment activity is still associated with stronger environmental pressure patterns through the broader dependency structure of the network, reflecting its role as an interface between socioeconomic development pressures and environmental outcomes.

4 Conclusions

The results show that the built environment cannot be interpreted as a simple direct source of environmental harm. In the learned network, built environment activity variables do not exhibit direct dependencies with environmental pressure/harm variables; instead, their direct links are mainly observed with circularity- and mitigation-related variables such as Circular Material Use Rate, Trade in Recyclable Raw Materials, Recycling Rate of Municipal Waste, and Energy Productivity. However, evidence observation indicates that high built environment activity still shifts the system toward stronger environmental pressure patterns, particularly through higher posterior probabilities for Greenhouse Gas Emissions and Material Footprint. This suggests that the built environment operates as an interface between socioeconomic development pressures and environmental outcomes, rather than as an isolated driver of harm. Overall, the findings support the need to understand the built environment–circular economy–environmental pressure nexus as a multidimensional and probabilistically interdependent system. Bayesian Networks are therefore useful for tracing both direct dependencies and indirect posterior shifts within this system.

Climate Implications of Roof Leakages: Scenario-Based Assessment for Norwegian Buildings

Roberta Moschetti(✉), Håvard Bergsdal, Lars Gullbrekken, and Berit Time

Department of Architecture, Materials and Structures, SINTEF Community, Trondheim, Norway
roberta.moschetti@sintef.no

Abstract. Roof leakages are a frequent source of building damage, but their climate impacts remain poorly quantified. This study assesses the greenhouse gas emissions associated with representative leakage scenarios in common Norwegian roof constructions, including ventilated pitched roofs and compact flat roofs with different configurations. Three damage scenarios are analysed: (1) early detection with localised and limited damage, (2) late detection leading to moisture penetration into the insulation layer, and (3) long-term undetected leakage resulting in extensive deterioration of roof coverings and underlying components. For each scenario, the analysis includes emissions from material replacement, waste management, and energy consumption for mechanical drying. The results demonstrate a strong increase in emissions with increasing damage severity. Early detection scenarios show limited climate impact due to minor material replacement and short drying periods, whereas late detection scenarios require insulation renewal and prolonged drying, substantially increasing emissions. In the most severe long-term scenario, total emissions for a 100 m^2 compact flat roof exceed 9,000 kg CO_2-eq, driven by extensive reconstruction following prolonged moisture exposure and constrained drying conditions. To provide a broader context, the scenario-based analysis is complemented by an exploratory national-level assessment based on available statistics and building databases, showing the potential climate significance of roof leakages at the national scale. The findings highlight that proactive maintenance, timely leak identification and climate-robust roof design can significantly reduce climate impacts, underscoring the importance of preventive maintenance strategies for a resilient Norwegian building stock.

Keywords: Roof Leakage · Moisture Damage · GHG Emissions · Roof Constructions · Building Stock Resilience

1 Introduction

Worldwide, the existing building stock faces increasing risks from climate change, leading to more frequent and intense climatic events such as heavy rain, floods, frost, and heat waves. Norway is particularly exposed due to its varied climate and rugged topography,

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 1243–1251, 2026.
https://doi.org/10.1007/978-3-032-34930-9_145

which create large local climatic differences and pronounced seasonal variations [1]. As a result, building envelopes in Norwegian construction must withstand demanding weather conditions, including strong winds, heavy snow loads, precipitation, freeze–thaw cycles, and large temperature variations, all of which can affect the durability and long-term performance of building components [2]. Moisture-related problems such as leaks, condensation, and water penetration can cause material deterioration, mould growth, and structural damage, often requiring resource-intensive repairs. In Norway, precipitation accounted for over 40% of building defects between 2017 and 2020. More than 70% of these defects were related to the building envelope, with most linked to roof structures [3]. Gullbrekken et al. [4] found that precipitation moisture was the primary cause in 49% of 465 pitched-roof defect cases recorded between 1993 and 2002. For compact flat roofs, precipitation or condensation of indoor moisture accounted for 73% of all defect cases [5].

Building defects can result in significant economic expenses and lead to increased greenhouse gas (GHG) emissions, thereby raising the building's overall carbon footprint [6]. Repairs or replacement of damaged components require additional extraction of materials, manufacturing, transport, and installation, all of which contribute to environmental impacts. However, quantified data on emissions associated with moisture-related damage remain limited [7]. Previous life-cycle assessment (LCA) studies have mainly focused on operational energy use and energy-related renovation, while environmental impacts of damage-related repairs have received less attention (e.g. [8]). Although some studies consider moisture safety together with the environmental performance of building envelopes [9], the climate impacts of leakage-related damage remain insufficiently quantified.

This study investigates the environmental impacts of roof-leakage-related defects in Norwegian buildings, focusing on: 1. How do leakage defects of varying severity affect typical Norwegian roof assemblies? 2. What are the associated GHG emissions from repairing such defects?

2 Methods

2.1 Roof Types and Damage Scenarios

This study explores two common roof constructions in relation to three specific damage scenarios. The analysed roof types are compact roof and ventilated roof (Figs. 1 and 2). Several alternative configurations were analysed.

Compact roofs, often referred to as warm roofs, include an insulation layer placed above the load-bearing system. The roofing layer consisted of either bitumen or PVC membrane. The 250 mm insulation layer was modelled using EPS, XPS, or mineral wool. A polyethylene vapour barrier was placed above the load-bearing structure, which varied between hollow-core concrete slabs (low-carbon), profiled steel sheets, cross-laminated timber (CLT) slabs, or timber beam systems with OSB sheathing. Ventilated roofs, also known as cold roofs, integrate an air cavity between the insulation and the roof covering. Roofing alternatives included concrete tiles, clay tiles, slate, metal sheets, and asphalt shingles. The substructure consisted of either roof decking (e.g., OSB) with a plastic wind barrier and underlay membrane, or a combined underlayment and wind barrier

solution (e.g., wood fibreboard). The insulation layer comprised 250 mm mineral wool above a polyethylene vapour barrier, with interior layers of timber battens and gypsum board.

Fig. 1. Ventilated roof: (a) with separated underlayment and wind barrier; (b) combined underlayment and wind barrier. Images adapted from [10].

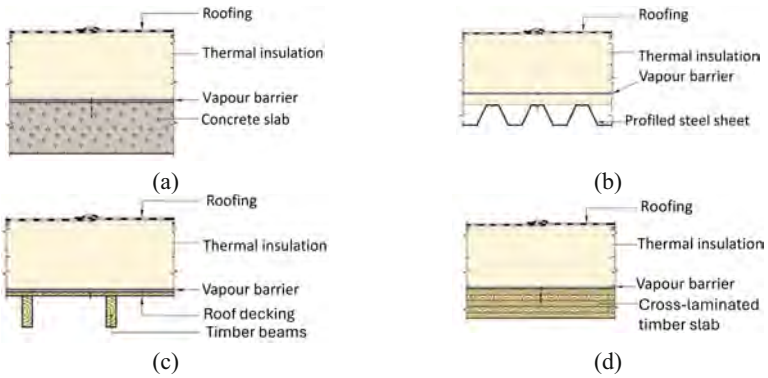

Fig. 2. Compact roof with different load-bearing structures (a. concrete slab; b. profiled steel sheet; c. timber beams; d. CLT slab. Images adapted from [11].

The three damage scenarios assessed in this study are defined as follows. Scenario 1: Minor leakage, early detection: A small perforation in the roofing layer causes localised water intrusion that does not penetrate beyond the outer membrane or significantly affect the insulation or vapour barrier. Only limited material replacement is required, corresponding to a small affected area of the roofing membrane (on the order of ~1 m^2), whereas underlying components remain unaffected. A drying period of 24 h is assumed for the locally affected roofing materials before installing the replacement membrane. This scenario applies only to compact roofs. Scenario 2: Moderate leakage, delayed detection: Water intrusion penetrates the insulation layer but does not affect the vapour barrier or primary load-bearing structure. For both ventilated and compact roofs, partial replacement of roofing and insulation layers is required, corresponding to a moderately affected area (on the order of ~10 m^2). A drying period of 14 days is assumed to dry

the affected roof materials before reconstruction. Scenario 3: Severe leakage, long-term damage: Prolonged undetected leakage causes extensive moisture damage affecting insulation, vapour barrier, and structural components. For both roof types, the entire roof area (on the order of ~100 m^2) is replaced, including roofing layers, insulation, vapour barrier, and structural elements. Structural components such as CLT slabs, timber beams, steel roof decking, and hollow-core concrete slabs are assumed to be entirely replaced due to the risk of severe moisture damage and potential corrosion. Although moisture may affect materials differently, all structural components are assumed to be replaced for consistency. This represents a conservative assumption. A 60-day drying period is applied to dry the affected building components before reconstruction.

In all scenarios, drying energy is calculated as the product of drying power (10 kW) and the scenario-specific drying duration, following [7].

2.2 GHG Emission Calculations

For each roof configuration and scenario defined in Sect. 2.1, CO_2 emissions were calculated by accounting for emissions associated with material replacement and energy consumption related to drying processes during the product stage (A1–A3). Emissions generated during the end-of-life stages (C1–C4) of the replaced materials were also included. Material-related emission factors were obtained from Environmental Product Declarations (EPDs) for representative Norwegian or Nordic building products.[1] For most materials, GWP-IOBC (Global Warming Potential – instantaneous oxidation of biogenic carbon) values reported in the EPDs were used. Energy use for drying was calculated using both Norwegian and European electricity mixes to reflect differences in carbon intensity [12]. Total emissions were calculated as shown in Eq.(1).

$$\mathrm{GHG}_{\mathrm{total}} = \sum_i \left(\mathrm{Q}_i \times \mathrm{EF}_{i,\mathrm{A1\text{--}A3}}\right) + \left(E_{\mathrm{drying}} \times \mathrm{EF}_{\mathrm{el}}\right) + \sum_j \left(\mathrm{Q}_j \times \mathrm{EF}_{j,\mathrm{C1\text{--}C4}}\right) \quad (1)$$

Where: Q_i is the quantity of new materials replacing damaged layers; $EF_{i,A1–A3}$ is the emission factor for product stage (A1–A3); E_{drying} is the electricity consumption for drying (operating hours × dehumidifier power); EF_{el} is the emission factor of the electricity mix; Q_j is the quantity of materials removed and sent to waste treatment; $EF_{j,C1–C4}$ is the emission factor for end-of-life stages (C1–C4).

2.3 National Level Assessment

A simplified assessment was conducted to analyse the potential effect of roof damages on national-level GHG emissions. The aim was to present a possible order of magnitude rather than precise estimates. National statistics on the number of dwellings by age cohort and dwelling type (detached, semi-detached, terraced, multi-apartment and co-housing) were used to estimate the total number of buildings. A simplified classification of roof types across building types and age cohorts was then applied to estimate the distribution between ventilated and compact roofs, resulting in an approximate split of 78% ventilated and 22% compact constructions. However, compact roofs are more prevalent in building types with a larger roof area. Crude estimates for roof area at the national building stock level indicate a roughly equal distribution between the two types.

Emissions were estimated per building based on the three scenarios described earlier, representing repair or replacement of approximately 1 m^2, 10 m^2 and 100 m^2 of roof area. Total emissions were calculated by multiplying the number of buildings in each roof category by the emission factor associated with the respective scenario. A conservative approach is applied by selecting the highest emission factor for each of the three assessed scenarios and roof type. Three shares of the building stock (1%, 5%, and 10%) were assumed to experience roof damage, as no empirical data were available for this parameter. Damage extent followed the three scenarios, assuming uniform damage magnitude within each scenario.

3 Results and Discussion

This section presents the life-cycle GHG emissions of the analysed roof configurations across three damage scenarios, expressed per square metre of affected roof area for comparison. Within each scenario, material-related emissions may be assumed to scale linearly with the affected roof area when extrapolating results to other damage extents. In contrast, drying energy does not necessarily scale proportionally with area, as it depends on drying duration and practical constraints such as equipment capacity.

Scenario 1 considers compact roofs only. Total emissions are relatively low (approximately 7–12 kg CO_2-eq), with plastic membranes showing higher impacts than bitumen membranes. For bitumen membranes, emissions are mainly driven by the product stage and drying energy use, whereas end-of-life stages contribute only a minor share. For plastic membranes, the product stage, end-of-life stages, and energy use all contribute substantially.

Figures 3 and 4 present results for Scenario 2, where both compact and ventilated pitched roofs are considered. Emissions increase compared to Scenario 1 due to larger replacement areas, ranging from about 21 to 57 kg CO_2-eq/m^2, depending on roof configuration. The product stage dominates the life-cycle impact, while drying energy contributes with a smaller share. Differences between compact and ventilated roofs are generally moderate, with the relative ranking depending on the materials included in each configuration. For compact roofs, XPS insulation with plastic membranes causes more emissions, while mineral wool with bitumen membranes results in lower impacts. For ventilated roofs, emissions mainly depend on the roof covering, with concrete tiles showing the lowest values.

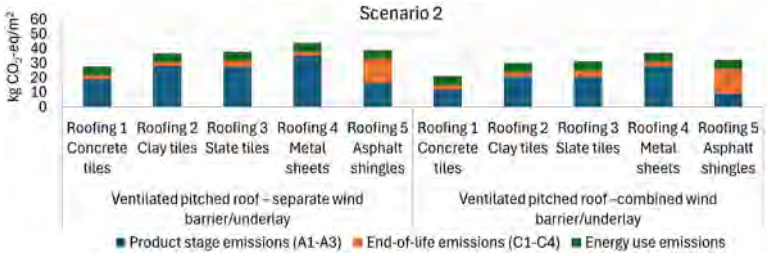

Fig. 3. Life-cycle GHG emissions for ventilated roofs under Scenario 2, expressed per m^2 (based on an affected area of 10 m^2).

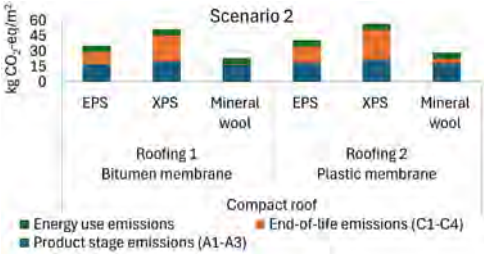

Fig. 4. Life-cycle GHG emissions for compact roofs under Scenario 2, expressed per m^2 (based on an affected area of 10 m^2).

Figures 5 and 6 show results for Scenario 3, considering both compact and ventilated pitched roofs. Emissions increase substantially compared to Scenario 2, reaching approximately 20 to 95 kg CO_2-eq/m^2 depending on the roof configuration.

Differences between compact and ventilated roofs become more pronounced, with the highest values observed for compact roof configurations combining XPS insulation and plastic membranes. The product stage generally represents the dominant contributor to total impacts. Overall, insulation type and membrane choice significantly influence results, with XPS insulation and plastic membranes consistently leading to higher impacts than EPS, mineral wool, or bitumen alternatives.

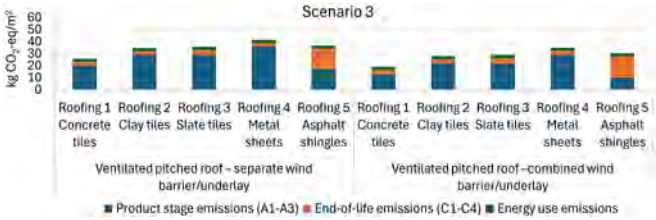

Fig. 5. Life-cycle GHG emissions for ventilated pitched roofs under Scenario 3, expressed per m^2 (based on an affected area of 100 m^2).

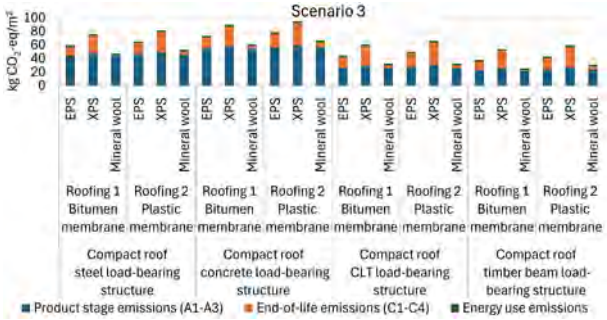

Fig. 6. Life-cycle GHG emissions for compact roofs under Scenario 3, expressed per m^2 (based on an affected area of 100 m^2).

In the graphs of Figs. 3–6, emissions from energy use are calculated with the Norwegian electricity mix (0.018 kg CO_2-eq/kWh). Using the EU electricity mix (0.136 kg CO_2-eq/kWh) rather than the Norwegian mix would substantially increase drying-related emissions across all scenarios, particularly for those requiring longer drying periods.

The results of the national-level GHG assessment are presented in Table 1. Estimated emissions show a wide range of outcomes, ranging from 72 t CO_2-eq for the lowest share of affected buildings and smallest damage scenario to 0.9 Mt. CO_2-eq for the worst-case scenario. Although emissions per damage event are lower for ventilated roofs, their contribution to total emissions is higher since more than three-quarters of buildings are estimated to have this roof type.

Table 1 Estimated national GHG emissions from roof damage by scenario and share of affected buildings. Scenario 1 applies only to compact roofs.

Share of affected buildings	t CO_2-eq					
	Scenario 1 (small damage)		Scenario 2 (medium damage)		Scenario 3 (large damage)	
	Ventilated roof	Compact roof	Ventilated roof	Compact roof	Ventilated roof	Compact roof
1%	–	72	9,200	3,300	87,470	54,940
5%	–	359	46,000	16,470	437,370	274,720
10%	–	719	92,000	32,950	874,740	549,440

4 Conclusions

This study evaluates greenhouse gas (GHG) emissions from leakage scenarios in typical Norwegian roofs, including ventilated pitched and compact flat roofs with various structures. Three scenarios are considered: (1) early detection with minor damage, (2)

delayed detection with insulation affected, and (3) long-term unnoticed leakage causing major deterioration. Emissions from material replacement, waste, and drying are analysed. As expected, emissions increase with damage severity; early detection results in low impacts, while long-term leakage exceeds 9,000 kg CO_2-eq for a 100 m^2 flat roof. At the national level, estimated emissions vary widely depending on the share of affected buildings and the damage scenario, ranging from tens of tonnes to nearly 1 Mt. CO_2-eq in worst-case scenarios (approximately equivalent to the annual emissions of 140,000 Norwegians). These findings highlight the importance of early leak detection and maintenance to reduce repair needs and associated emissions. Limitations of this study should be acknowledged. The scenarios are based on simplified assumptions about the extent of damage, repair needs, and drying periods, which may vary in practice. The results also rely on emission factors from Environmental Product Declarations (EPDs), which may rely on varying assumptions, particularly for end-of-life stages. Building- and national-level estimates are therefore indicative. Future research should incorporate empirical damage data and more detailed modelling of moisture development, repair strategies, and related emissions.

Abstract. The cement industry is a major contributor to global greenhouse gas emissions, predominantly due to clinker production. Supplementary Cementitious Materials (SCMs) represent an effective mitigation strategy, yet conventional SCMs such as Fly Ash (FA) and Ground Granulated Blast Furnace Slag (GGBFS) are becoming increasingly scarce. Volcanic pozzolans offer a promising natural alternative, and Iceland possesses extensive deposits that have not yet been evaluated from an environmental perspective. This study presents the first cradle-to-gate Life Cycle Assessment (LCA) of Icelandic Volcanic Pozzolan (VPI) production, drawing on primary data from three extraction sites and a planned processing facility in Þorlákshöfn—Lambafell, Litla Sandfell, and Landeyjahöfn—and secondary data from GaBi and Ecoinvent. A declared unit of one tonne of VPI is assessed across all ReCiPe 2016 midpoint impact categories. Results show that VPI's climate change impact of 25.5 kg CO_2-eq/t falls between FA (3–10 kg CO_2-eq/t) and GGBFS (50–80 kg CO_2-eq/t), confirming its competitiveness with established SCMs while offering the strategic advantage of abundant local supply. Marine dredging operations emerge as the dominant environmental hotspot, accounting for approximately 48.1% of total CO_2-equivalent emissions. The findings confirm VPI as a robustly low-carbon SCM and support its large-scale adoption in sustainable cement production.

Keywords: Life Cycle Assessment · Supplementary Cementitious Materials · Icelandic Volcanic Pozzolan · Low-Carbon Cement

1 Introduction

The cement industry accounts for nearly 8% of global anthropogenic CO_2 emissions, driven primarily by clinker production, while concrete is the second most consumed material worldwide after water. It simultaneously faces accelerated deterioration under changing climatic conditions [1, 2]. This creates a self-reinforcing cycle: greater emissions from cement production intensify climate change, which accelerates concrete degradation and increases demand for new construction. At the regional scale, concrete represents approximately 70% of the Icelandic building stock [3], underscoring the urgency of sustainable production strategies in this context.

Partially substituting clinker with Supplementary Cementitious Materials (SCMs) is a widely accepted decarbonization pathway [4]. Industrial by-products such as Fly Ash (FA) and Ground Granulated Blast Furnace Slag (GGBFS) are the most established SCMs, with substitution levels reaching up to 40% [5]. However, their dwindling availability has driven growing interest in natural pozzolans—siliceous or aluminosilicate materials of volcanic origin that react chemically with calcium hydroxide to form cementitious compounds [6]. In the Nordic context, Adediran et al. [7] identified Icelandic volcanic pozzolans (VPI) as a promising and abundant SCM candidate, subsequently confirmed in a comparative evaluation of 15 SCMs in which VPI ranked as high-performing owing to its elevated reactivity and highly amorphous microstructure [7].

Life Cycle Assessment (LCA) is the most comprehensive methodology for evaluating SCM environmental performance across multiple impact categories [8]. The growing literature on volcanic pozzolans consistently demonstrates their technical viability while revealing a critical gap: no study has yet conducted a multi-impact-category LCA of volcanic pozzolans sourced from geographically distinct extraction sites. Existing assessments have been largely limited to global warming potential, neglecting acidification, eutrophication, and resource depletion. The influence of extraction location on environmental profile also remains entirely unexamined, despite the well-documented mineralogical variability of Icelandic volcanic deposits.

To address these gaps, this study conducts a process-based LCA of VPI from three distinct Icelandic sites, with site-specific inventory data. The study aims to: (1) quantify the environmental impacts of VPI production and VPI-blended cement across multiple categories relative to OPC; (2) evaluate the influence of extraction site on environmental performance; and (3) identify, through contribution analysis, the key hotspots driving environmental burdens.

2 Methodology

This study employs process-type LCA (PLCA), following the ISO 14040/14044 framework, encompassing four phases: goal and scope definition, life cycle inventory analysis, life cycle impact assessment, and interpretation [9].

2.1 Case Study Description

VPI material is extracted from three sites in southern Iceland (Fig. 1): (i) Lambafell (LF), an active quarry transitioning to VPI extraction with an annual capacity of approximately 541,390 t; (ii) Litla Sandfell (LS), a newly identified deposit projected to yield 1.0 Mt./year; and (iii) Landeyjahöfn (LH), an offshore marine sediment site also anticipated to yield approximately 1.0 Mt./year. Centralized processing is conducted at a proposed facility in Þorlákshöfn (TPH). The production mix corresponds to 10% from LF, 23% from LS, and 67% from LH per tonne of VPI. Processing includes freshwater washing of LH material (chloride reduction to $<0.1\%$), sequential ball milling to below 10 μm, and waste-heat-integrated drying.

Fig. 1. Geographical distribution of VPI extraction sites and the Þorlákshöfn processing facility.

2.2 Goal, Scope, and Declared Units

The declared unit is one tonne of VPI (cradle-to-gate). System boundaries follow EN 15804 modules A1–A3: raw material extraction (A1), transport to TPH (A2), and centralized processing including washing, grinding, and drying (A3). Where co-products arise, specifically the aggregate by-product at LF (34% by mass) and LS (10% by mass), environmental burdens are allocated on a mass basis in accordance with the ISO 14044 physical allocation hierarchy. This approach is considered appropriate given that VPI constitutes the dominant mass fraction at both sites (66% and 90%, respectively), and that LH, contributing 67% of the total production mix, yields no by-product, rendering allocation irrelevant for the majority of system inputs. Moisture content was assumed to be 30% for LB and LS, and 50% for LH.

2.3 Life Cycle Inventory

Primary inventory data were collected between September 2023 and April 2024 from engineers and project managers at BM Vallá, Hornsteinn, and Heidelberg Materials. LF provided detailed operational data as the only active site; LS and TPH inventories were estimated from anticipated operational parameters. Secondary data were sourced from GaBi (v8.0) and Ecoinvent. Key inventory parameters are summarised in Table 1. The complete process-level inventory, including energy inputs per unit process, is provided as supplementary material at: LCA for the VPI Material.mmap

The mass flow of different processes on the GaBi model is shown on Fig. 2.

Table 1. Key life cycle inventory parameters per production site.

Parameter	LF	LS	TPH (incl. LH)
Material mined (t/yr)	541,390	1,000,000	1,000,000
Diesel (L/yr)	621,308	1,185,000	2,575,000
Electricity (kWh/yr)	–	3,600,000	410,000,000
Water (m^3/yr)	–	–	1,000,000

2.4 Life Cycle Impact Assessment (LCIA)

Environmental impacts were characterised using the ReCiPe 2016 Midpoint (H) method, implemented in GaBi 8.0, covering 10 midpoint impact categories. Results are further interpreted through Environmental Footprint (EF 3.1) normalisation to enable cross-category comparison [10].

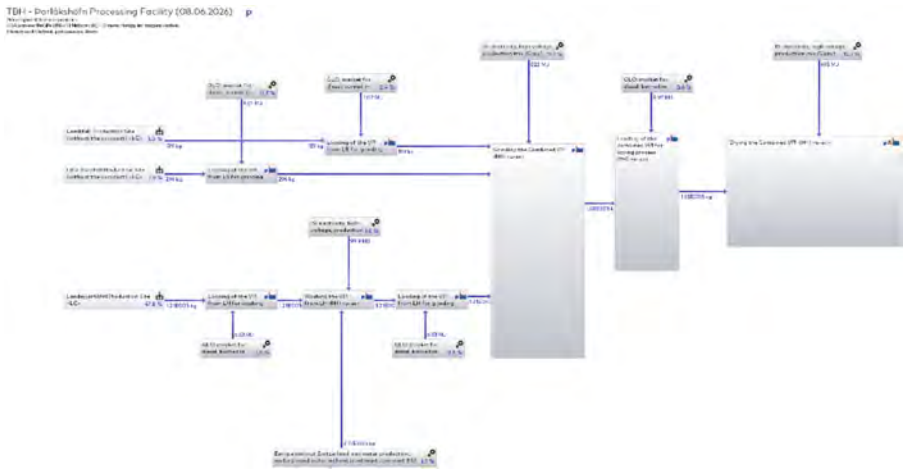

Fig. 2. Mass flow of Production Processes of the VPI Material – GaBi Model.

3 Results

3.1 LCIA Results

The LCIA results are presented in Table 2. The climate change impact of VPI production is 25.5 kg CO_2-eq per tonne of Icelandic Volcanic Pozzolan (VPI) produced. For context, OPC production typically generates 750–900 kg CO_2-eq/t [11], meaning VPI carries approximately 97% lower climate change impact per tonne of material. At an 18% clinker substitution rate, incorporating VPI reduces the carbon intensity of blended

cement from approximately 820 kg CO_2-eq/t (OPC) to approximately 698 kg CO_2-eq/t—a reduction of approximately 15% per tonne of cement binder. Other notable impact categories include Terrestrial Acidification (0.097 kg SO_2-eq), Fossil Resource Depletion (6.79 kg oil-eq), and Land Use (0.235 annual crop eq·yr), all substantially lower than OPC benchmarks.

Table 2. Cradle-to-gate LCIA results (per 1 t of VPI, ReCiPe 2016 Midpoint H).

Impact Category	Value	Unit
Climate Change	2.55E+01	kg CO_2-eq
Stratospheric Ozone Depletion	8.45E−06	kg CFC-11 eq
Photochemical Ozone Formation	1.99E−01	kg NO_n eq
Fine Particulate Matter Formation	4.89E−02	kg PM2.5 eq
Terrestrial Acidification	9.70E−02	kg SO_2 eq
Freshwater Eutrophication	2.38E−03	kg P eq
Marine Eutrophication	3.49E−04	kg N eq
Freshwater Ecotoxicity	1.95E−01	kg 1,4-DCB eq
Fossil Resource Depletion	6.79E+00	kg oil eq
Land Use	2.35E−01	annual crop eq·yr

3.2 Contribution (Hotspot) Analysis

The site-level contribution analysis reveals that LH dominates the climate change impact, accounting for 48.1% of total emissions, attributed entirely to marine dredging, the 70 km sailing distance, and onshore pumping operations. The terrestrial sites contribute comparatively little: LF accounts for 3.1%, of which 71% arises from truck transport to TPH, while LS contributes 8.0%, with 58.6% attributable to its high emissions factor despite the proximity to TPH site (22 km for LF and 16 km for LS). At the process level, grinding (14.19%), drying (12.6%), and diesel-powered loading operations (14.15%) are the next most significant contributors, with washing accounting for a further 2.1%. Together, these findings confirm that the environmental profile of the system is predominantly shaped by the energy and logistics intensity of the LH marine extraction stage rather than by the processing operations at TPH, which benefit substantially from Iceland's near-zero-carbon renewable electricity grid. The site- and process-level contributions are illustrated in Figs. 3 and 4, respectively.

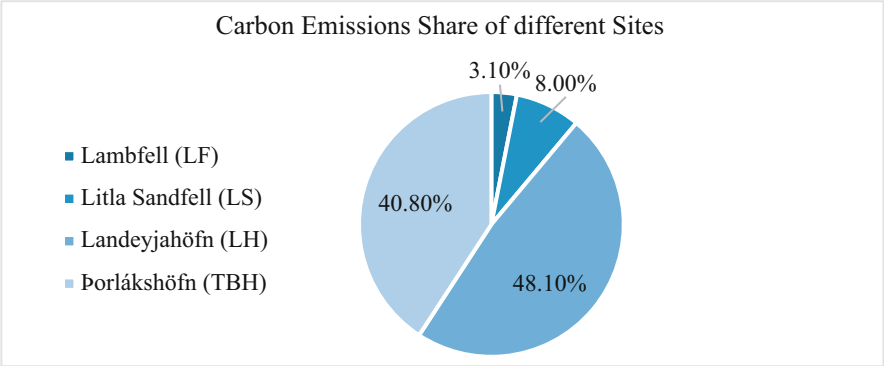

Fig. 3. Site-level contribution to the Climate Change impact category per tonne of VPI produced.

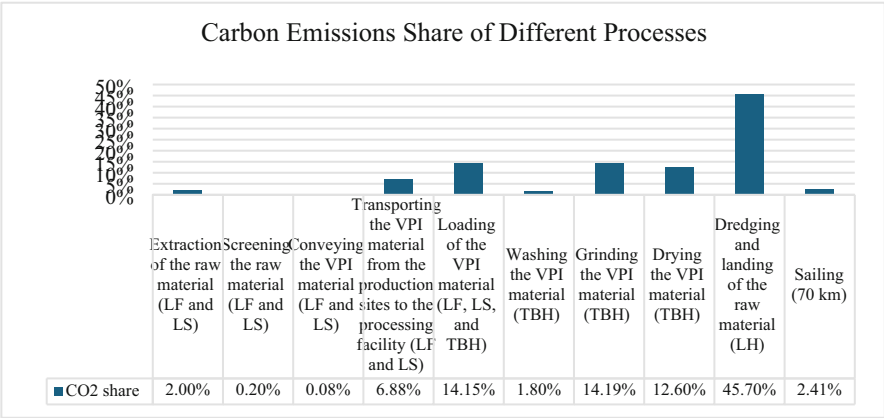

Fig. 4. Process-level contribution to the Climate Change impact category per tonne of VPI produced.

4 Discussion

This study presents the first publicly available, multi-impact-category process LCA of Icelandic volcanic pozzolans, benchmarked across three geographically distinct extraction sites. The result of 25.5 kg CO_2-eq/t reflects the advantageous combination of Iceland's renewable electricity grid and a fully domestic supply chain, firmly establishing VPI as a low-carbon competitive SCM. These findings directly respond to the research gap identified by Liu et al. [12] and Adediran et al. [7], who established the technical merit of volcanic pozzolans in the Nordic context while calling for rigorous environmental assessment. The result also highlights the significant environmental benefit of processing VPI domestically in Iceland compared to exporting raw material for

processing abroad, where fossil fuel-based energy sources and international shipping would substantially increase the overall climate change impact.

Compared to conventional SCMs, VPI is highly competitive. FA typically generates 3–10 kg CO_2-eq/t and GGBFS around 50–80 kg CO_2-eq/t when accounting for full processing impacts, meaning VPI's climate change impact of 25.5 kg CO_2-eq/t falls between these two established alternatives. However, both FA and GGBFS are industrial by-products with limited and declining availability. VPI, by contrast, is an abundant primary resource in Iceland with multi-million-tonne extraction potential, making it a strategically robust alternative independent of industrial supply chains. Importantly, the present study demonstrates that this climate advantage extends to other impact categories—including acidification, eutrophication, and resource depletion—providing a more complete environmental justification for VPI adoption than previously available. The VPI result is also notably lower than the 60 kg CO_2-eq/t reported for volcanic ash sourced from Indonesia and processed for use in Hong Kong by Hossain et al. [13], a difference attributable to Iceland's near-zero-carbon electricity grid and the absence of international shipping in the present system boundary—both structural advantages of domestic Icelandic production that further strengthen the environmental case for VPI.

The dominance of LH marine dredging (48.1% of total climate change impact) is the most actionable finding of this study. It indicates that the overall environmental performance of the system is highly sensitive to the share of LH-sourced material in the production mix and the transportation distance to TPH, which explains the low emissions of LF and LS for their proximity to TPH. Increasing the proportion of terrestrial feedstock from LF and LS, or improving vessel fuel efficiency, would yield the greatest environmental gains. This finding should directly inform production strategy decisions by Heidelberg Materials and associated stakeholders.

Several limitations should be noted. First, inventory data for LS and TPH are based on anticipated rather than measured operational parameters, introducing uncertainty in those estimates. Second, the cradle-to-gate boundary excludes use-phase benefits; a full cradle-to-grave analysis incorporating VPI's service life extension effects would likely strengthen the environmental case further. Third, a formal uncertainty and scenario analysis is planned for the journal version of this work to quantify result variability across all impact categories.

5 Conclusions

This study presents the first publicly available, multi-impact-category process LCA of Icelandic volcanic pozzolans. The principal findings are as follows:

1) VPI production generates 25.5 kg CO_2-eq per tonne (cradle-to-gate), representing approximately 97% lower climate change impact than OPC (750–900 kg CO_2-eq/t), firmly establishing VPI as a low-carbon SCM.
2) VPI carries 49–68% lower climate change impact than GGBFS (50–80 kg CO_2-eq/t), making it highly competitive with the most widely used industrial SCM.
3) VPI's climate change impact is higher than FA (3–10 kg CO_2-eq/t); however, FA is an industrial by-product with declining availability, whereas VPI is an abundant primary resource with multi-million-tonne extraction potential in Iceland.

4) Marine dredging at the LH site accounts for 48.1% of total climate change impact, confirming it as the dominant environmental hotspot and the primary lever for mitigation through production mix optimisation.
5) Grinding (14.19%) and drying (12.6%) are the next largest contributors, reflecting the energy intensity of fine comminution—substantially mitigated by Iceland's near-zero-carbon renewable electricity grid.
6) Domestic processing in Iceland using renewable energy offers a substantial environmental advantage over exporting raw material for processing abroad using fossil fuel-based energy, where international shipping and oil-based drying would increase the climate change impact by an order of magnitude.
7) At an 18% clinker substitution rate, VPI-blended cement carries approximately 15% lower climate change impact than OPC, from ~820 kg CO_2-eq/t to ~698 kg CO_2-eq/t, given VPI's near-negligible carbon footprint of 25.5 kg CO_2-eq/t relative to clinker.

jana.budajova@tuke.sk

Abstract. This paper presents a comparative life cycle assessment (LCA) of five construction variants of wooden flat roofs with the aim of evaluating their environmental impact depending on the thermal insulation used. The assessment focuses on conventional materials such as mineral wool in direct comparison with ecological alternatives in the form of cellulose, sheep's wool, linen and hemp insulation. The main indicator monitored is global warming potential (GWP), with the results pointing to significant differences in biogenic carbon, where natural insulations benefit from their ability to sequester CO_2. The study provides relevant data for optimizing the design of wooden buildings in the context of reducing the carbon footprint and transitioning to a circular economy in construction.

Keywords: Life Cycle Assessment · Wooden Flat Roof · Global Warming Potential · Carbon Footprint

1 Introduction

The construction sector urgently needs to reduce greenhouse gas emissions contributing to global warming [1]. In the context of European climate targets, attention is shifting from operational energy to minimizing embodied carbon in building materials [2]. Conventional insulation materials like mineral wool, despite excellent thermal properties, require high energy consumption during production [3]. Conversely, natural materials reduce the carbon footprint by storing atmospheric carbon through photosynthesis, creating temporary carbon storage within the structure [4]. Beyond insulation, roof cladding is crucial for climate change adaptation [5], with green roofs increasingly used to mitigate the urban heat island effect and improve rainwater management [6]. Although LCA analyses can show higher operational impacts for green roofs due to maintenance and water use, their long-term ecosystem services such as evapotranspiration and thermal stabilization are often not fully captured by standard GWP indicators [7, 8]. study presents a comprehensive LCA comparison of five wooden flat roof structures, combining conventional mineral wool with natural alternatives (hemp, cellulose, linen, sheep's wool) across three vegetation and two gravel variants. The aim is to evaluate their GWP impacts and identify the most environmentally optimal solution for sustainable construction.

2 Materials and Methods

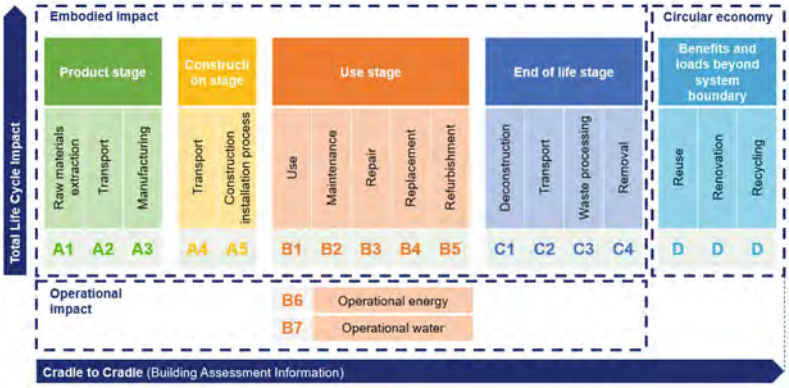
The study analyzes five variants of wooden flat roof structures with an emphasis on comparing conventional and natural insulation materials. The life cycle of these structures was assessed using the LCA method. This complex method enables systematic collection and analysis of data on inputs, outputs, and environmental impacts of individual components throughout the entire life cycle of the composition.

2.1 Goal and Scope

The main goal was to compare the environmental impact of five proposed roof composition variants (R1 – mineral wool, R2 – hemp, R3 – sheep's wool, R4 – cellulose, R5 – linen). The service life of the structures was estimated at 50 years, which is the standard period for LCA analyses, and the functional unit (FU) was 1 m^2 of gross floor area. The analysis was performed using a Cradle-to-Grave approach. The phases included in the assessment, A (production and construction), B (use and maintenance), C (end of life), and D (benefits beyond the system boundaries), are described more in detail in Fig. 1.

Software and Standards. OneClickLCA (OCL) software was used to quantify environmental impacts. The LCA method complies with the requirements of ISO 14040, ISO 14044, and European standards for the sustainability of materials and buildings EN 15804 + A2/AC and EN 15978. The assessment focused on GWP indicators to provide a transparent comparison of the climate change impacts of different materials. Four key indicators were analyzed according to methodological standards: GWP-total, GWP-fossil, GWP-biogenic, and GWP-LULUC.

Statistical analysis. A multi-criteria analysis (MCA) was used to comprehensively compare the environmental performance of five roof composition variants within the four GWP indicators monitored. This method allows alternatives to be evaluated based on multiple indicators simultaneously, providing a comprehensive view of the decision-making process and helping to identify the most environmentally suitable solution. The analysis was performed in MCA7 software using the TOPSIS (Technique for Order Preference by Similarity to Ideal Solution) method. In the context of this study, this method means identifying the composition that minimizes negative environmental impacts (such as GWP-fossil) and maximizes positive benefits (such as GWP-biogenic). Four indicators were considered in the MCA analysis (GWP-total, GWP-fossil, GWP-biogenic, and GWP-LULUC). All four indicators were assigned the same weight (25%) with a total sum of 1, ensuring a neutral and balanced approach to assessing the various aspects of global warming potential.



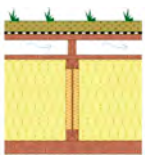


Fig. 1. System boundaries considered in the LCA analysis.

2.2 Life Cycle Inventory (LCI)

An LCI analysis was performed for five wooden flat roof variants designed to meet the Slovak passive building standard STN 73 0540-2, achieving a heat transfer coefficient U = 0.08 W/(m^2·K). Data was sourced from Ecoinvent, GaBi, and specific EPDs. For natural insulations (hemp, flax, cellulose), carbon sequestration was emphasized, while their higher specific heat capacity improves the building's summer thermal response compared to mineral wool. Vegetated variants (R1–R3) included maintenance and water requirements (modules B6, B7) based on Central European climate data in OCL software. The extensive green roof maintenance assumes two visits per year (weed removal, drain inspection), with irrigation water consumption modeled at 20 l/m^2 per year (July–August). All variants feature a ventilated air gap to remove moisture and protect moisture-sensitive natural insulation materials. Roof compositions are detailed in Table 1.

Table 1. Composition of wooden flat roofs.

COMPOSITION R1 – Mineral wool	*Thickness d[m]*	*λ [W/(m·K)]*	***U W/(m^2·K)***

3 Results and Discussion

An evaluation of five wooden flat roof compositions from LCA shows a significant advantage of natural insulants in terms of their ability to store carbon, with the most significant environmental benefit in the production phase (A1–A3) achieved by composition R2 with hemp insulation, which sequesters up to −102.13 kg CO_{2e}/m^2. Although the maintenance of green roofs increases their emissions, their environmental benefits are significantly higher. In terms of overall balance, the R4 composition with blown cellulose appears to produce the least emissions in GWP-total, but when the benefits of module D and high initial carbon sequestration are considered, all three natural variants (R2, R3, R5) are the best solutions for sustainable construction, significantly outperforming conventional mineral wool. The results for the impact categories are shown in Table 2 and Fig. 2. The GWP-fossil indicator represents the energy intensity of production and operation without considering the carbon stored in plants. The lowest emissions occur in the production phase (A1–A3) and are reported by the R4 composition with cellulose insulation (35.94 kg CO_{2e}/m^2), which confirms its low industrial intensity compared to R1 mineral wool thermal insulation (67.69 kg CO_{2e}/m^2), which requires energy-intensive extraction of raw materials.

Table 2. Results for impact categories.

Impact category	Unit	R1	R2	R3	R4	R5
GWP-total	[$kgCO_{2e}/m^2$]	563.18	564.35	548.48	54.94	61.38
GWP-fossil	[$kgCO_{2e}/m^2$]	563.07	564.16	548.17	54.79	61.29
GWP-biogenic	[$kgCO_{2e\ bio}/m^2$]	0.003	0	0	0	0
GWP-LULUC	[$kgCO_{2e}/m^2$]	0.109	0.173	0.289	0.132	0.088

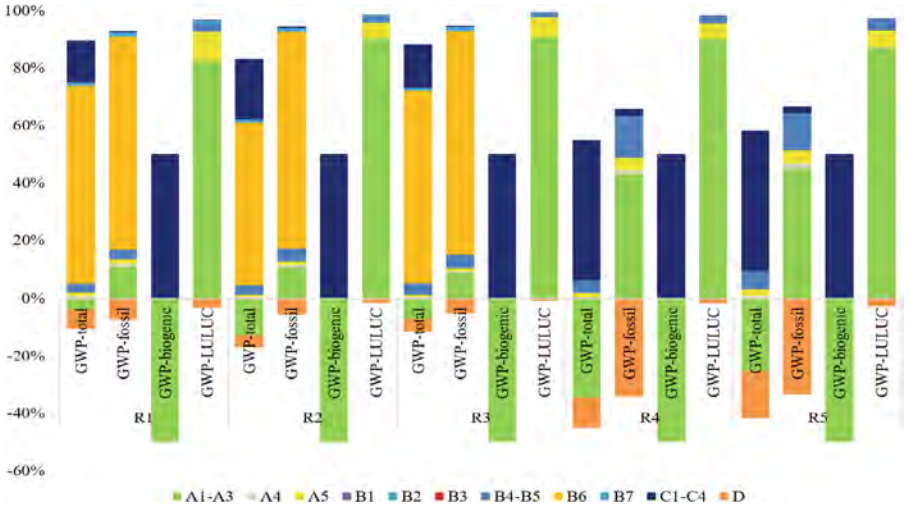

Fig. 2. Life cycle phase results for GWP impact categories in percentages (%).

In the variants of flat wooden roof structures with extensive vegetation (R1, R2, R3), emissions in the operational phase B6 and B7 are high (451.34 and 8.26 kg CO_{2e}/m^2 respectively), reflecting the fuel and energy consumption associated with regular maintenance and irrigation of vegetation. In terms of GWP-fossil, emissions are lowest for structures without a green roof (R4, R5), with cellulose thermal insulation remaining the most energy-efficient solution with minimal impact on the depletion of non-renewable resources. An evaluation of the thermal insulation materials used confirms the fundamental difference between conventional and natural insulators in terms of their environmental impact. Natural materials such as hemp (R2), sheep wool (R3), cellulose (R4) and linen (R5) demonstrate excellent carbon sequestration capabilities, which are reflected in the analysis by negative GWP-biogenic values. Hemp insulation (R2) achieves the highest contribution in GWP-biogenic, while blown cellulose (R4) dominates in energy efficiency in production in GWP-fossil. C The mineral wool roof variant (R1) is a conventional solution with high consumption of non-renewable resources and zero carbon sequestration, but offers good recycling potential in module D. In terms of operation,

green roof components in compositions R1–R3, despite higher emissions from maintenance, provide important ecosystem services such as evapotranspiration and water retention, which increase the overall sustainability of the solution beyond the GWP figures alone. Analysis of biogenic GWP confirms the key role of natural materials as temporary carbon storage reservoirs. The highest sequestration capacity is demonstrated by the R2 wooden roof structure with hemp insulation, which binds up to −167.39 kg CO_{2e}/m^2 during the production phase (A1–A3), which is almost double that of the R1 mineral wool structure (−93.14 kg CO_{2e}/m^2), where only the wooden load-bearing elements store carbon. Although this stored CO_{2e} is released back into the atmosphere when the structure is demolished at the end of its life cycle (C1–C4), thereby offsetting the biogenic carbon balance, the long-term incorporation of these materials into buildings is an effective way of decarbonizing the construction industry. Compositions with cellulose thermal insulation (R4) and hemp insulation (R2) thus provide a significantly higher initial environmental benefit in the form of a negative carbon footprint of the material phase compared to compositions with mineral wool. The GWP-LULUC analysis confirms that the impact of material compositions on the landscape is minimal in relation to the total carbon footprint, with the highest value in the production phase (A1–A3) being shown by the composition of the R3 flat wooden roof with sheep's wool thermal insulation (0.265 kg CO_{2e}/m^2). This slightly higher value compared to other insulants reflects the demands on agricultural land associated with livestock farming. On the contrary, the most soil-friendly option appears to be the cultivation of raw materials for the R5 flat wooden roof structure with linen insulation (0.079 kg CO_{2e}/m^2) and the R1 variant (0.093 kg CO_{2e}/m^2). In accordance with the study by Füchsl et al. [9], the analyzed compositions of wooden flat roofs with vegetation (R1–R3) show higher operational demands, but this is compensated by their contribution to the microclimate and rainwater management. At the same time, according to the findings of Llantoy et al. [10], the use of natural materials in the compositions of external walls provides a GWP-biogenic area. The results confirm that natural materials have a significantly lower GWP-fossil than conventional mineral wool, which is key to the decarbonization of the construction industry. The study also emphasizes the importance of assessing roofs over a period of 50 years or more, when the energy savings of vegetation layers become fully apparent.

The TOPSIS analysis confirmed that, when all GWP indicators are considered in a balanced manner, the most optimal solution is the R4 composition with cellulose thermal insulation. This variant came closest to the ideal with the lowest GWP-fossil emissions (A1–A3) and zero operational load (modules B6, B7). Other natural insulants were close behind, with hemp (R2), for example, achieving a high score thanks to its significant sequestration of biogenic carbon. The analysis thus confirmed a sustainability hierarchy in which natural materials (R4, R5, R2, R3) consistently dominate mineral wool (R1), which has high embodied energy and no carbon storage.

3.1 Limitations of the Study

Although this LCA study adheres to methodological standards, it is subject to several limitations and uncertainties associated with modeling assumptions. The first significant limitation concerns the end-of-life scenarios in modules C and D. The resulting biogenic

carbon balance (GWP-biogenic) is highly sensitive to whether natural insulation materials (hemp, linen, cellulose) will be landfilled, incinerated for energy recovery, or recycled in accordance with the principles of the circular economy following the demolition of the building. At the same time, it is necessary to emphasize the limitations of the life cycle assessment methodology itself, which focuses primarily on global warming potential (GWP) indicators. Green roofs provide key ecosystem services, such as mitigating the urban heat island effect through evapotranspiration and advanced stormwater management. In practice, these factors reduce the need for mechanical cooling of the entire building, which, in a comprehensive building energy model (excluding the roof structure), would lead to an additional reduction in operational CO_{2e} emissions.

4 Conclusion

A comparison of five compositions for wooden flat roofs confirmed that the choice of thermal insulation has a significant impact not only on thermal properties but also on the overall environmental footprint of a building. All variants achieved excellent heat transfer coefficient values, making them ideal for passive and zero-energy houses. However, from an LCA perspective, the most advantageous options are those with natural thermal insulation. Options using linen (R2) and cellulose (R4) as thermal insulation have a negative carbon footprint in phases A1–A3 due to their GWP-biogenic character. Hemp insulation (R2) has the lowest emissions. Blown cellulose (R4) achieved the lowest emissions in GWP-fossil, while its processing requires significantly less primary energy compared to conventional mineral wool (R1). Although variants with a vegetation layer (R1–R3) show higher values in the GWP-fossil analysis due to operational maintenance and water consumption, their benefit lies in reducing the urban heat island effect through evapotranspiration and rainwater management. The impact on land use change (GWP-LULUC) is low for all variants, with flax cultivation appearing to be the most soil-friendly (R5). Based on these results, it can be concluded that the combination of natural insulation materials (hemp and cellulose) with a vegetation layer can be considered the most environmentally optimal solution. This approach not only minimizes greenhouse gas emissions during the life cycle, but also actively contributes to the adaptation of buildings to climate change.

Abstract. Decarbonizing Europe's built environment requires tackling embodied greenhouse gas (GHG) emissions alongside operational energy use. Using the PULSE-EU building stock model, we quantify embodied GHG mitigation strategies across the EU-27 from the demand-side (circularity and sufficiency), as well as supply-side. The model dynamically links new construction, maintenance, renovation, and demolition activities to life cycle assessment results in a consistent framework until 2050. We compare (i) circular economy interventions (service life extension via renovation, vacancy reduction, efficient structural material use, and increased reuse and recycling facilitated by on-site waste sorting) against (ii) reductions in per capita space demand via higher use intensity of residential buildings, (iii) shifts to low-carbon bio-based materials (timber construction and bio-based insulation), (iv) improvements in material production processes (efficiency, alternative fuels, and innovative technologies such as carbon capture and storage), and (v) improvements in transport and construction processes (alternative fuels, machine optimization, and shorter transport distances). The results indicate that by 2050 circular economy measures can deliver the largest embodied GHG reduction (33%), followed by improvements in material production (32%) and lower per capita space demand (27%). Combining all strategies reduces embodied emissions by about 60% relative to a 2020 baseline, with less-than-additive effects due to overlapping savings. The findings underscore the primacy of circularity (especially avoiding new material demand) and the necessity of parallel supply-side decarbonization to reach substantial reductions. While results are reported for the EU-27, reductions vary across Member States, owing to differences in stock age, vacancy state, material mix, and potential for industrial change.

1 Introduction

Reducing greenhouse gas (GHG) emissions in the built environment is essential to achieving the European Union (EU)'s climate neutrality targets. While policy and research have traditionally focused on reducing operational emissions from buildings, interest in embodied emissions, those associated with the production, transport, construction, maintenance, and end-of-life treatment of materials, has increased in recent years [1]. This shift is driven by both improvements in operational efficiency and the projected expansion of the building stock, which increases demand for carbon-intensive construction materials such as cement, steel, and insulation products. Embodied GHG emissions from buildings and construction are now directly targeted in EU policies, in particular with the recast of the *Energy Performance of Buildings Directive* [2].

In this context, circular economy strategies have emerged as key levers for reducing material-related emissions by slowing, narrowing, and closing material loops [3]. These strategies encompass a broad range of interventions, including, for example, material substitution, reuse of building components, design for disassembly, service life extension, and reductions in material demand through changes in building use patterns [4]. Across sectors, circular economy measures have demonstrated substantial mitigation potential, with a recent literature review reporting an average relative reduction in GHG emissions of around one-third compared with baseline scenarios. Notably, the buildings and construction sector has been identified as one of the most promising areas, with relative reduction potentials averaging 48% [5].

Despite this potential, the current literature on circular economy and climate mitigation reveals important limitations [5]. First, existing studies are heavily skewed towards downstream measures, particularly recycling and waste management. In contrast, upstream strategies, such as demand reduction, material efficiency, reuse, and service life extension, remain comparatively underexplored, despite evidence suggesting they may offer equal or greater mitigation potential. Second, there is substantial heterogeneity in the definition of circular economy strategies, their modeling approaches, system boundaries, and assumptions, which makes it difficult to compare results with other mitigation strategies. Third, most studies focus on individual materials, products, or technical interventions rather than assessing integrated mitigation strategies across entire building stocks or comparing circular economy measures with alternative approaches, such as efficiency improvements.

This paper contributes to closing this gap by systematically evaluating the mitigation potential of circular economy strategies compared with alternative approaches for reducing embodied GHG emissions in the EU building stock. By quantifying the effects of circular economy strategies and alternatives in an integrated and consistent modeling approach that captures material flows, building stock dynamics, and life cycle emissions, this study provides new insights into the relative effectiveness of different mitigation strategies. In doing so, it aims to support evidence-based policymaking and contribute to the development of coherent strategies for achieving climate neutrality in the EU's built environment.

2 Methods

2.1 Building Stock Model

PULSE-EU is a high-resolution model of the EU-27 building stock that projects life cycle GHG emissions from 2020 to 2050 and simulates the extent to which different mitigation strategies can reduce these emissions [6, 7]. It links projected building stock dynamics, including new construction, maintenance, renovation, replacement, and demolition from the PULSE modeling logic, to life cycle assessment (LCA) results generated with the MMG-SLiCE framework [8, 9].

From a modeling perspective, PULSE-EU represents the existing stock through a comprehensive set of building archetypes that capture differences in age, size, construction methods, technical systems, and emission profiles. Archetypes are defined per EU Member State by clustering buildings across sector (residential vs. non-residential), building type (single-family houses, multi-family houses, apartment blocks, offices, education, healthcare, trade, hotels and restaurants, and other non-residential), and construction period. A total of 15,026 archetypes are used for modeling the EU building stock. Floor area data and typologies are aligned with the EU Building Stock Observatory [10] to ensure consistency and represent buildings as they exist today, whether original or already renovated.

Life cycle inventories are assembled via the SLiCE data model [8] and the KU Leuven MMG framework [9], following the modular EN 15978 approach [11] and a hierarchical decomposition from building to elements and materials. This framework attributes impacts to specific building parts and materials, and tracks when emissions occur across life cycle stages. The LCA follows the EN 15978 [11] and EN 15804 + A2 [12] standards, and uses generic inventory data from ecoinvent 3.6 [13] with the MMG impact assessment method [9].

2.2 Future Scenarios

Future scenarios are created by combining and deploying GHG emission reduction strategies. Strategy deployment in the model follows a structured, country-specific process. First, for each strategy, quantitative diffusion targets (e.g., how quickly it could spread through the building stock) are defined at three milestone years (2030, 2040, and 2050) with three ambition levels: low, medium, and high. Second, the capacity of each EU Member State to put these strategies into practice is assessed. This capacity rating, again low, medium, or high, captures local conditions such as resource availability, market readiness, and policy context. Both the quantitative diffusion targets and the capacity ratings are informed by the literature and refined through discussions with stakeholders. They are transparently reported in a previous publication [14], alongside with their theoretical GHG emission reduction potential.

Finally, we combine these two layers. For every country–strategy pair, the model selects the diffusion value that corresponds to that country's capacity level (low with low, medium with medium, high with high). This produces a single, integrated scenario where each Member State pushes each strategy to its plausible upper bound, ensuring the overall pathway is grounded in local constraints. All of the available strategies,

and the data used for their implementation (e.g., diffusion values for each decade), are summarized in a supplementary table (available in a public repository [15]). Due to the large amount of strategies and data collected, only a simplified overview is shown in Table 1. Interested readers are referred to these previous publications for more details on the strategies [7, 15]. In this study, we model a set of scenarios by applying the following combination of strategies:

- *CIRCULARITY*: circular economy interventions (service life extension via renovation, vacancy reduction, efficient structural material use, and increased material reuse and recycling facilitated by on-site waste sorting).
- *SPACE DEMAND*: reductions in per capita space demand via higher use intensity of residential buildings. This strategy is sometimes included under the umbrella of the circular economy, but considering its strong influence in our modeling approach, it is here considered as a separate scenario.
- *BIO-BASED*: shifts to low-carbon bio-based materials (timber construction and bio-based insulation).
- *MATERIALS*: improvements in material production processes (efficiency improvements, use of alternative fuels and innovative technologies such as carbon capture and storage).
- *PROCESS*: improvements in transport and construction processes (alternative fuels, machine optimization, and shorter transport distances).
- *ALL*: All of the above-mentioned strategies combined.

In these scenarios, circular economy measures are approached from a demand-side perspective (e.g., strategies that reduce the need for virgin material by slowing, narrowing, or closing loops). Although sometimes included under the umbrella of the circular economy, material and process-related changes denote supply-side decarbonization (not reducing demand *per se*), and the use of bio-based materials rather refers to material substitution. We therefore acknowledge that some measures are sometimes framed as circular, but we separate them here to keep levers analytically distinct.

Table 1. Example of strategies included in each scenario and diffusion potentials in 2050.

Scenario	Example of strategies included in each scenario (full list available online [15])	Diffusion in 2050 (low/medium/high)
CIRCULARITY	Percentage of empty dwellings which are renovated and put back to use.	15%/30%/45%
SPACE DEMAND	Percentage of reduction in per capita space demand compared to the business-as-usual projection (based on historical trends).	10%/20%/30%
BIO-BASED	Share of synthetic and mineral insulation materials substituted by bio-based materials.	20%/50%/80%

(*continued*)

Table 1. (*continued*)

Scenario	Example of strategies included in each scenario (full list available online [15])	Diffusion in 2050 (low/medium/high)
MATERIALS	Percentage of process emissions in cement production effectively captured and stored.	23%/42%/90%
PROCESS	Percentage of the transportation fleet using alternative fuels or electricity.	30%/60%/100%

3 Results and Discussion

3.1 Embodied Emission Trajectories

Circular economy measures can deliver the largest embodied GHG reduction by 2050 compared with 2020 (33%), followed by improvements in material production (32%) and lower per capita space demand (27%), as shown in Fig. 1. The use of bio-based materials reaches a non-negligible 12% embodied emissions reduction, while improvements in transport and construction processes only reach 6%. Differences in timing of implementation can also be observed. While circular economy interventions and per capita space demand reduction have a rapid emission reduction potential, by 2030, the potential for additional reductions decreases with time. On the contrary, improving material production has more gradual benefits, reaching additional similar GHG emission reductions over time.

These scenarios also target different life cycle stages of the buildings. For example, the circularity scenario almost entirely reduces demolition-related emissions by 2050, and considerably reduces construction-related emissions, but a trade-off is observed for renovation-related emissions. On the contrary, the materials scenario reduces both construction, renovation, and use phase related emissions. Combining all strategies reduces embodied emissions by about 60% by 2050, with less-than-additive effects due to overlapping savings. This complementarity of the different strategies, from the time of implementation to impact of the different life cycle stages, highlights the necessity of parallel demand and supply-side approaches to reach substantial emission reductions.

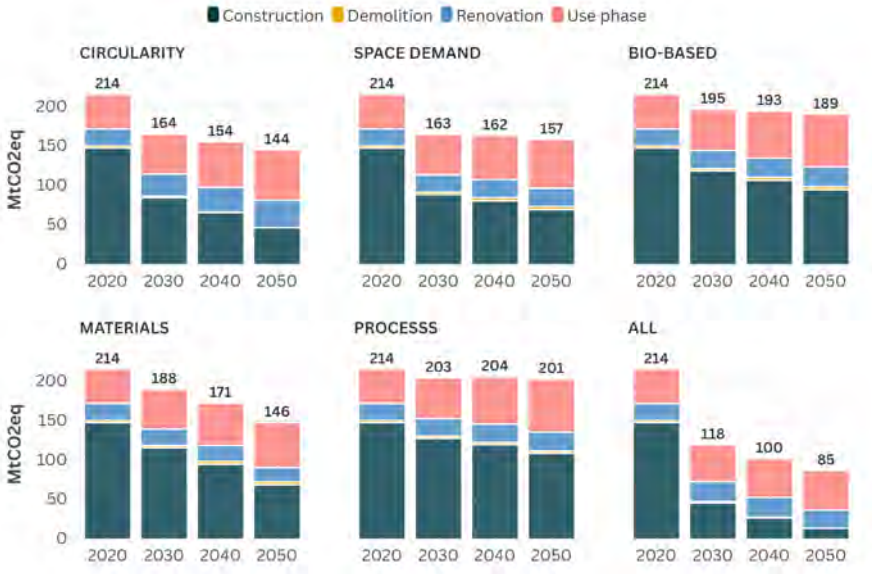

Fig. 1. Annual embodied GHG emissions from building construction (A1–5), demolition (C1–4), renovation (B5), and use (B2, B4), for each of the scenarios. Figure made with flourish.studio.

3.2 Differences Across EU Member States

The impact of circular economy interventions (e.g., from the circularity scenario) varies across EU Member States, owing to differences in building stock age, density, vacancy state, material mix, and potentials for industrial change, as shown in Fig. 2. Higher GHG emissions reductions (more than 41%) can be achieved as a result of circular economy interventions in Spain, the Netherlands and Bulgaria, while lower reductions (less than 16%) can be seen in Hungary and Finland. More modest reductions (16 to 41%) can be reached in the other EU Member States. For Member States with lower reduction potentials, it is worth noting that only Hungary and Finland reach very low reduction potentials (less than 7%), while all other countries reach at least 16%, highlighting that, although other Member States might have higher mitigation potentials, circular economy strategies are still quite promising.

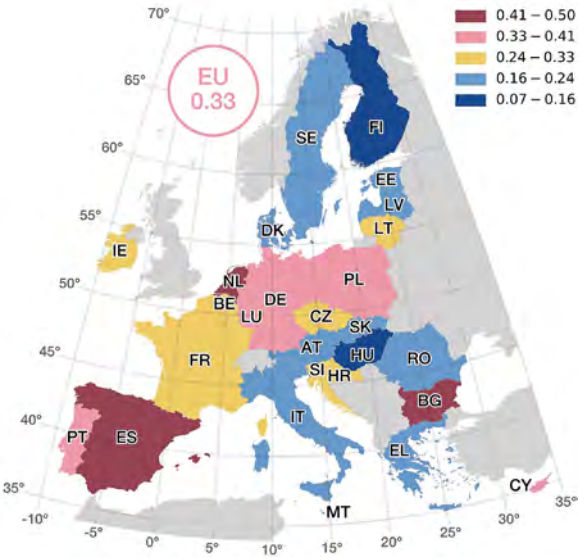

Fig. 2. Relative reduction in embodied GHG emissions by 2050 compared with 2020, for the circularity scenario, reported for each Member State and for the EU average. A 0.4 relative reduction means that embodied emissions of this country were 40% lower in 2050 than in 2020 with this particular scenario. The administrative areas used in this figure are from GADM (v2.8).

Both the Netherlands and Spain exhibit emission reduction potentials exceeding 45% under circular economy strategies. This high potential can be attributed to three structural characteristics: (i) very high population density, particularly in the Netherlands (in comparison to Finland), which amplifies the gains from more intensive use of the existing building stock and from material reuse, thereby lowering embodied emissions; (ii) a relatively balanced split between embodied and operational emissions (approximately 50% each) combined with high vacancy rates, particularly in Spain, but also in Bulgaria and Portugal, conditions under which circular economy measures deliver especially large benefits; and (iii) high per capita emissions, as in Luxembourg, Germany, and Poland, which increase the absolute scope for emission reductions.

3.3 Model Limitations

To develop future projections, building stock models use input data, such as information on building archetypes or life cycle scenarios, and dynamic parameters, including construction rates, which are inherently uncertain and challenging to predict. These uncertainties should be acknowledged when interpreting the results. In addition, this study does not include the potential rebound effects or unexpected dynamics from the implementation of the strategies, for which further empirical evidence is required to improve modeling. For example, reducing per capita space demand also has resilience implications, for which other aspects might be considered. An increase of ceiling height

could be necessary to reduce overheating while increasing spatial quality and construction adaptability. Similar considerations can be made for vacancy, and considering the typology or location of the vacant buildings in more detail could change these results.

4 Conclusion

Combining demand- and supply-side measures can reduce embodied GHG emissions from EU buildings by about 60% by 2050 relative to 2020. Circular economy actions provide the largest single potential (33%), followed by improved material production (32%), reduced per capita space demand (27%), bio-based substitution (12%), and construction/transport improvements (6%), with circularity and per capita space demand reduction delivering early gains while improvements in material production develop steadily over time. Reduction potentials vary across Member States, underscoring the need for tailored national roadmaps. Results should be interpreted in light of modeling uncertainties and potential trade-offs.

From Material Cadastre to Data-Driven Innovations

Georg Shiller(✉) and Karin Gruhler

Leibniz Institute of Ecological Urban and Regional Development, 01217 Dresden, Germany
g.schiller@ioer.de

Abstract. Construction industry consumes the largest share of resources worldwide. Natural resources are predominantly used for this purpose. There is comprehensive knowledge about the availability and deposits of these resources. The situation is different for anthropogenic resources incorporated into existing buildings. Until now, little was known about the extent, composition and dynamics of these already used building materials. In recent years, however, a number of studies have been presented to explore and map these materials in existing buildings. This provides important information to support circular approaches in construction. But how can this information be used to support circular action? This article presents the development of a national materials register designed to enable circular construction stakeholders to access the information and develop it further in their own business models. The data set is presented in terms of its content and spatial resolution, and initial examples are given of how it is being used and developed by circular construction stakeholders.

Keywords: Material Cadastre · Data driven Innovation · Circular Construction

1 Introduction

The development of the built environment goes hand in hand with a constant demand for building materials. This will double worldwide over the next three decades [1]. Today, our built environment, i.e. buildings and infrastructure, already consumes around 50% of global resources and 25–40% of global energy [2] and generates 15–40% of global waste [2].

Buildings shape the visual character of cities and constitute a central component of the built environment as residential, office, public, and commercial structures. While many of these buildings are publicly accessible and can be located via digital mapping services, little is known about their material composition. Information on the materials used, their quantities, provenance, and the ecological impacts associated with their production, transport, and processing often remains inaccessible. Nor is so-called 'grey energy' – that is, the amount of energy consumed in the production of building materials and during the construction of a building– usually visible [3, 4]. This results in a significant data gap in the material metabolism of urban systems.

In fact, such information does exist: every building is based on planning processes in which material decisions are made and documented. However, these data are rarely

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 1279–1287, 2026.
https://doi.org/10.1007/978-3-032-34930-9_149

centrally accessible or systematically analyzable. Instead, they have been stored in a decentralized manner over decades—for example, in analog building records, on storage media such as floppy disks or CD-ROMs, on local hard drives, or within various cloud systems [5]. Consequently, material-related information about the built environment is distributed across a heterogeneous digital and physical archive whose structure reflects the historical evolution of construction practices. As buildings age, access to information regarding their material composition typically becomes increasingly difficult.

Yet it is precisely these data that are essential for unlocking a significant resource: the materials embedded in buildings and infrastructures constitute a substantial reservoir of anthropogenic raw materials [6, 7] that can be systematically exploited within the framework of urban mining concepts.

The digital representation of this anthropogenic material stock in three-dimensional maps [8], equipped with integrated processing and analytical functionalities, establishes a critical data foundation for a wide range of potential applications. This enables diverse stakeholder groups to develop their own analyses, applications, and planning tools on this basis. The spectrum of possible use cases is broad and depends largely on the type, scope, and quality of the integrated information and datasets. This paper provides an overview of these aspects and discusses associated challenges and fields of application.

2 Material Cadastre Covering the Building Stock of a Whole Nation

With the Material Cadastre Germany (Fig. 1), the authors and colleagues provide, for the first time, a nationwide, comprehensive database on the material composition of the building stock across all municipalities in Germany [9].

Approximately 20.8 billion tonnes of construction materials are embodied in Germany's roughly 51.6 million buildings. Concrete dominates this material stock, accounting for 46%, followed by calcium silicate brick and clay brick, each contributing just under 10%. Renewable materials such as wood, reed, or straw play only a marginal role, comprising around 1% of the total mass.

By linking cadastre data with regional construction and demolition data [10], it becomes possible to estimate both the potential for recycling processes and the future demand for construction materials in new construction and refurbishment. In addition, anticipated volumes of construction and demolition waste can be projected comprehensively across the entire territory.

Linking the material data with life cycle assessment datasets allows for inferences regarding embodied greenhouse gas (GHG) emissions [11, 12]. Theoretically, the production of the materials used in construction would release approximately 2.7 billion tonnes of GHGs—roughly four times Germany's annual emissions. This highlights the substantial value contained in materials already built into the urban environment. If these materials can be reused or their service life extended, additional GHG emissions can be avoided.

The cadastre is based on a typological approach applying the bottom-up principle [13]. In this framework, building stocks are recorded, assigned to corresponding typologies [14], linked with indicators for construction materials and embodied emissions, and used to calculate material composition and emissions.

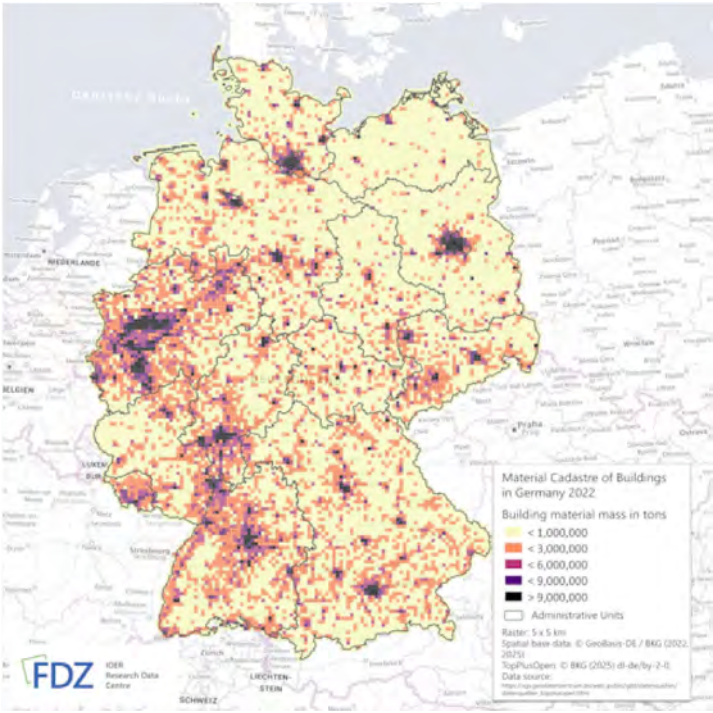

Fig. 1. Material Cadastre Germany – material mass of buildings [data source: 9].

The basis for capturing the building stock is a comprehensive 3D building model of Germany's building inventory [15], provided by the Federal Agency for Cartography and Geodesy (BKG). These digital models contain information on building function, which is used for the typological classification of buildings. This approach ultimately produces a reliable representation of the volume of each building by building type—from single-family houses to office buildings and logistics halls.

The types and quantities of materials typically used per cubic meter of building volume are expressed through so-called material indicators. The development of these indicators was based on extensive long-term research, in which numerous individual buildings were analyzed to represent the characteristic construction methods of each building type. Material use for each component, from the foundation to the roof, was recorded and aggregated at the level of building typologies [14, 16] (Fig. 2).

In total, 44 construction material groups are differentiated, with the relative use of materials varying by building type—for example, higher proportions of concrete in industrial buildings, and greater use of wood or brick in single-family houses. The material indicators are accessible via the IOER's Built Environment Information System [16] (Fig. 3). The complete dataset of the Material Cadastre Germany is made available through the open-data repository of the IOER Research Data Center [17].

The typology-based approach, however, does not replace detailed analyses at the individual building level. This method does not allow for precise determination of the

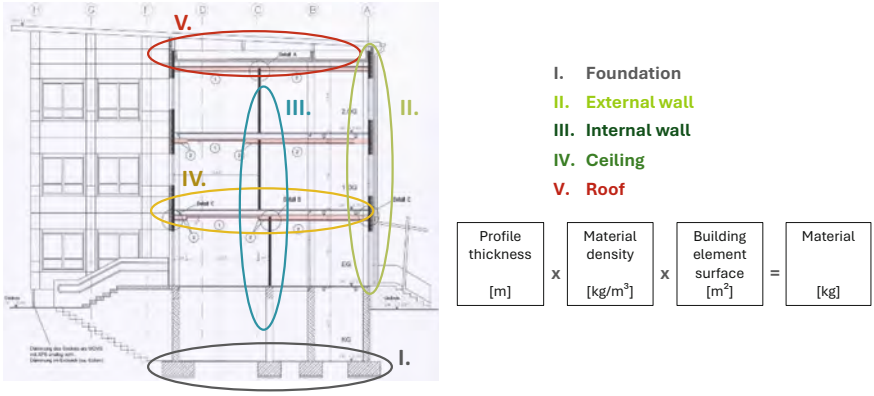

Fig. 2. Development of specific material indicators based on the analysis of planning documents for representative buildings (changed according to [13])

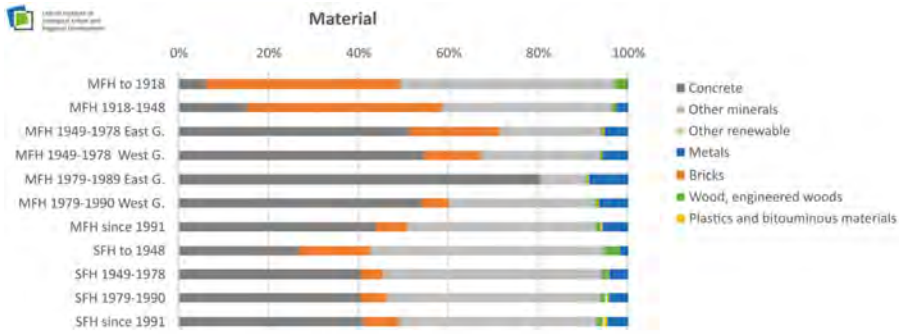

Fig. 3. Material indicators (MI) of typical German (G.) multi-family houses (MFH) and single-family houses (SFH) by main material groups – examples from ISBE [16].

material composition of specific buildings but provides indicative reference values. Nevertheless, its utility is significant, as the cadastre reduces the costs of data acquisition, increases transparency regarding material flows within the building stock, and enables new business models—from the development of building passports to the support of pre-demolition audits and digitally assisted deconstruction planning. Municipalities, planning offices, property owners, and consulting firms can directly use the provided data or complement it with their own analyses. Similarly, recycling companies can use the information to more accurately estimate which secondary raw materials will be regionally available.

3 Materia Cadastre: Knowledge Base for Stakeholder Activities

Research achieves its full impact only when it is translated into real-world practice, particularly in the construction industry. What knowledge can be extracted from extensive datasets on buildings? What value does a digital map offer, and how can these insights be implemented effectively in practical contexts?

The publication of the national Material Cadastre has attracted significant attention in Germany. Several initial applications have been developed based on this dataset, which are exemplarily outlined here. For instance, the start-up company Concular [18] used the openly available Material Cadastre dataset to develop an Urban Mining Cadastre and now provides advisory services to cities and municipalities. In the city of Osnabrück, e.g., questions were posed regarding the materials, stored energy, and reusable resources contained within the urban environment. With support from the start-up, Osnabrück's entire building stock was analyzed using the Urban Mining Cadastre, aiming to make the city's material composition visible and thereby establish a foundation for circular building management. Similarly, the platform supported the city of Stuttgart within the framework of a climate innovation initiative, enabling a comprehensive analysis of its building stock through the Urban Mining Cadastre. To facilitate low-threshold adoption of the digital platform in the public sector, initial workshops were held to systematically analyze objectives and potential applications [19]. An example from Prague takes a similar approach and examines the role that material inventories can play in supporting pre-demolition audits [8]

The practical value of digital data ultimately lies in its implementation on construction sites. However, translating the environmental impact analysis of an entire city's building stock into concrete decisions for individual buildings requires intermediate steps. Here, the interface of the Urban Mining Cadastre with digital planning data for individual buildings plays a crucial role. For older buildings, such data is often unavailable, and the dataset must be supplemented manually when action is required at the respective building. Because the cadastre links each building to an accessible and editable dataset, this interface has been established. Furthermore, Concular's life cycle assessment software (Fig. 4) enables material decisions to be evaluated already during the planning phase, allowing different renovation scenarios to be compared and the identified potential for material reuse to be verified and utilized in a subsequent process according to DIN SPEC 91414. The so-called Pre-Deconstruction Audit (PDA) represents the first step toward actual reuse at the level of individual buildings. Similar examples can also be found among other market players or local governments that utilize the IOER data from the material cadastre, such as Madaster Germany, which advises states and local governments on circularity based on the dataset of the cadastre described above [20].

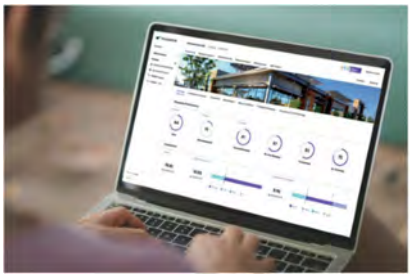

Fig. 4. Softwaretool CircularLCA.that is based on Material Cadastre data to support pre demolition audits for buildings (source: [18])

4 Limitations and Uncertainties

The typological approach underpinning the cadastre is subject to fundamental limitations. The material indicators used are based on average values for building types, age categories or usage categories, and thus abstract away from the actual heterogeneity of the real building stock. This simplification leads to uncertainties, particularly in high-resolution, location-specific analyses. As spatial resolution increases, so does the tendency for errors [21]. This can be countered by further refining the typologies through additional characteristics like building age. However, the fundamental limitation of typological approaches remains [14].

When considering the transferability of material indicators used to other spatial contexts or locations, it is important to take into account the impact of these contexts on construction methods and, consequently, on the material composition of the buildings – for example, by considering geologically induced natural hazards or socio-cultural conditions – as this helps to narrow down uncertainties [8, 22].

The issue of hazardous substances is also of particular interest in the context of recycling practice [23]. Type-based material flow analyses are limited in terms of the quality of potential secondary materials, particularly because they are based on highly aggregated average values and do not explicitly reflect the heterogeneous and pollutant-related material composition of real buildings [14]. As a result, relevant contamination—particularly from pollutants associated with the age of the building and the type of materials used—is not taken into account [24]. Recent research shows that hazardous substances in building stocks (e.g., asbestos and PCBs) are increasingly being assessed using machine learning models trained on building registers and demolition inventories, enabling probabilistic risk mapping at building level, whereas traditional material flow analysis lacks the chemical and spatial resolution required for such assessments [25].

5 Conclusion

Digital datasets on the anthropogenic material stock can stimulate innovations and circular construction activities when they are well-founded, reliably provided, easily accessible, and equipped with interfaces for integration with advanced applications and combination with other datasets. Such datasets can also enable the development of

economically viable business models, as illustrated by the examples presented in this paper.

The role of science is to develop methodologies, generate suitable data, and make these data available. However, this alone does not guarantee a profound transformation of the construction sector. The risk remains that applications will be limited to isolated projects or niche innovations. Therefore, science also has a responsibility to actively shape the intended transformation in order to enhance societal impact. This entails addressing the question of how such a transformation can be guided. Transdisciplinary approaches are required, and levers for change must be identified and promoted, for example by providing knowledge and data to be incorporated into comprehensive data ecosystems shaped by both science and practice. The development of niche areas should be encouraged, as should the creation of the necessary regulatory and policy frameworks, for example in the form of regulations or specific strategies. - because one thing is clear: the mere provision of data is not sufficient.

Integrating Digital Technologies for Automated Circularity Assessment of Construction Products

Giuliana Parisi[1(✉)], Eleonora Giuffrida[1], Stefano Cascone[2], and Rosa Caponetto[1]

[1] University of Catania, Catania 95125, Italy
giuliana.parisi@phd.unict.it
[2] Politecnico di Torino, Turin 10129, Italy

Abstract. In the construction sector, circular approaches are increasingly recognized as a key strategy to reduce demand for primary raw materials while supporting economic development. Concurrently, the adoption of digital tools enables automated collection and management of information, thereby improving the ability to evaluate alternative scenarios and enhance environmental performance. This study presents a decision support system (DSS) that includes an automated calculation of the Circularity Level (LC) of products and services and a BIM-based digitalization of product data, enabling circularity information sharing across the construction supply chain. The LC is an index derived from a set of 68 circularity indicators specified in UNI/TS 11820, aligned with ISO/TC 323 Circular Economy and the EU Level(s) framework. In this research, an Excel-based calculator is developed to automate LC calculations from manufacturer-provided data. Subsequently, an LC Report is automatically generated via APIs, providing supporting documentation to ensure data traceability and to identify potential areas for improvement. Finally, a bidirectional information flow is established between Excel and Autodesk Revit via Dynamo parametric scripts, enabling automated customization of product-related BIM objects. The proposed workflow enables scalability across different product categories and regulatory requirements. The challenges associated with LC improvement strategies are identified, and future research directions are outlined to leverage AI-based predictive tools to support the evaluation of alternative scenarios. Moreover, the workflow should be tested through a case study to assess its validity in a real-world context. This research advances the digitalisation of circularity assessment, supporting green and digital transitions in the construction sector.

Keywords: Building Information Modeling · Visual Programming Language · Sustainable Development · Circular Economy · Green Transition

1 Introduction

Over the past decades, the limitations of the traditional linear economy (LE) model are increasingly highlighted by rising resource demand and waste production. LE is based on intensive resource use and short product life cycles and is considered incompatible

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 1288–1295, 2026.
https://doi.org/10.1007/978-3-032-34930-9_150

with international sustainability objectives. In this context, a paradigm shift from the LE to the circular economy (CE) is required, aiming to close material loops, reduce waste production and enhance the value of resources throughout the life cycle [1].

In response to these challenges, several regulatory frameworks have been developed to support the transition toward more sustainable models, such as the United Nations' Agenda 2030 [2] and the EU Level(s) framework [3]. Specifically, at the international level the International Organization for Standardization (ISO) has established the technical committee ISO/TC 323 "Circular economy" [4], which has defined standards such as ISO 59004 [5], ISO 59010 [6] and ISO 59020 [7], respectively addressing circular economy principles, business model transition and the assessment of circularity performance. These standards have also been adopted at the European and national levels. Within this framework, the Italian standard UNI/TS 11820 [8], further detailed in Sect. 2, is introduced as an operational tool for assessing the Circularity Level (LC) of products and services.

In parallel, within the construction sector, the digital transition requires the structured management of information flows related to circularity assessments to support the integration of environmental sustainability and technological innovation. In this context, digital technologies are adopted, among which Building Information Modeling (BIM) is recognized as an enabling methodology for managing information throughout the entire building life cycle [9]. To improve interoperability and data management efficiency, BIM is integrated with Visual Programming Languages (VPL), such as Dynamo, which enables the development of parametric scripts to facilitate the extraction and integration of the data required to assess circularity performance across the life cycle of products [10].

However, several gaps remain in the development of digital workflows for circularity assessment. Circularity evaluation processes are often carried out manually, resulting in procedures that are difficult to replicate and to verify, thereby limiting the standardization and traceability of results [11]. Moreover, when such assessments are digitalized, they are frequently conducted through workflows that integrate BIM with external software, such as Life Cycle Assessment (LCA) tools (e.g., SimaPro, Athena Impact Estimator) and Excel databases [12]. This approach generates interoperability issues across platforms and challenges in managing information flow and preventing data loss. Although tools such as VPLs enable the development of parametric scripts to support specific analyses, their application to circularity assessment remains limited and dependent on customized configurations [13].

To address these gaps, this research develops a Decision Support System (DSS) to automate the calculation of product LCs and their subsequent BIM-based digitalization, thereby enabling the integration and sharing of information along the supply chain among different stakeholders. The resulting digital tool, developed through the automated integration of Microsoft Excel, Microsoft Word, Autodesk Revit and Dynamo, meets the requirements of UNI/TS 11820. However, due to the presence of a parametric core, the proposed methodology is scalable and can potentially be adapted to other regulatory contexts.

2 UNI/TS 11820: European Context and Key Features

In this research, the focus on UNI/TS 11820 is driven by its role as a detailed tool within the regulatory framework for assessing circularity. Specifically, the UNI/TS 11820 is developed considering the work of the ISO/TC 323 "Circular economy" technical committee [4–7], as reported in the Introduction section. Furthermore, within the European context, UNI/TS 11820 aligns with the EU Level(s) framework, which promotes the assessment of building sustainability across its life cycle, specifically with Macro-objective 2 "Resource Efficient Circular Material Life Cycles" [3]. In detail, UNI/TS 11820 specifies a set of 68 CE indicators, classified according to their applicability to products (P), services (S) or both products and services (P/S), used to evaluate, through a final score, the product or service's LC. The final score does not establish minimum circularity thresholds but provides an overall evaluation of the level achieved.

Moreover, UNI/TS 11820 distinguishes three evaluation approaches: semi-quantitative, in which measurements are carried out using predefined thresholds; quantitative, based on numerical values; and qualitative, in which binary criteria are used to verify specific conditions. Furthermore, the indicators are grouped into six thematic categories that assess circularity from complementary perspectives across the entire organizational system. An additional classification is provided by subdividing the indicators into Core, Specific and Rewarding. The Core category includes mandatory indicators. The Specific category includes indicators that must be completed unless they are deemed technically inapplicable. Finally, the Rewarding category includes optional indicators that increase the final circularity score. A specific weight is also assigned to each indicator type for the calculation of the final score: 1 for core and specific indicators and 0.5 for rewarding indicators.

Figure 1 shows the classification of UNI/TS 11820 indicators across the six categories, distinguishing between Core, Specific and Rewarding Indicators.

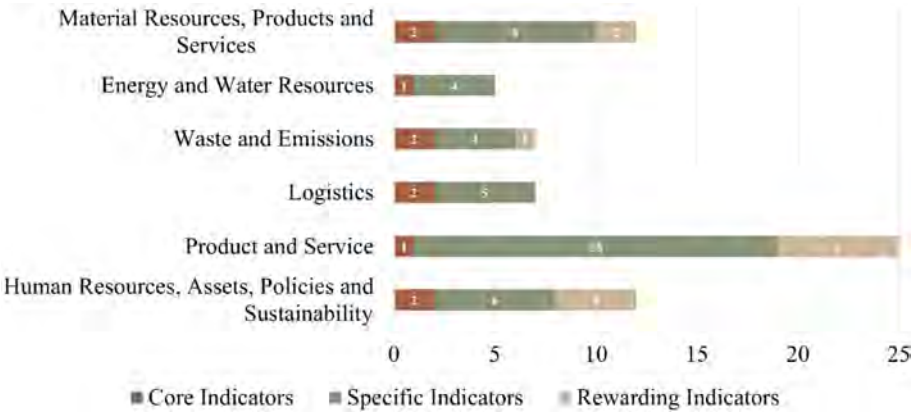

Fig. 1. Classification of UNI/TS 11820 indicators by thematic category and type (Core, Specific and Rewarding).

The "Product and Service" category includes the highest number of indicators, with a prevalence of specific and rewarding indicators, highlighting the central role assigned to circular product and service design and life cycle management. The "Human Resources, Assets, Policies and Sustainability" category presents a structured set of indicators, underscoring the importance of the organizational and strategic dimensions in implementing circular-economy principles. Conversely, the categories "Energy and Water Resources", "Waste and Emissions" and "Logistics" include fewer indicators, mainly specific, focusing on operational aspects. Finally, the "Material Resources, Products and Services" category includes core, specific, and rewarding indicators, underlining the importance of material flow management in circularity assessment.

In conclusion, the LC is defined as a percentage index obtained by aggregating the scores of the Core, Specific and Rewarding indicators, expressed as the ratio of the achieved score to the maximum theoretical score, ranging from 0% to 100%.

3 Framework for Digital Circularity Assessment

UNI/TS 11820 provides a framework for assessing circularity. In the construction sector, where many materials are evaluated and documented throughout the building lifecycle, the digitalization of the standard, particularly through BIM-based processes, becomes a key aspect. Figure 2 summarizes the digital workflow presented in this research to automate LC calculation and integrate product-related circularity data into BIM.

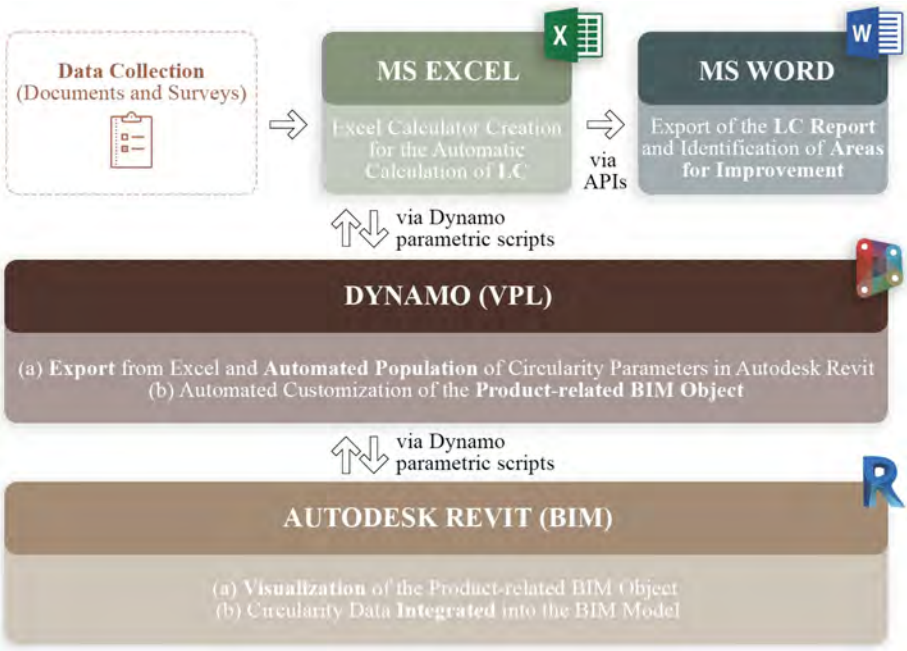

Fig. 2. Overview of the Proposed Methodology.

Specifically, an Excel-based calculator automates the calculation of circularity indicators and the generation of the LC value for both products and services, integrating survey and documentation data. The results are then automatically transferred to MS Word, where the LC Report is generated in accordance with UNI/TS 11820. In the following step, a bidirectional workflow between Excel and Autodesk Revit is implemented through Dynamo, enabling the automated creation of BIM object parameters and the integration of circularity data for construction products. Interoperability is ensured through APIs and Dynamo scripts, while the parametric structure allows replicability and scalability across different regulatory contexts.

The methodological validation of the proposed tool is supported by the detailed technical specifications, calculation procedures and weighting criteria of the circularity indicators defined in UNI/TS 11820. These specifications provide a methodological reference for implementing the automated calculation process, aligning the digital workflow with the standard's requirements and ensuring the consistency and reliability of the generated LC values and reports.

3.1 Automated LC Assessment and Report Generation

In an initial phase, the study develops an Excel-based calculator that automates the calculation of circularity indicators selected from manufacturer-provided inputs and returns the LC value.

The digital tool is organized into a series of spreadsheets. On the first sheet, guidelines for completing the form are provided to help users enter data correctly. A second group of sheets summarizes the 68 indicators, reporting their main characteristics described in Sect. 2, including the description, reference category, type (Core, Specific or Rewarding), weight and evaluation approach (qualitative, quantitative or semi-quantitative). Users can automatically select the indicators to include in the LC calculation based on the product or service under assessment. The third group of sheets constitutes the key section of the calculator, since the calculation method for each indicator is automatically defined and implemented, and both the indicator's specific and weighted values are automatically obtained. The calculation of this set of indicators represents a preliminary phase to the automatic calculation of LC, which is subsequently determined according to Eq. (1):

$$LC = \frac{\sum_{i=1}^{n} c_i + \sum_{j=1}^{m} s_j + 0,5 \sum_{k=1}^{f} p_k}{c + s} \quad (1)$$

where c_i is the value of the i-th core indicator, s_j is the value of the j-th applied specific indicator and p_k is the value of the k-th compiled rewarding indicator; n is the number of evaluated core indicators, m is the number of applied specific indicators and f is the number of compiled rewarding indicators; c is the total number of core indicators provided and s is the total number of applicable specific indicators [8].

To automatically generate the required LC Report as supporting documentation to ensure data traceability, the obtained results are imported into MS Word via APIs, allowing the direct extraction of the report. The document also provides automatic generation of a radar chart, enabling visualization of the overall score across the six indicator categories. This graphical representation allows potential areas for improvement to be identified and supports optimizing the LC value.

3.2 VPL-Based Customization of Product-Related BIM Objects

To digitalize product circularity indicators and make them available to stakeholders in BIM, a parametric Dynamo script is developed to enable automatic customization of Product-Related BIM Object parameters (Fig. 3).

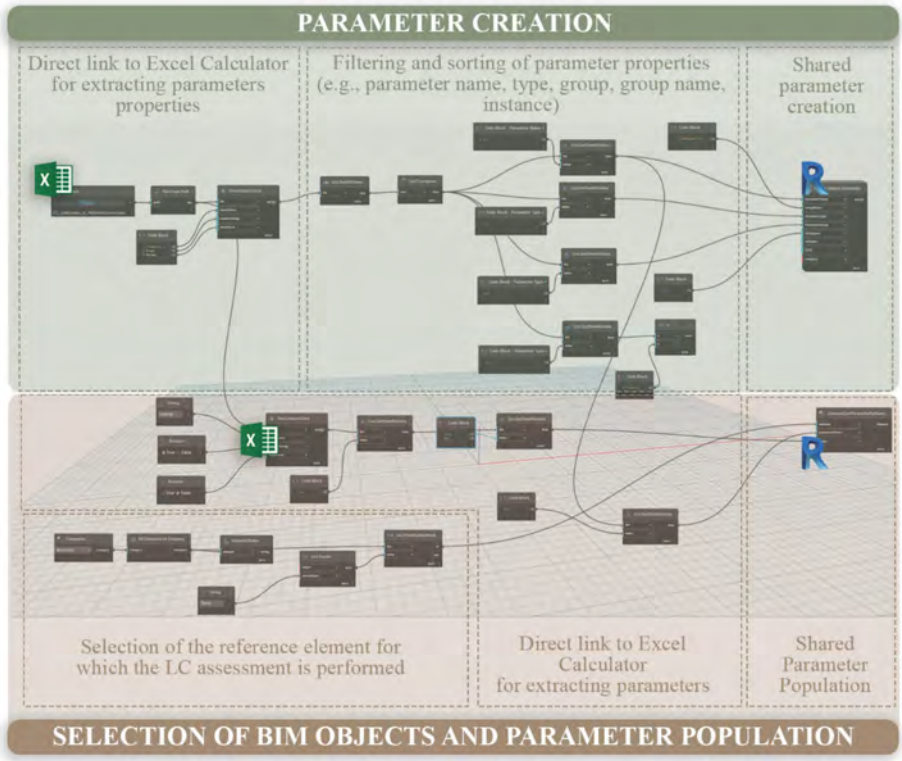

Fig. 3. Dynamo Parametric Script for the Automatic Creation of Shared Parameters in Revit (Green) and the Population of Circularity Data in BIM Objects (Orange) through Integration with the Excel Calculator.

The first section enables the automatic creation of parameters in Autodesk Revit. The script is configured with a direct link to the Excel Calculator to extract parameter properties through the nodes "File.Path" and "Data.ImportExcel". The extracted properties include the parameter name (e.g., LC_Value), parameter group, parameter type, reference category and the Type/Instance property. Subsequently, these data are filtered and sorted using nodes from the Dynamo package "Crumple". The resulting data are then used as inputs for the "Parameter.CreateSharedParameter" node from the "Genius Loci" package, through which shared parameters are automatically created in Autodesk Revit.

The second section of the script enables selection of the element or material for which the LC assessment is performed, using nodes such as "Element" and

"List.FilterByBoolMask". At the same time, to import the parameter value, a connection to the Excel Calculator is established. Specifically, the reference sheet is selected through the "String" nodes, while the coordinates of the cell containing the value to be assigned to the parameters are specified through the "List.GetItemAtIndex" and "Code Block" nodes. The BIM object, the parameter value and the name of the parameter to be filled are then provided as inputs to the "Element.SetParameterByName" node, through which the automatic population of the parameter within the BIM model is performed.

4 Research Implications and Future Perspectives

The proposed workflow ensures a scalable and replicable tool for assessing and digitalising circularity. The research develops a digital workflow integrating MS Excel, MS Word, Autodesk Revit and Dynamo. The Excel-based calculator automatically computes the LC for both products and services, while BIM-based digitalisation is applied to construction products. This configuration allows circularity data to be automatically transferred and updated within BIM objects. This is relevant to construction materials, as regulations require evaluating multiple materials in buildings and using BIM. Integrating circularity information into BIM supports systematic data management across the lifecycle and can be scaled to other sectors.

A specific focus is placed on the workflow's operational structure. The Excel-based calculator features a user-friendly interface to facilitate data entry by manufacturers, while the calculation rules align with the regulatory framework, ensuring consistency between the implemented methodology and existing requirements. Interoperability is ensured through a bidirectional, continuous data flow enabled by APIs and Dynamo parametric scripts.

However, some limitations are identified in this study, opening directions for future research. First, the developed digital tool needs to be tested and validated through case studies to assess its effectiveness in a real operational context. In this regard, the proposed workflow has been developed as an operational background study of the ITER Project and will be applied in the related case study, where earthen plasters enhanced with by-products from the agricultural and stone supply chains are implemented. Another limitation concerns the fact that input data in the Excel calculator are currently entered manually by the user. The integration of Artificial Intelligence (AI) methods, particularly Large Language Models (LLMs) based on Natural Language Processing (NLP), could enable the automatic extraction of information from technical product documentation. Finally, the DSS is structured as a parametric basis for future AI-based optimization tools that aim to improve the LC value by suggesting alternative scenarios.

Abstract. The escalating global focus on sustainability and circularity in the built environment calls for innovative approaches to evaluate and optimize building performance across its life cycle, particularly during the critical early design phase. To address this challenge, strategic governance and robust performance measurement are essential. Accordingly, this paper introduces a novel Building Information Modeling-based Balanced Scorecard framework to govern and measure BIM implementation quality in building design projects. Drawing on the well-established Balanced Scorecard approach, it breaks down BIM's strategic importance into four interconnected perspectives: Virtual Model, Technology, Processes and Documentation, and Technical Team. The resulting BSC-BIM framework thus enables strategic planning, BIM maturity benchmarking, and enhanced decision-making. Moreover, by providing defined principles, criteria, and verifiable indicators, it empowers project teams to monitor process standardization, information quality, technological interoperability, and organizational shifts toward digital adoption, ultimately supporting whole-life cycle performance and sustainable design. In turn, this ensures high-quality, sustainable design-phase information for subsequent analyses, operations, renewals, and circular economy practices in construction.

Keywords: Building Information Modeling (BIM) · Balanced Scorecard (BSC) · Whole-Life Cycle (WLC) · Sustainable Design; Performance Metrics

1 Introduction

The Civil Construction Industry (CCI) requires integrated products, processes, and services, along with a shift in mindset to consider the entire building life cycle—from concept and construction to operation and demolition. BIM emerges as a key methodology, several studies highlight BIM benefits regarding interoperability, collaboration, and process optimization within the construction industry [1, 2, 5, 6]. Defined by ISO 19650-1:2018 [3] as the use of a shared digital representation of a built asset, BIM integrates

functional, geometric, and material data across project stages. Its dimensions include 3D modeling for virtual construction and documentation, 4D integration of scheduling, and 5D linkage of cost information.

Strategic planning tools such as SWOT, SSP, and especially the Balanced Scorecard (BSC) [7–10] support performance measurement and systemic integration in large-scale projects. BSC has been applied to engineering and adapted to contexts like sustainability certifications (e.g., BREEAM) and major projects such as the London Olympics and Brazil's PISAC. In Brazil, BIM-based frameworks combined with BSC have guided multidisciplinary design, incorporating architecture, engineering systems, and cross-cutting themes like sustainability, accessibility, innovation, and ergonomics throughout the building life cycle.

2 Theoretical Framework of Balanced Scorecard

The Balanced Scorecard (BSC) is a dynamic planning and management methodology that supports continuous monitoring, evaluation, and feedback throughout the design process. It enhances strategic visualization, decision-making, communication, and performance measurement while aligning goals, indicators, and action plans with broader objectives. Functioning as an integrated dashboard, the BSC structures project monitoring systems and promotes continuous improvement, learning, and multidisciplinary coordination. Its comprehensive approach strengthens project management efficiency and supports the achievement of positive and measurable outcomes, such as:

- Strategic mapping, as it is one of the tools used to implement a strategy by identifying elements and stakeholders within a given process, including their responsibilities.
- Definition of strategic objectives, which act as previously established guidelines aimed at long-term aspirations;
- Establishment of clear performance indicators, which are easy to obtain and measure, allowing the assessment of progress toward strategic objectives;
- Setting of targets with specific outcomes, where targets serve as identifiable temporal milestones along the path toward achieving each strategic objective.

The BSC also serves as an instrument of internal and external communication, aligning strategies and individual, organizational, and interdepartmental initiatives, while taking into account all levels of information within a continuous learning process [7]. The methodology has also been applied in industrial engineering and organizational management contexts [11]

2.1 BIM (Building Information Modeling)

BIM can be understood differently depending on context: for governments, it is a policy to improve construction processes; for economists, a tool to boost industry efficiency; and for engineers, a project methodology. According to ISO standards, BIM is a 3D digital representation of a construction project containing information for building and operation. This model, created with architectural, structural, and systems software, is stored in a shared data environment and enables virtual construction, issue detection,

and decision-making. Research on automated BIM generation and interoperability has also demonstrated the growing importance of digital data integration and parametric information management [4, 5].

ISO 19650-1:2018 [3] defines specific BIM roles such as information manager, delivery manager, lead designer, task team manager, interface manager, and BIM authors. BIM processes are dynamic, evolving through implementation to optimize deliverables, including file sharing, information control, workflow management, training, and model development. These processes must be documented to ensure good practices. BIM is built on three dimensions—technology, processes, and people—supported by standards and best-practice documents like manuals, flowcharts, and diagrams.

BIM software solutions vary in features, affecting interoperability, production, and organizational capacity. Because BIM models are complex and data-heavy, they require advanced hardware and IT infrastructure. BIM processes involve multidisciplinary teams and demand collaboration, training, and adaptation. According to ISO 19650-1 [3], BIM defines roles such as information managers, delivery managers, lead designers, and BIM authors. These processes, covering data sharing, workflow management, training, and model development, must be formally documented to ensure standards and best practices.

The three fundamental BIM dimensions, technology, processes, and people, support the creation of procedures, standards, and management documentation. Such documentation was organized into three categories for the BIM scorecard: (a) strategic and pre-contract planning documents; (b) management and coordination documents for people and processes; and (c) technical documents supporting deliverable production, including manuals for nomenclature, coordination, federated models, parametric objects, file management, and design processes. Together, these categories structure BIM implementation and support project management, coordination, and quality control.

3 Methodology

The use of the BSC organizes all design related and methodological expectations of the project production process. It is important in a BIM implementation context, because helps define goals and processes of design and management. The BIM process organizes design information through computational tools originated from various design disciplines, as well as other disciplines throughout the entire process, with impacts across the whole building life cycle. To greater clarity with BIM-based project organization process, was adopted a similar method of scorecard proposed by Kaplan and Norton [7], primarily adapted by BRE sustainability assessment framework developed for the PISAC project [12]. This experience is grounded in numerous applications of BSC-like analytical frameworks worldwide [13]. Therefore, the model served as a basis for developing discussions with PISAC researchers, with the aim of constructing a broader strategic planning framework (beyond sustainability) within a BIM context, while simultaneously refining the methodological tool itself. The discussion had three stages: (a) interviews with each discipline to identify activities, according to the proposed methodology; (b) mapping relations among activities in order to establish the necessary integrations of the overall process; and (c) validation of the methodological matrix encompassing all disciplines. The process provided an empirical review, identifying and mapping requirements

that support the organization of resources and processes, with different perspectives and objectives, and integrating requirements along a timeline. This process provides a guideline for integration and, ultimately, is a framework for organizing design process and project execution monitoring.

The proposed framework systematized information into analytical categories structured through categories, principles, criteria, descriptions, indicators, verifiers, and references. The methodology was collaboratively discussed with researchers and refined through a series of internal multidisciplinary workshops, supported by theoretical, normative, and legal references. The validation process focused on the collective review and refinement of the proposed framework elements, including categories, principles, criteria, indicators, verifiers, and reference parameters. Rather than conducting a quantitative simulation, the study adopted a qualitative and collaborative validation approach, in which the applicability and coherence of the framework were assessed through technical discussions and interdisciplinary review meetings developed within the scope of the research project.

The results follow the proposed structure. The Table 1 presents the identified categories

The proposed Scorecard framework was validated through a series of internal workshops conducted with the multidisciplinary teams involved in the project development process, including architecture, complementary engineering disciplines, technical specifications, cost estimation, institutional security, BIM coordination, and environmental comfort. The workshops were carried out in up to two meetings with each team coordination, enabling a collaborative review and refinement of the elements composing the Scorecard structure, such as categories, principles, descriptions, indicators, verification criteria, and reference parameters.

The validation process aimed to ensure that the proposed framework comprehensively addressed key dimensions related to sustainability, accessibility, ergonomics, energy and water efficiency, and innovation within a BIM-based project management context. The process involved multidisciplinary technical teams composed of architects, engineers, BIM coordinators, and project specialists participating in up to two review meetings per discipline. The framework elements were evaluated according to applicability, interoperability, information management relevance, and compatibility with BIM-based workflows (Table 2).

It is important to emphasize that the study did not involve quantitative simulations or performance testing procedures. Instead, the validation was conducted qualitatively through interdisciplinary technical review processes and collaborative workshops developed within the scope of the research project.

Table 1. Categories identified.

Principles	Description
Category: Virtual Model This category consists of the integrated development of multiple disciplines simultaneously, monitored at each stage of the building project. Development is carried out in three dimensions, enabling visualization and continuous improvement of the building.	
Creation of the BIM model:	Addresses the definition of characteristics and criteria for BIM modeling of the de-signed buildings. The resulting model should be a digital version identical to the constructed building and should be used in the stages of design, planning and construction site management, building operation and maintenance, demolition, dismantling, and retrofit.
Design coordination	Defines the parameters necessary for information sharing among different teams.
BIM library	Establishes aspects for creating a repository of parametric elements that will serve as the basis for project development. The BIM library brings together materials, components, equipment, frames, and other elements used by the design disciplines, including the appropriate information and shared within a single database.
As-built updates in the virtual model	Refers to the need to plan cadastral updates of BIM-integrated projects in order to record modifications that occur throughout all phases of the building's life cycle. The objective is to enable accurate assessment of the condition of systems, allowing performance assessment and analysis of the technical and financial impacts of changes required over the life cycle.
Category: Technology This category involves defining and organizing the technical parameters necessary for the simultaneous sharing of projects within a BIM process. BIM-based project development depends on compatible and integrated technological and methodological resources.	
Software interoperability	Addresses the requirements for technological compatibility among different software applications. Design disciplines may use specific software tools; however, they must be able to exchange digital information completely and without loss of content.

(*continued*)

Table 1. (*continued*)

Principles	Description
Definition and sizing of appropriate hardware	Addresses the technical aspects of hardware configuration required for BIM project development and performance.
Common Data Environment (CDE)	Addresses aspects related to a shared environment for receiving information and storing contributions and deliverables from multiple disciplines in an organized and accessible manner. The CDE must be continuously managed to: ensure data accessibility and security, thereby supporting efficient project development.
Category: Processes and Documentation This category focuses on the functional organization of information, with the aim of standardizing production procedures and ensuring proper data, process, and product storage.	
Project process management	Addresses issues related to mapping and monitoring project activities.
Information management	Addresses issues related to communication, information flow, and information quality.
Monitoring of deliverables	Addresses aspects related to monitoring technical quality and the delivery of products.
General documentation	Addresses issues related to the proper organization and storage of documents.
Category: Technical Team This category focuses on identifying key aspects for the selection and formation of the technical team.	
Selection and organization of the technical team	Addresses aspects related to selecting and structuring technical teams according to the profiles required for BIM project development.
Assignment of responsibilities	Addresses the allocation of responsibilities to each individual within the teams, with the aim of identifying those responsible for each task and deliverable.
Cultural change	Addresses issues related to the individual adaptation required to carry out the BIM-based design process.

Table 2. Framework Application and Validation Example.

Category	Principle	Example of Indicator	Example of Verifier	Validation Approach
Virtual Model	Design coordination	Federated model integration	Coordination reports	Reviewed in interdisciplinary workshops
Technology	Software interoperability	IFC compatibility	Shared model exchange	Evaluated during BIM coordination meetings
Processes and Documentation	Information management	Communication flow	Meeting minutes and CDE records	Assessed collaboratively by project teams
Technical Team	Assignment of responsibilities	Responsibility matrix	BIM execution documentation	Validated with multidisciplinary coordinators

4 Conclusion

In conclusion, the proposed scorecard-like methodology integrated with BIM demonstrated potential as a management and planning support tool for multidisciplinary design processes. The collaborative validation process enabled the identification of relevant relationships among technical teams, project workflows, responsibilities, and information management requirements within BIM-based project environments.

Although the framework was not quantitatively tested through simulation or operational performance assessments, the internal multidisciplinary workshops contributed to refining and validating the methodological structure, supporting its applicability as a qualitative framework for organizing BIM-related processes, documentation, and strategic planning activities.

Furthermore, the structure supported the planning of project stages, workflows, and operational sequences, facilitating greater control over schedules, requirements, and expected outcomes. The integration of categories, principles, criteria, and indicators strengthened the capacity to monitor performance and detect inconsistencies at early stages. However, it is important to emphasize that the study did not advance toward the development of quantitative scoring systems, resulting in an evaluation framework that remained predominantly qualitative in nature. Even so, as a flexible and adaptive framework, the proposed BSC-oriented approach demonstrated significant potential to optimize BIM-based project management and enhance efficiency, integration, and strategic alignment within complex engineering and architectural projects.

This study presented a model in a similar format of a scorecard, based on the categories identified in the BIM design phase. The categories are related to the BIM dimensions of technology, people and processes, which generate procedures, standards, and best practices in the form of documentation. The scorecard itself can be considered part of these procedures, as it enables the evaluation of the design process and supports the

structuring of actions, assists decision-making, provides greater control over strategies, and helps identify strengths and weaknesses. The main contribution of this work is the proposal of a scorecard-like structure organized into categories for BIM in the design phase. The methodology supports the structuring of the BIM adoption process, as it encourages the definition of strategies for implementation based on its core dimensions (people, technology, and processes). It is important to emphasize that the structure is flexible and can (and should) be adapted to structural, political, and economic changes, which are common in an innovation-driven environment such as BIM. The scorecard-like methodology combined with BIM enabled a paradigm shift in the design process for project teams, as it allowed, within a shorter time frame, the analysis of formal and conceptual aspects, the identification of formal inconsistencies, and potential normative and behavioral gaps among the professionals involved in the projects. Ultimately, it facilitated the management process, especially during the phases of organizing and integrating design disciplines.

Abstract. Mitigating the pressures that climate change and the increasing frequency of natural hazards impose on urban infrastructure requires decision processes that can integrate heterogeneous evidence, quantify uncertainty, and remain operational under incomplete or conflicting data. This paper presents the architecture of a reliability-centred GeoAI decision support engine, the Nature-Based Intelligence (NBI) Geo NLP Orchestrator, developed within the EU-funded EPD Net project. NBI operationalises a risk-informed planning logic consistent with the hazard, exposure, vulnerability, and capacity framing used in disaster risk reduction [1, 7] and with the climate risk perspective emphasised for cities and critical infrastructure [2]. The engine ingests multi-disciplinary data streams, ranging from macro-socioeconomic indicators to environmental and hazard-related platforms, and processes numerical and textual evidence in parallel. "NBI Core" computes a cross-source consensus value and assigns a propagation-based reliability score that quantifies the trustworthiness of the resulting synthesis. "GeoResolver" produces location-specific environmental risk diagnostics at the local scale, while "AGIForecastEngine" learns from historical records to generate interpretable linear trend baselines relevant to infrastructure decisions. The workflow presented in this paper operationalises this claim through explicit hazard–exposure–vulnerability–capacity (HEVC) screening, two compact scoring equations, an Eskişehir pilot demonstration, and validation by triangulation, plausibility testing, sensitivity checks and data-lineage control.

1 Introduction

Climate change has become a foreground stressor on urban infrastructure, reshaping design thresholds, maintenance burdens, and failure cascades across interdependent networks. The most consequential shift is not merely that hazards are intensifying,

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 1308–1314, 2026.
https://doi.org/10.1007/978-3-032-34930-9_152

but that exposure and vulnerability are accelerating precisely where institutional capacity is weakest. IPCC AR6 WGII states directly: "the most rapid growth in urban vulnerability and exposure has been in cities and settlements where adaptive capacity is limited" [2]. Infrastructure planning must therefore engage with socio-economic conditions and governance constraints, not only with engineering specifications. Nature-based solutions (NbS) offer a planning pathway that can align climate adaptation, ecological resilience and disaster risk reduction. NbS are defined as actions to protect, manage and restore ecosystems while addressing societal challenges and generating well-being and biodiversity benefits [3]. Yet NbS benefits are not automatic; their reliability and cost-effectiveness depend on context, maintenance capacity and evidence quality [4]. Urban resilience questions require evidence with different temporal scales, spatial resolutions and validation regimes; APIs and open platforms frequently supply data that are stale, inconsistent or semantically misaligned. What is needed is an orchestration layer that treats data as contestable evidence, fuses numerical and textual sources, and quantifies reliability under contradiction and incompleteness.

This paper introduces the NBI Geo NLP Orchestrator, developed within the EU-funded EPD Net project, as a reliability-centered GeoAI decision-support engine for climate-resilient urban infrastructure. The engine formalises three commitments: risk is treated as a dynamic signal; cross-source consensus is computed across heterogeneous evidence; and trustworthiness is reported through a propagation-based reliability score. GeoResolver binds diagnostics to place, while AGIForecastEngine provides transparent trend baselines for scenario reasoning. The following sections position NBI within DRR, NbS and GeoAI, describe the methodological core, and discuss conditions for institutional use in high-stakes planning.

1.1 Background/Related Work

UNDRR frames disaster risk assessment as contingent on prevailing hazards and on patterns of population and socioeconomic development [1, 7, 8], so hazard layers alone cannot represent risk when exposure, vulnerability and capacity are moving targets. Social vulnerability research shows that demographic, socio-economic and built-environment conditions shape who is harmed and who can recover [11]. NbS must be effective and adaptive while delivering co-benefits [3], yet reliability and cost-effectiveness remain context dependent [4]. GeoAI expands computability from complex geomatics data but intensifies evidence-governance demands under heterogeneity and scale effects [5]. The gap is architectural: decision support needs an orchestration layer that binds a planning question to relevant evidence, fuses numerical and textual signals, computes a defensible synthesis, and discloses reliability under contradiction and incompleteness.

1.2 Nature-Based Intelligence as a Decision Support Language

NBI is defined as a reliability-centered GeoAI decision support paradigm for infrastructure planning. It orchestrates nature-based, hazard-related and socio-economic evidence; fuses heterogeneous numerical and textual sources; and quantifies trustworthiness through a propagation-based reliability score. The definition is constrained by DRR risk grammar, where risk depends on hazards, exposed assets, vulnerability and capacity [1,

7, 8], and by NbS validity conditions requiring interventions to be effective, adaptive and beneficial for people and biodiversity [3]. NBI therefore treats provenance, consistency and uncertainty as planning objects. Its contribution is not a catalogue of NbS measures or a black-box predictor, but an auditable reasoning layer that translates a planning question into a location-bound diagnostic, computes consensus, and signals when evidence is weak, stale or contradictory. The operational loop has three layers: signal extraction, evidence interpretation and scenario baselining. These are implemented through the orchestrator, NBI Core, GeoResolver and AGIForecastEngine.

2 System Architecture of the NBI Geo NLP Orchestrator and Pilot Operationalisation

2.1 Architectural Overview and Design Rationale

The NBI Geo NLP Orchestrator is designed as an evidence-driven decision support pipeline that begins with a planning question and ends with a reliability-signalled set of diagnostics and scenario baselines. The central architectural choice is to treat the question as an executable specification. This is dictated by DRR risk grammar: if the question is underspecified, the workflow defaults to convenient data rather than relevant evidence, producing outputs that may be computationally coherent yet decision-irrelevant. The second architectural choice is to make reliability a computed output rather than an implicit assumption. This is motivated by the empirical reality of open data ecosystems: sources are heterogeneous in temporal coverage, spatial granularity, and validation regimes. The system therefore assumes inconsistency as a normal condition rather than an exceptional failure mode. The orchestrator resolves three properties for each query: the risk domain, the spatial scale, and the time horizon required for planning relevance. This creates a stable interface between institutional decision needs and heterogeneous evidence streams, guarding against the common failure mode in which a vague question triggers a technically impressive but semantically misaligned output. Once the workflow is resolved, the orchestrator activates multi-disciplinary evidence ingestion integrating nature-related indicators, hazard and environmental signals, and socio-economic descriptors, because DRR definitions explicitly embed development patterns into risk assessment [1]. The system ingests numerical time series, semi-structured event feeds, and unstructured or lightly structured textual sources. The design constraint is harmonisation: evidence arriving with different temporal granularities, inconsistent units, and ambiguous geographic references must be transformed into a comparable internal representation without silently discarding uncertainty, which is why NBI binds ingestion tightly to the reliability layer rather than treating data acquisition as a separate stage. For risk assessment tasks, the workflow is decomposed into hazard, exposure, vulnerability and capacity components rather than treating hazard intensity as a proxy for risk.

2.2 NBI Core: Consensus Computation as Evidence Fusion

NBI Core performs cross-source synthesis by computing a consensus value across heterogeneous evidence streams, preventing single-source dominance and stabilising outputs in the presence of partial disagreement. In a planning context, this is not an exercise in statistical elegance but in institutional defensibility: if two sources disagree on

an environmental stress indicator or on the socio-economic baseline, the engine must represent the disagreement, incorporate it into synthesis, and communicate it through reliability scoring. Consensus computation is used as a controlled mechanism for producing a decision-relevant summary in the presence of heterogeneous evidence. The propagation-based reliability score is the epistemic anchor of the architecture: it tracks source support, spatial-temporal alignment, timeliness and disagreement as evidence is transformed and combined. Reliability is not treated as a fixed source attribute, because a source can be locally valid and globally misleading, current in one domain and stale in another, or coherent alone but contradictory in combination. Outputs with weak support are therefore downgraded rather than allowed to become apparently authoritative recommendations. GeoResolver protects the workflow against scale mismatch by ensuring that diagnostics remain legible at the scale of action, where exposure is defined by the presence of people, infrastructure, services and ecological assets in hazard-prone areas.

2.3 AGIForecastEngine: Interpretable Trend Baselines for Scenario Reasoning

AGIForecastEngine provides linear trend projections derived from historical records for variables relevant to infrastructure planning. These outputs are explicitly baselines, not deterministic forecasts. Linear trends are used because they are transparent, rapidly falsifiable and useful for comparing scenarios under constrained evidence, whereas more complex models can create a false sense of precision when data quality is uneven. The forecast layer is coupled to the reliability layer: weak or inconsistent evidence triggers limited-confidence signalling and shifts the output toward diagnostic stability rather than speculative extrapolation. This supports NbS evaluation by making interventions comparable as alternatives rather than presenting them as generic defaults [3, 4].

2.4 Safety-Constrained HEVC Screening, Pilot Operationalisation and Validation

NBI treats risk assessment as a safety-constrained screening problem, not as automated hazard labelling. For each spatial unit i, the workflow separates four normalised 0–1 components: hazard intensity H, exposure of people, infrastructure and services E, vulnerability of exposed elements V, and adaptive capacity C. The integrated screening score R is computed as in Eq. (1)

$$R_i = 0.30H_i + 0.25E_i + 0.25V_i + 0.20(1 - C_i) \tag{1}$$

The weights are not claimed as universal constants; they are a transparent default used for the pilot and can be recalibrated by the competent authority. Reliability score Q is reported separately as in Eq. (2)

$$Q_i = S_i^* A_i^* T_i^* (1 - D_i) \tag{2}$$

where S is source support, A is spatial-temporal alignment, T is timeliness and D is disagreement penalty. Thus, a high-risk output is not accepted merely because a hazard layer is intense; it also requires exposed assets, vulnerable conditions, insufficient capacity and adequate reliability. Three operational gates prevent unsupported outputs

from becoming planning advice. The scope gate requires an explicit location, scale, risk domain and time horizon. The evidence gate requires at least two independent evidence streams for infrastructure-relevant interpretation. The confidence gate classifies outputs as actionable screening evidence only when $Q_i \geq 0.60$; outputs with $0.50 \leq Q_i < 0.60$ are flagged for expert review, and outputs with $Q_i < 0.50$ are treated as provisional. These thresholds follow the risk-management logic of documenting criteria, uncertainty and review triggers rather than silently converting weak evidence into recommendations [9, 10]. A compact Eskişehir city-center pilot demonstrates the computation. Values are not statutory hazard values; they are reproducible 0–1 screening scores derived from open spatial proxies and the NBI workflow to show how HEVC decomposition, reliability scoring and prioritisation operate across distinct planning conditions (Table 1).

Table 1. Eskişehir pilot HEVC screening and reliability demonstration

Pilot unit	HEVC and reliability values	Screening interpretation
Porsuk corridor	H = 0.78; E = 0.82; V = 0.64; C = 0.48; R = 0.70; Q = 0.72	High priority; requires municipal GIS review
Emek	H = 0.61; E = 0.88; V = 0.86; C = 0.42; R = 0.74; Q = 0.68	High priority; cooling-refuge and schoolyard greening
Gökmeydan	H = 0.58; E = 0.81; V = 0.82; C = 0.45; R = 0.70; Q = 0.66	High priority; heat-health corridor
Sazova–Sarısu	H = 0.80; E = 0.52; V = 0.48; C = 0.62; R = 0.57; Q = 0.70	Medium priority; retention and blue-infrastructure pilot
Şeker/industrial edge	H = 0.66; E = 0.74; V = 0.58; C = 0.40; R = 0.65; Q = 0.64	Medium-high priority; green buffer and runoff control

Validation is bounded to diagnostic defensibility. Internal tests perturb missing inputs, source conflict and spatial scale; cross-source checks test consensus stability; plausibility checks test conformity with disaster-risk logic; and one-at-a-time sensitivity varies each HEVC weight by $\pm 10\%$. Data integrity records source, access date, spatial reference, temporal coverage, unit, transformation and proxy status.

3 Conclusion

This paper introduced Nature-Based Intelligence as a reliability-centred GeoAI decision support engine for climate-resilient urban infrastructure, implemented through the NBI Geo NLP Orchestrator. The motivation is a structural mismatch between how risk is defined in disaster risk reduction and how decision support is commonly implemented in practice. UNDRR frames disaster risk assessment as contingent on prevailing hazards and on "the patterns of population and socioeconomic development" [1]. If this condition is taken seriously, hazard-centric outputs and single-stream analytics are insufficient for infrastructure planning, because they fail to represent the socio-ecological coupling that produces risk. NBI responds by treating evidence fusion and trustworthiness as first-class

design objects: the orchestrator translates a planning question into an executable workflow with a propagation-based reliability score qualifying the synthesis; GeoResolver binds diagnostics to place and scale [7]; and AGIForecastEngine provides interpretable linear trend baselines enabling forward-looking scenario reasoning without promoting the illusion of high-fidelity long-range forecasting. The architecture thereby aligns with the NbS demand for actions that address societal challenges "effectively and adaptively" [3], and the reliability signalling layer prevents that demand from collapsing into generic narratives by forcing the system to disclose when evidence support is weak or contradictory. NBI is not proposed as a single predictive model, nor as an automated authority that replaces planning judgment. It is proposed as an auditable decision-support language that can stabilize infrastructure-planning workflows under heterogeneous evidence by computing consensus and communicating reliability, while keeping outputs legible as location-bound diagnostics and scenario baselines. Future work should formalize the propagation-based reliability model through systematic evaluation, extend scenario baselines beyond linear trends where warranted by data quality and governance capacity, and integrate official local datasets and sensor-based observations to strengthen accountability in operational deployments. The framework presented in this paper clarifies that NBI is a conservative screening and prioritisation layer: it does not equate hazard detection with risk assessment, and it does not substitute for statutory engineering assessment or emergency authority judgement. This paper has operationalised NBI through an HEVC screening equation, a separate reliability equation, confidence gates and an Eskişehir pilot demonstration.

Acknowledgements. This study builds on the operator-theoretic learning core described in the patent application titled "Functional Analysis–Based Artificial General Intelligence Method." The intellectual property rights of the invention are held by Eskişehir Teknik Üniversitesi and HAVELSAN. The authors also acknowledge the EU Erasmus+ supported EPD-Net project for enabling collaboration and knowledge exchange, which facilitated the development and validation of the workflow. The GeoAI outputs, HEVC screening scores, reliability calculations, prototype spatial artefacts, computational experiments and reproducible analyses reported in this paper were produced within the NBI/EPD-Net scientific workflow. General-purpose generative AI tools were used only for drafting support, language refinement and prototype visual communication; all scientific claims, methodological choices, calculations, interpretations and final revisions were reviewed and approved by the authors.

Abstract. This review explores the potential of geopolymers for 3D printing applications, with a focus on construction. The study first examines the prospects of 3D printing technology, highlighting its growth, particularly in housing construction, and the requirements for suitable materials that address current challenges related to climate change and resource scarcity. Modern research indicates that geopolymers are highly suitable alternatives to Portland cement, offering comparable or superior physical and mechanical properties without the need for costly additives. Their environmental advantages include reduced CO_2 emissions, lower energy requirements during manufacturing, and the potential use of secondary raw materials through industrial symbiosis. The review further discusses the enhancement of the reactivity of geopolymer binders through mechanical activation applied to precursors. This method is more economical, efficient, and environmentally friendly compared to calcination, as it requires lower energy consumption and does not involve high temperatures, which reduces the carbon footprint. Additionally, mechanical activation enhances the reactivity of the materials, which can accelerate the curing process and reduce production time. Two generations of geopolymers are examined: metakaolin-based and fly ash-based, with particular attention to the mechanical activation of fly ash and clay minerals, especially kaolinite, which increases strength and enables production without thermal curing. The findings demonstrate that 3D printing technology in construction is expected to expand, and geopolymers based on mechanically activated kaolin are promising materials for this application, highlighting their relevance to sustainable and innovative building technologies.

1 Prospects for 3D Printing

Construction 3D printers have appeared on the market relatively recently and are now developing very rapidly, disrupting the conservative construction industry. By reducing material consumption, saving time, minimizing space requirements, and allowing unprecedented geometric freedom, these printers accelerate construction and eliminate

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 1315–1322, 2026.
https://doi.org/10.1007/978-3-032-34930-9_153

the human factor, as demonstrated by the case studies reviewed in this article. According to the Grand View Research report [1], the 3D printing market is projected to grow at a cumulative annual rate of 20.8% from 2022 to 2030, with the number of printers in use worldwide increasing from 2.2 million to 21.5 million units.

Below are examples of building and construction projects implemented using 3D printers.

China:	A 10-unit residential building (2015), a 1,100 sq. m mansion (2015), and a 105.91 sq. m farmhouse (Wujiazhuang Village, October 2021) [2–5].
UAE:	A 640 sq. m municipal office (Dubai, 2016–2019) [6–10].
Russia:	A 38 sq. m house (Stupino, Moscow Oblast, 2017) and a 34-unit cottage village of 80 sq. m each (Zelenodolsk District, Republic of Tatarstan, 2022) [6, 11, 12].
USA:	A 32.52 sq. m house (Austin, Texas, 2018); a wind turbine tower (2020); a prefabricated two-bedroom home (Southern California, 2022); a 185.81 sq. m house (Long Island, New York, August 2022); and a social housing project of two single-story houses (63 sq. m each, 2.2 m-high printed walls; La Unión, western Antioquia, Colombia, April 2026) [6, 13–20].
Europe:	A 30 sq. m house (Ravenna, Italy, 2018); a 95 sq. m house (Nantes, France, 2018); a 60 sq. m house (Ravenna, Italy, 2019–2021); an apartment building (380 sq. m, Wallenhausen, Germany, November 2020–April 2021); and a 94 sq. m house (Eindhoven, Netherlands, April 2021) [6, 20–29].
Africa:	A school building (55.74 sq. m, Malawi, June 2021) [30].
Australia:	A recycled plastic house (28 sq. m, currently under production, May 2026) [31].

From the list above, it is evident that 3D printing will become increasingly attractive, as it addresses challenges such as constructing houses in cramped conditions. Traditional housing methods are often too time-consuming and expensive, making homes unaffordable for many people. At the same time, our planet is facing increasing pollution and the progressive depletion of natural resources. 3D printing technology enables houses to be built relatively cheaply and quickly [20, 32, 33]. For instance, Cementos Argos constructed two single-story houses, each with a 63 sq. m floor plan, 3D-printed directly on site in just 16 h over 3 days. According to COBOD, this process is 30% faster than traditional building methods [20]. Similarly, ICON aims to address homelessness by producing small houses that can be 3D-printed in 48 h at a cost of only $10,000 [32]. In addition, this technology helps conserve conventional concrete—where Portland cement is a significant source of CO_2 emissions—and reduces material waste [20].

In the context of research on projects implemented using 3D printing from 2015 to 2026, it can be seen that 3D printing is most often used for the construction of walls. This approach allows for both manual and automated work to be performed simultaneously, saving time and money. For example, the walls of a school with an area of 55.74 sq. m were printed in just 18 h. According to the author [30], such a school will help attract more students and provide solutions for a country facing a shortage of 36,000 classrooms. Filling this deficit using traditional construction methods would take approximately 70 years. Another example is the “Yhnova” house [24, 25], which was part of a social housing project aimed at building affordable, adaptive, and energy-efficient homes in

the shortest possible time and at minimal cost. Printing the 95 sq. m house took 54 h, not including the 4 months that contractors spent installing windows, doors, and roofing. The construction of such a house cost 20% less than an identical house built using traditional methods. Yet another example is the "Gaia" house [21], with an area of 30 sq. m, built in 240 h. This prototype has the potential to serve as a model for constructing homes in poorer countries or regions where housing affordability is a critical issue.

From all of the above, we can conclude that 3D printing is no longer just a theoretical concept, but a practical and achievable solution to modern and future human needs. There are already projects aimed at creating suburban neighborhoods using the same construction principles [12]. It is also clear that in the future, 3D printing will be applied not only to residential buildings [10, 14, 34].

2 Studies on Geopolymers as a Material for 3D Printing

Population growth and ongoing urbanization continue to drive strong demand for cement and concrete, which are key materials for infrastructure and construction. According to the International Energy Agency (IEA) [35], global cement demand in 2026 is estimated at approximately 4.2–4.3 billion tonnes, with long-term projections suggesting an increase to 4.7 billion tonnes by 2050 (~12%). At the same time, alternative scenarios indicate the possibility of demand stabilization or even decline due to the adoption of new construction materials and improvements in resource efficiency.

Against this background, there is growing interest in geopolymer compositions as promising materials for construction and 3D printing. Geopolymer binders are considered a more environmentally friendly alternative to conventional cement, as their production can significantly reduce the carbon footprint while maintaining high mechanical performance and durability [36]. The use of geopolymers offers opportunities for developing a more sustainable construction industry that addresses current challenges related to climate change and resource scarcity.

Table 1 below compares the density and strength of selected printed geopolymer specimens with those of molded specimens.

Table 1. Characterization of printed and molded geopolymer specimens (density and strength).

References	Technology	Density (g/cm^3)	Comp. strength (MPa)		Flex. strength (MPa)	
			7 days	≥ 28 days	7 days	≥ 28 days
[37]	printed	2.0–2.3	22.7–55.2	34.2–95.6	5.9–10.3	8.7–12.6

Nowadays, geopolymers are classified into five generations [48]. As shown in Table 2, the most extensively studied compositions for 3D printing are metakaolin-based (first-generation) and fly ash-based (second-generation) geopolymer mixtures.

2.1 Mechanical Activation of Fly Ash and Kaolin: A More Sustainable Approach

In this study, a search was also conducted for more sustainable methods for the development of geopolymer formulations suitable for 3D printing. It was found that one such solution could be the mechanical activation of fly ash and kaolin. A comparative analysis of methods for enhancing the physico-mechanical properties of fly ash-based geopolymers was performed [47, 49–56]. Methods of mechanical activation of kaolin clays were also examined [57–60], and an analysis of approaches to improving the physico-mechanical properties of geopolymers based on mechanically activated kaolin was carried out [61–64]. It was concluded that the mechanical activation of fly ash and kaolin represents a more sustainable approach compared to thermal activation, as it involves lower energy consumption and potentially reduced CO_2 emissions. However, its effectiveness depends on the processing conditions, energy source, and the required reactivity of the material.

3 Conclusions and Future Recommendations

This review first considers the prospects for 3D printing development. It was found that this technology holds promise for affordable and emergency housing projects, especially in developing countries, and can be scaled up for larger residential and commercial buildings. Secondly, the use of non-cementitious materials is explored, reflecting the search for new binder systems for 3D printing. The use of geopolymers in this technology shows significant potential, though their properties depend on the precursor and curing conditions. Researchers typically propose tailored recipes based on local raw materials and environmental factors. Based on compressive and flexural strength tests, geopolymer mixtures are considered a viable alternative to cement-based compositions in 3D printing construction. Thirdly, fly ash, granulated blast furnace slag, and calcined kaolin are the most studied precursors for geopolymer formulations used in 3D printing. However, the availability of fly ash is declining as coal-fired power plants are phased out. By 2050, the availability of these materials is expected to decrease by more than half, increasing competition for these by-products. This underscores the importance of studying alternative geopolymers based on clay minerals, which are widely available and can meet the demands of the cement industry. Mechanical activation of clay minerals can also reduce energy consumption and carbon footprint, making geopolymer formulations more sustainable.

It is recommended to develop geopolymer formulations based on mechanically activated kaolin, considering the following parameters:

Viscosity and yield stress: The mixtures should exhibit shear thinning behavior similar to cement pastes. No plateau should be observed when using the Stress-Plateau method, and the Bingham model should show a good linear relationship between shear stress and shear rate. The coefficient of determination (R^2) for different models (Modified Bingham, Stress-Plateau, Herschel-Bulkley, De Kee, and Casson) should be consistent to ensure measurement reliability.

Mechanical properties: The mixtures should be designed to achieve maximum compressive strength by promoting pore filling and matrix densification. In this context, various curing strategies for 3D-printed mortars, including ambient, thermal, moisture-controlled, electrical, and hybrid approaches, should also be considered.

Data Availability Challenges in Construction to Support Circularity and Decision-Making Processes

Juan Antonio Ferriz-Papi(✉), Vahid Babaveisi, and Angel Jimenez-Aranda

University of Salford, Manchester M5 4WT,, UK

Vahid_1110@yahoo.com

Abstract. The construction industry plays a major role in the transition toward a circular economy, yet its progress is constrained by persistent challenges in data availability and quality. Lifecycle-based circularity assessments require detailed information such as material composition, quantities, structural performance, maintenance records and end-of-life scenarios to support accurate decision-making, but this information is often fragmented across stakeholders who operate in isolated digital environments and rely on incomplete or outdated documentation. Legacy buildings add another layer of uncertainty due to poor as-built records and limited material traceability, making it difficult to identify feasible pathways for reuse, recycling and recovery.

This paper presents a PRISMA-based systematic review of peer-reviewed studies from 2020 onwards which aims to examine data-availability barriers specific to construction and their implications for implementing circularity strategies, including material passports, design for disassembly and closed-loop material flows. The analysis identifies recurrent challenges across design, manufacturing, construction, use and end-of-life stages, as well as five key data categories and the stakeholder groups responsible for them. It also synthesizes technical and organizational solutions such as interoperable BIM-based data schemas, standardized digital product passports, digital inventories, IoT-enabled performance monitoring, geospatial material stock mapping, blockchain-supported traceability and collaborative data-sharing platforms. By bringing together current initiatives and best practices, the paper outlines a practical roadmap for overcoming data challenges and supporting more robust circularity practices across the construction sector.

Keywords: construction · circular economy · data availability · traceability · digital product passport · BIM

1 Introduction

The construction sector requires a digital transition shift to support circular economy implementation. Efforts are being taken to support this shift, but it is currently held back by limited data availability across the asset lifecycle. Information on aspects such as material composition, quantities, performance and end-of-life options is scattered across

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 1323–1331, 2026.
https://doi.org/10.1007/978-3-032-34930-9_154

organizations and systems, or not structured properly, this way becoming fragmented, inconsistent and difficult to access [1, 2]. Therefore, practitioners often base construction project decisions on incomplete, non-comparable data, and makes it difficult to evaluate circularity on a consistent, evidence-based way and support decision-making processes [2, 3].

Data gaps have evident consequences. Circular strategies such as design for disassembly (DfD), high-value reuse, selective demolition and robust life cycle assessment (LCA) all depend on reliable and interoperable information, but stakeholders involved (e.g. designers, contractors or asset managers) cannot have a full picture of material stocks, flows and performance over time [3]. As a result, it is not easy to identify opportunities to recover value from existing buildings, and circularity solutions tend to remain confined to isolated pilots or high-profile projects rather than influencing day-to-day practice across the sector [2, 4].

The aim of the article is to understand where and why data-availability problems arise along the construction lifecycle, which types of data and stakeholders are most affected and what kinds of digital solutions are being proposed to address them [1, 5]. Through a systematic literature review, it is developed a clear picture of the key data categories, actors and decision points that matter for circular construction. The intended impact is to provide researchers, practitioners and policy-makers with a more concrete map of priority data issues and promising digital solutions, supporting more targeted research agendas and guiding investments in digital infrastructure, as well as indicating more effective regulations and guidance that better support circular practices in the built environment [2, 4].

2 Methodology

This study adopts a systematic literature review following PRISMA 2020 [6] to examine data-availability challenges and digital solutions for the implementation of circular economy strategies in construction. The review protocol specified the research questions, search strategy, eligibility criteria and data-extraction procedures in advance to ensure transparency and reproducibility.

The literature search was conducted in Scopus database due to its broad coverage of peer-reviewed journals and conference proceedings in construction, engineering and environmental fields. The final search string was: “construction” AND “circular economy” AND (“data” OR “data availability”) AND (“challenge” OR “challenges” OR “barrier” OR “barriers”) AND “digital” AND (“solution” OR “solutions”).

Results were limited to English-language scientific articles (journals and conferences) published from 2020 onwards, since preliminary checks found little relevant work before this date. No restrictions were placed on geographical scope or methodological design, whenever the construction sector was explicitly addressed.

A total of 37 records were identified in the search. In a first step, seven papers were excluded because full-text access was not available. For the rest, titles and abstracts were reviewed to exclude publications which were clearly not linked to construction, circular economy or data-related challenges and digital solutions, as well as non-article items (e.g. editorials, short notes). Next, a full-text screening identified those articles

that explicitly focus on construction or the built environment, include circular economy, discuss data-related aspects (availability, quality, interoperability, traceability, monitoring) and address the use of digital technologies. This process yielded a final sample of 22 articles, including primary research and review papers.

For each included study, information was extracted using a structured template covering bibliographic details, study context, challenges per lifecycle stage, data types, stakeholder groups, critical decision points, digital technologies, solutions and limitations for implementation. The extracted descriptions were coded and harmonized to enable cross-comparison across studies. The dataset forms the basis for the synthesis of challenges, data needs, stakeholder roles and solutions in sect. 3.

3 Findings

3.1 Data Availability Challenges

Table 1 presents the main challenges identified for data availability that limit the implementation of circular economy strategies across the construction lifecycle. The meta-analysis developed compares how data gaps happen at different stages of the built asset life cycle. This cross-cutting view highlights that, although the specific issues vary by lifecycle stage, they consistently relate to fragmentation, lack of standardization and limited feedback loops.

Table 1. Main challenges for data availability.

Design
1. Static and geometry-based BIM Models with limited integration of cost, circularity and waste data and weak connectivity between systems [1, 4, 7, 8]; 2. Scarce data on existing buildings and material stocks [4, 5, 8, 9]; 3. Fragmented, non-standardized definition of inventories, passports and circularity indicators, limiting interoperability and comparability [3, 4, 10–12]; 4. Lack of guidance on how to combine structural, energy, environmental and occupancy data, or on which product-level attributes are needed to support future reuse [4, 8, 10–17].
Manufacturing
1. Low digitalization and fragmented records of environmental and lifecycle data across material and product supply chains, and weak integration of manufacturers' internal systems with tracking platforms [5, 8, 9, 11, 13–16, 18]; 2. Incomplete, inconsistent data on material properties, environmental impacts and recovery rates across databases and companies [4, 5, 8, 10, 13–15, 18]; 3. Lack of interoperable standards for product-level circularity and passport data across suppliers and regions [3, 4, 9–12, 15, 16, 18]; 4. Technical and organizational barriers to real-time data capture from production, especially for SMEs [8, 11, 14, 15, 18, 19].

(*continued*)

Table 1. (*continued*)

Construction
1. Fragmented, poorly integrated digital tools on site, with low use of Building Information Modelling (BIM) and poor interoperability between platforms and devices [4, 5, 7–9, 14, 16–21]; 2. Non-standardized and largely manual collection of data on materials, waste, logistics and productivity, with lack of links to BIM and circularity indicators [4, 5, 7–9, 14, 18–23]; 3. Difficulties integrating tracking technologies and digital twins (DT) with BIM to locate and monitor components in real time [4, 8, 12, 14, 16–20]; 4. Scarcity of robust, labelled datasets for AI-based monitoring of progress, quality and construction and demolition waste [4, 9, 12, 14, 16, 19, 22, 23].
Use/maintenance
1. Limited, non-standardized recording of operational data, and weak integration into BIM or inventory systems [3–5, 7, 8, 10, 13–18, 20, 21]; 2. Persistent gaps between predicted and measured performance (e.g. energy, resource use) due to missing in-use data [4, 7, 10, 13–15, 21]; 3. Inefficient feedback loops from facility-management systems to design models and product data [3, 5, 8, 10, 16–18, 20, 21]; 4. Poor component traceability, condition and modifications during use, limiting potential reuse and recovery options [2, 4, 8, 10, 12, 16, 18, 21, 23].
End of life
1. Incomplete, unreliable information on material composition, hazards and recyclability of existing assets [3–5, 9, 10, 13–15, 21, 23]; 2. Lack of structured digital inventories and passports, and limited open data on construction and demolition waste (CDW) composition and recovery options, limiting selective demolition, reuse and recycling at large scale [3–5, 8–10, 12–14, 16, 18, 21, 23]; 3. Weak digital traceability for reclaimed elements, undermining trust and quality assurance [4, 8–10, 12, 16, 18, 21]; 4. Methodological and data gaps for representing alternative end-of-life and circular scenarios in LCA and decision-support tools [4, 5, 8, 10, 13–15, 18].
Whole life cycle
1. Strong fragmentation of data, tools and responsibilities, and a lack of common data models and standards linking product, building and city-level information [1–4, 8, 10–12, 16]; 2. Data quality, completeness and traceability issues that accumulate from early design to end-of-life and reduce confidence in circularity assessments [2, 4, 5, 7–10, 13–16]; 3. Limited longitudinal data and feedback to support learning across projects and assets over time [2–4, 7–10, 14, 16, 18]; 4. Organizational and governance barriers that prevent stakeholders from sharing data and maintaining lifecycle-wide digital records [2–4, 8–10, 12, 16–18].

3.2 Types of Data, Stakeholders and Critical Decision Points for Circularity

This section synthesizes the reviewed studies to clarify which data support circular practices in construction, which stakeholders generate and use them, and when these data become critical for decision-making. The literature shows that circularity depends less on collecting new data than on ensuring that existing information is structured, interoperable, and trustworthy so it can move across organizational boundaries throughout the

asset lifecycle [1–5, 7–10, 12, 16]. Based on the coded fields "Types of data," "Stakeholders," and "Critical decision points," a framework links data categories, actors, and decisions by grouping stakeholders into five roles according to their responsibilities for producing, managing, and using circularity data. Table 2 maps these groups to key data categories and the digital systems used to manage them, highlighting coordination needs to better support circular strategies.

Table 2. Main stakeholder groups, data categories and typical tools and systems.

Stakeholder group	Main data categories	Typical tools and systems
Upstream actors (manufacturers, suppliers, logistics)	Product geometry and technical specs; environmental and circularity data (EPDs, recyclability, LCA); prices and logistics costs; basic traceability data [2–5, 8–10, 12, 16, 18]	ERP/PLM/MES systems; LCA/EPD databases; product data templates; passport/EPD portals; logistics tracking [2–5, 8–10, 12, 16, 18].
Project delivery actors (designers, engineers, contractors, site/BIM managers)	BIM geometry and quantities; design-stage LCA and circularity KPIs; project and waste costs; site productivity and logistics; installed-product traceability [1, 3–5, 7–10, 12–14, 16–21].	BIM authoring tools; CDEs; 4D/5D planning and cost tools; site-management and ERP software; on-site tracking (RFID/ QR/sensors) linked to BIM/DT [4, 5, 7–10, 12, 14, 16–21].
Asset and city actors (owners, facility/asset managers, housing associations, infrastructure operators, municipalities)	Operational and maintenance data (energy, comfort, failures); portfolio-level environmental and circularity metrics; lifecycle costs; building and stock inventories [1–5, 8–10, 12, 14, 16, 18, 21].	CAFM/CMMS; BMS/BEMS; asset- and portfolio-management tools; GIS; digital building logbooks and inventory platforms; dashboards linked to BIM/DT [2–5, 8–10, 12, 14, 16, 18, 21].
Regulatory and governance actors (policymakers, standardisation bodies, certification schemes, auditors)	Regulatory indicators and reporting data; circularity and waste metrics; compliance-oriented traceability and passport information; aggregated performance statistics [2–5, 8–10, 12, 16, 18, 20, 21].	Regulatory and reporting portals; certification/rating systems; standardized data models and code lists (e.g. for BIM, waste, passports) [2–5, 8–10, 12, 16, 18, 21].

(*continued*)

Table 2. (*continued*)

Stakeholder group	Main data categories	Typical tools and systems
Market and innovation actors (platform providers, technology vendors, consultants, researchers)	Integrated views of all data categories to enable analytics, benchmarking and circular business models [2–5, 8–10, 12–14, 16–21].	Circularity and reuse platforms; digital marketplaces; data-integration platforms/data lakes; analytics and AI services; development environments for BIM, DT, inventories and passports [2–5, 8–10, 12–14, 16–21].

The "Critical decision points" highlighted in the reviewed articles show that the value of data for circularity is concentrated in a relatively small number of key moments across the life cycle. These can be grouped into five main clusters:

(i) Early concept and schematic design decisions fix the main spatial, structural and material choices, so access to reliable geometric, environmental and cost data, together with information on reuse and recycling options, is essential to avoid locking in linear solutions [1, 3–5, 7–10, 12–16, 18].
(ii) System and material selection then specifies products and suppliers, where detailed technical data, environmental declarations (EPD), circularity indicators and origin information are needed to compare alternatives and check whether they support disassembly, reuse or high-value recycling [2–5, 7–10, 12–16, 18, 21].
(iii) During construction, planning and site management decisions depend on data about quantities, sequencing, logistics, waste options and on-site monitoring. The degree of integration between BIM, site-management tools and tracking technologies strongly influences how far circular practices can be implemented [4, 5, 7–10, 12, 14, 16–21].
(iv) In the use phase, major refurbishment, retrofitting and maintenance decisions require up-to-date information on component condition, performance, accessibility and potential reuse markets, alongside data on environmental and economic impacts of different interventions [3–5, 7–10, 12–16, 18, 20, 21].
(v) Demolition and deconstruction strategies determine whether buildings become waste streams or material banks. At this stage, high-quality inventories, material passports and data on hazards, recyclability, markets and regulations are needed to plan selective dismantling, reuse and recycling. Otherwise, conventional demolition and low-value recycling remain [2–5, 8–10, 12, 14–16, 18, 21, 23].

These decision points indicate that circularity depends on aligning data and stakeholder responsibilities, rather than trying to capture all possible data continuously.

3.3 Emerging Digital and Organizational Solutions for Circular Data Flows

This section examines how digital and organizational solutions can address data-availability challenges and help embed circular practices in construction, arguing that

progress depends on three complementary layers: (i) information backbones that integrate lifecycle data across actors and stages, (ii) data-capture and traceability technologies that feed these backbones with reliable, timely information, and (iii) governance and standards that make data sharing and interoperability viable in practice. Rather than adding more tools, the priority is to align these layers so that circularity-relevant data are structured, connected, and maintained where they can influence design, construction, operation, and end-of-life decisions. Table 3 outlines main solution types, technologies typically involved in each layer, and their role in enabling circular data flows, improving data availability and usability for circular construction.

Table 3. Digital solutions for circular data flows

Solution layer	Technologies	Main role
Information backbone [1–5, 7–10, 12–14, 16–21]	BIM/CDE; semantic digital twins; digital inventories and building logbooks	Integrate and host lifecycle data across stages and stakeholders
Data capture & traceability [2–5, 8–10, 12–14, 16–21]	IoT/sensors; laser scanning; robotics; material/digital product passports; product circularity data sheets; circular economy platforms	Populate backbone with reliable, real-time and traceability data
Governance & standards [1–5, 7–12, 14–21]	BIM/IFC standards; waste/material codes; LCA schemas; passport standards; data-sharing agreements; procurement clauses; skills and roles	Enable interoperability, trust and sustained data quality

Further analyses can include other practical factors such as implementation conditions, costs organizational readiness and real-world barriers. Progress towards circularity will depend on the co-evolution of digital infrastructures, standards and practices that improve data availability and usability across the construction lifecycle.

4 Conclusions

The review confirms that data availability remains a major challenge for circular construction. Information across the asset lifecycle stages is often scattered, incomplete, and difficult to connect, with particularly large gaps for existing buildings and later lifecycle stages where decisions on reuse, refurbishment, and demolition are made. These conditions limit the ability of designers and practitioners to plan and implement circular strategies beyond isolated pilot projects, even though a range of digital tools (e.g., BIM, CDE, digital twins, inventories and logbooks, IoT monitoring, and product or material passports) already exist and could address many of these gaps if used in a more coordinated way. Their limited impact is mainly due to poor interoperability, fragmented

responsibilities, and weak data governance rather than technological constraints, underscoring the need for shared data models, clearer responsibilities for data management, and stronger alignment between research, practice, and policy so that relevant data are captured and used throughout the facility lifecycle.

The review also has some limitations, as the search was restricted to the Scopus database, a relatively high-level search string, only peer-reviewed journal and conference papers, with 7 papers excluded due to lack of full-text access. Therefore, some studies may have been missed. Future research should therefore broaden databases and document types, deepen full-text and case-based analyses, and empirically test the digital solutions identified here to validate, refine and extend the roadmap for improving data availability in support of circular construction.

A Machine Learning–Based Hybrid Framework for Multi-Criteria Material Selection

Berfin Yildiz(✉)

Department of Architecture, Bilkent University, Ankara, Turkey
berfin.yildiz@bilkent.edu.tr

Abstract. The increasing impacts of global warming have made energy-efficient design and low-carbon material selection critical challenges in the built environment. Externally insulated composite wall systems involve complex multi-criteria decision-making processes because operational thermal performance is closely related to the embodied carbon associated with material production. This study proposes a hybrid methodology that integrates machine learning (ML) and multi-objective optimization to evaluate material combinations, simultaneously considering both thermal performance and embodied carbon indicators. A dataset was constructed using key design inputs, including insulation material type (mineral wool, glass wool, EPS, XPS, etc.), layer configuration, insulation thickness, climate zone, and wall surface area. Based on these inputs, a multi-output regression model was developed to predict both thermal performance and embodied carbon. Replacing computationally expensive simulations with ML-based predictions significantly accelerates the exploration of larger design spaces. The predicted performance indicators were then integrated into a multi-criteria evaluation framework that also incorporates acoustic insulation performance as an additional decision parameter. The results indicate that aerated autoclaved concrete (AAC) combined with glass wool provides balanced performance in several climatic conditions. The findings demonstrate that ML-based decision-support models can substantially improve computational efficiency while enabling broader exploration of sustainable material alternatives. However, the proposed framework relies on the scope and quality of the available dataset and considers a limited set of wall assemblies and insulation materials. Despite these limitations, the methodology provides a scalable approach for supporting early-stage material selection in performance-driven architectural design.

Keywords: Machine learning · Embodied carbon · Thermal performance · Multi-objective optimization · Sustainable material selection

1 Introduction

The construction sector is responsible for a substantial share of global energy consumption and greenhouse gas emissions. The environmental impacts associated with buildings occur not only during the operational phase but also throughout the life cycle of construction materials, including production, transportation, and installation. For this reason, sustainable building design increasingly requires a holistic perspective that considers both

operational energy and embodied impacts. Building energy consumption is influenced by multiple parameters, including climatic conditions, occupant behavior, mechanical systems, and architectural design decisions. Among these factors, the building envelope plays a crucial role in regulating heat transfer between indoor and outdoor environments, thereby significantly influencing overall building energy efficiency. Externally insulated composite wall systems enable a wide range of design alternatives through variations in material types, insulation thicknesses, and layer configurations. However, this diversity also increases the number of design alternatives, making insulation material selection a complex multi-criteria decision problem.

Traditionally, evaluating such alternatives relies on physics-based simulations and detailed thermal calculations. Performing energy analyses for each alternative separately can be computationally intensive, particularly during early design stages. As a result, designers often evaluate only a limited set of alternatives, which may lead to overlooking optimal solutions. Recent advances in machine learning (ML) offer promising opportunities to address these limitations. ML models can learn complex relationships from data and rapidly predict building performance, enabling efficient exploration of large design spaces. In this context, the present study proposes a machine-learning-based hybrid material selection model for externally insulated composite wall systems. The model simultaneously predicts thermal performance and embodied emissions, integrating these outputs into a multi-objective decision-making framework that also considers acoustic insulation performance. By combining ML-based prediction with multi-criteria evaluation, the proposed approach aims to provide a computationally efficient decision-support method.

2 Related Works

2.1 Machine Learning in Performance Prediction

In recent years, data-driven models have been used to predict building energy consumption, thermal performance indicators, and environmental impacts by learning complex relationships between material properties, climatic conditions, and design parameters. Compared with traditional physics-based simulations, ML models can significantly reduce computational time while enabling rapid exploration of large design spaces. Several studies have demonstrated the potential of ML approaches for predicting building energy performance and lifecycle impacts. Sharif et al. [1] developed artificial neural network models capable of predicting energy consumption, lifecycle cost, and environmental indicators of building systems. Similarly, Abdolvand et al. [2] proposed an integrated ML framework for estimating building energy loads together with embodied energy metrics. Chen et al. [3] introduced a BIM-based prediction system that evaluates thermal performance and embodied energy values of insulation materials. Zhou et al. [4] investigated the relationship between operational and embodied carbon in energy-efficient buildings, showing that the relative importance of embodied carbon increases as operational energy demand decreases. These studies demonstrate that ML-based surrogate models can provide reliable predictions while significantly reducing the computational burden of detailed simulations. Despite these advances, most ML-based studies primarily focus on predicting energy consumption or thermal performance indicators,

while other performance aspects relevant to construction material selection are rarely incorporated into the modeling framework.

2.2 Performance Criteria in Material Selection

Establishing performance criteria is crucial for evaluating materials in building envelope design. Early studies focused primarily on improving operational energy efficiency by optimizing insulation materials and wall assemblies. Roberts et al. [5] compared different insulation materials in terms of thermal performance and environmental impact, highlighting the critical role of material selection in reducing building energy demand. With increasing attention to sustainable construction, lifecycle assessment (LCA) indicators have also been incorporated into evaluation frameworks for insulation materials. Carreras et al. [6, 7] proposed approaches that simultaneously evaluate the lifecycle environmental impacts and the economic performance of building envelope components. These studies emphasize the importance of considering embodied energy and carbon emissions associated with material production and transportation in addition to operational energy performance.

In addition to thermal and environmental considerations, acoustic insulation represents another important performance aspect in building envelope design. The composition and configuration of wall assemblies significantly influence sound transmission and indoor acoustic comfort [8, 9]. Fibrous insulation materials, such as mineral wool and glass wool, have been widely studied for their combined thermal and acoustic properties [10].

In particular, acoustic performance is rarely incorporated into multi-objective decision-making processes. To address this gap, the present study proposes a machine-learning–based hybrid framework for selecting insulation materials in externally insulated composite wall systems. The proposed model predicts thermal performance and embodied indicators using a multi-output ML model, while acoustic insulation performance is incorporated as an additional criterion in the subsequent multi-objective evaluation process. This approach enables a more comprehensive assessment of insulation materials while significantly reducing computational costs associated with traditional simulation-based methods.

3 Methodology

This study proposes a hybrid framework that integrates ML–based performance prediction with a multi-objective material selection approach for externally insulated composite wall systems. The framework aims to support the selection of insulation materials by simultaneously considering thermal performance, embodied carbon emissions, and acoustic insulation performance. The overall workflow of the proposed methodology can be summarized as follows: (i) preparation of the material dataset, (ii) training of the multi-output machine learning model, (iii) prediction of thermal and environmental performance indicators, and (iv) multi-objective evaluation and material selection. This hybrid approach allows rapid evaluation of a large number of design alternatives while maintaining a comprehensive performance assessment. The system boundaries of

the study are defined at the building envelope component level, focusing on material production, transport, and assembly stages (cradle-to-site). Operational energy effects are indirectly represented through thermal performance indicators, while end-of-life scenarios are not included.

3.1 Dataset and Input Parameters

The dataset was generated based on combinations of commonly used materials in externally insulated composite wall systems. The wall assembly consists of interior plaster, a structural wall layer, an insulation layer, and exterior plaster. As structural wall materials, conventional brick and autoclaved aerated concrete (AAC) blocks were considered. For the insulation layer, four widely used materials were evaluated: expanded polystyrene (EPS), extruded polystyrene (XPS), mineral wool, and glass wool. Material properties are obtained from manufacturer technical datasheets and Environmental Product Declarations (EPDs), while environmental indicators are derived from lifecycle assessment datasets. The input parameters used in the ML model are shown in Table 1.

Table 1. Input features

Feature	Unit	Description	Source
Material Property			
Density	kg/m^3	bulk density of insulation material	technical sheets, EPD
Thermal conductivity	W/mK	thermal conductivity coefficient	technical sheets, EPD
Recycled content	%	proportion of recycled material content	technical sheets, EPD
Additive content	%	percentage of binder or additives	technical sheets, EPD
Design Variable			
Thickness	mm	thickness of material layer	design parameter
Mass per area	kg/m^2	calculated material mass per square meter	design parameter
Window to wall ratio	%	ratio of total window area to exterior wall area	design parameter
Logistics			
Transport emission factor	$kgCO_2e/(ton{\cdot}km)$	emission factor for material transport	EPD

(*continued*)

Table 1. (*continued*)

Feature	Unit	Description	Source
Transport distance	km	distance between manufacturer and construction site	location parameter
Climate			
Heating degree days (HDD)	°C·day	indicator of heating demand	
Cooling degree days (CDD)	°C·day	indicator of cooling demand	
Climate zone	categorical	Climate classification	TS825

3.2 ML Model for Performance Prediction

A machine–learning–based surrogate model is developed to predict key performance indicators for insulation materials. The model is designed as a multi-output regression framework capable of simultaneously predicting thermal performance and embodied environmental impact indicators. In this study, the Extreme Gradient Boosting (XGB) [11] algorithm was selected as the primary regression model due to its high predictive performance, robustness to nonlinear relationships, and effectiveness when working with relatively small to medium-sized datasets. XGB is an ensemble learning method based on gradient boosting decision trees, which iteratively improves prediction accuracy by combining multiple weak learners into a strong predictive model. Compared with traditional machine learning algorithms, XGB offers several advantages, including regularization mechanisms that reduce overfitting, efficient handling of heterogeneous input features, and strong predictive performance in regression problems. The model outputs include: thermal performance indicators (thermal resistance, R-value) and global warming potential (GWP). The ML model learns the relationships between the input variables and the performance indicators using the prepared dataset.

3.3 Multi-Objective Material Selection

After obtaining the predicted thermal and environmental performance indicators, a multi-objective evaluation process is used to identify suitable materials. In addition, acoustic performance was incorporated as an additional decision criterion in the optimization process. Acoustic insulation performance was quantified using weighted sound reduction index values and empirical correlations with material density, thickness, and porosity [10]. For composite wall assemblies, the overall acoustic performance was approximated using mass-law-based formulations and layer-wise contribution models, enabling consistent integration into the multi-objective evaluation framework. To determine optimal trade-offs between these competing objectives, the Non-dominated Sorting Genetic

Algorithm (NSGA) III was employed. NSGA-III is a widely used evolutionary optimization algorithm for solving multi-objective problems and generating Pareto-optimal solutions. The algorithm iteratively evolves a population of candidate solutions using selection, crossover, and mutation operators, ranking them by Pareto dominance and crowding distance. Pareto-based analysis is used to determine optimal trade-offs between thermal efficiency and embodied energy while ensuring adequate acoustic performance. These solutions provide designers with a range of alternative insulation configurations rather than a single optimal solution, allowing flexible decision-making depending on project priorities.

4 Results

4.1 Machine Learning Model Performance

The predictive performance of the proposed machine learning model was evaluated using the Extreme Gradient Boosting (XGBoost) algorithm. To assess the model's accuracy, predicted values were compared with the reference dataset using scatter plots of predicted versus actual values. R^2 represents the proportion of variance in the target variable that can be explained by the input features and is therefore commonly used to evaluate the predictive performance of regression models. The R^2 value ranges from 0 to 1, with higher values indicating better model performance. Figure 1 illustrates the prediction performance of the XGBoost model for each output variable. The predicted–actual comparison for thermal performance (Fig. 1 - *left*) shows a strong linear relationship between predicted and actual values, indicating that the model captures the relationships among insulation thickness, thermal conductivity, and other material properties. R^2 values measured as 0.695. The high concentration of points around the diagonal line suggests that the model provides reliable predictions for thermal resistance values.

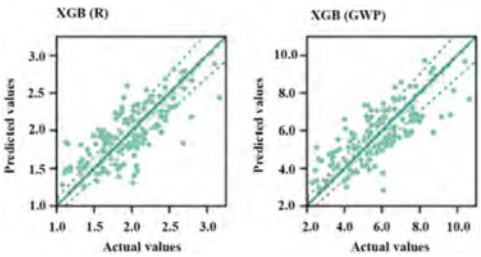

Fig. 1. Comparison between predicted and actual values of R and GWP.

Similarly, the results for global warming potential (Fig. 1 - *right*) show good agreement between predicted and actual values. The model effectively captures the influence of manufacturing energy, material density, and transport distance on lifecycle carbon emissions. The relevant R^2 value for this model is 0.711. Overall, the XGBoost model demonstrates strong predictive performance across the outputs, indicating that the selected input parameters adequately capture the factors influencing both thermal performance and embodied environmental impacts.

4.2 Multi-Objective Evaluation

Following the performance prediction stage, the predicted indicators were integrated into the multi-objective evaluation framework. The optimization model simultaneously considered three performance criteria: thermal performance (R-value), embodied environmental impacts (GWP), and acoustic insulation performance. A Pareto-based analysis was conducted to identify optimal trade-offs between these criteria (Fig. 2). Insulation configurations with higher thermal resistance generally exhibit increased embodied emissions due to greater material use or higher manufacturing energy requirements. Conversely, materials with lower environmental impacts may provide moderate thermal performance. When acoustic performance is incorporated as an additional decision parameter, fibrous insulation materials such as mineral wool and glass wool frequently appear among the Pareto-optimal solutions due to their balanced thermal and acoustic properties. In particular, systems combining autoclaved aerated concrete (AAC) structural walls with glass wool insulation demonstrate a favorable balance between relatively low embodied energy values and acceptable thermal performance. AAC exhibits lower density and thermal conductivity, contributing to improved thermal resistance, whereas conventional brick provides higher thermal mass.

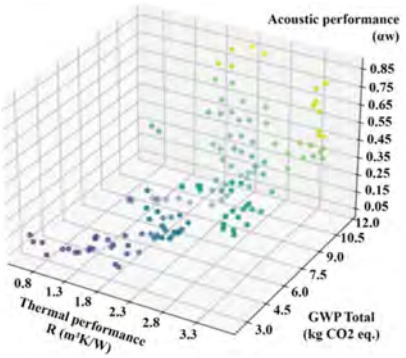

Fig. 2. 3-D Pareto-optimal solution space

5 Conclusion and Discussion

This study presented an ML–based hybrid framework for selecting insulation materials in externally insulated composite wall systems. The proposed approach integrates a multi-output XGBoost model for predicting thermal performance and embodied environmental impacts with a multi-objective evaluation process that also considers acoustic insulation performance. The results demonstrate that the machine learning model provides reliable predictions for thermal resistance and global warming potential (GWP). The strong agreement between predicted and actual values indicates that the selected input parameters effectively represent the relationships between material properties, design variables, and lifecycle environmental impacts. It should be noted that, while

thermal resistance is widely used as the primary thermal performance indicator due to its early-stage design and regulatory compliance, it does not fully capture dynamic thermal behavior, such as heat storage capacity and time-lag effects. Future extensions of the model could incorporate parameters such as heat capacity and thermal diffusivity to better capture time-dependent heat transfer behavior. The proposed framework is designed as a generalizable decision support model. Regulatory requirements can be included as external constraints depending on the geographical context.

The multi-objective analysis reveals the balance between thermal performance and embodied environmental impacts, highlighting the importance of considering multiple criteria in material selection. It should be noted that the dataset is limited to commonly used traditional insulation materials. Future studies aim to include alternatives with low carbon footprints, such as bio-based or recycled materials. Future research may also explore the application of alternative machine learning algorithms, such as random forests, support vector regression, and neural networks, and compare their predictive performance with that of the XGBoost model. Such comparisons could further improve the robustness and generalizability of machine learning–based material selection frameworks.

Abstract. Advancing circularity in the built environment requires harmonised methods for defining and managing Circular Economy (CE) indicators throughout the project lifecycle. This paper presents a structured survey-based investigation into current practices, data requirements, and digital workflows associated with CE assessment in construction. It also provides a survey-based investigation of stakeholder perspectives, data requirements, and digital workflows related to the integration of CE indicators into Building Information Modelling (BIM) environments. The survey engaged stakeholders from Portugal, Serbia, and Romania

to examine barriers, data structures, and reporting needs associated with CE–BIM integration. The findings show that CE indicators are mainly assessed during early design stages, while lifecycle-wide BIM integration remains limited due to fragmented data structures, insufficient standardisation, and unclear regulatory guidance. Unlike studies focused mainly on technical BIM functionalities, this paper provides stakeholder-driven insights and policy-oriented recommendations to support future harmonisation of CE–BIM practices and lifecycle data management.

Keywords: Building Information Modelling (BIM) · Circular Economy (CE) indicators · data requirements · life cycle assessment · stakeholders survey

1 Introduction

The transition toward a Circular Economy (CE) in the built environment is essential to reduce resource depletion, waste generation, and lifecycle carbon emissions, particularly given the construction sector's significant environmental footprint [1]. Recent EU-wide assessments further emphasise this urgency, showing that buildings account for around 36% of total greenhouse gas emissions in the European Union and highlighting the need for robust, harmonised lifecycle data to support decarbonisation strategies [2]. In this context, Building Information Modelling (BIM) has emerged as a promising digital approach for improving data management, traceability, and coordination across the building lifecycle. However, despite growing interest in CE–BIM integration, the implementation of consistent CE indicators within BIM workflows remains fragmented and insufficiently standardised across the AECO sector. Based on a structured stakeholder survey across the construction value chain, this paper investigates stakeholder perspectives, data needs, and implementation barriers related to the integration of CE indicators into Building Information Modelling (BIM) environments and discusses policy-oriented recommendations to support more harmonised CE data practices.

BIM is a collaborative digital methodology that supports the planning, design, construction, and management of buildings through intelligent nD models enriched with structured lifecycle data. By enabling multidisciplinary coordination, improved interoperability, and better decision-making, BIM enhances efficiency, cost control, and sustainability. As a combination of policies, processes, and technologies, it represents a major shift in the AEC industry by improving collaboration, reducing errors, and supporting integrated information management [3].

Furthermore, in CE research, indicators are diverse quantitative or semi-quantitative measures used for benchmarking, decision support, performance monitoring, and communication, varying by scale and purpose. While many indicators focus on material preservation - especially recycling - circularity in the built environment also depends on durability, adaptability, reusability, and design for disassembly [4–6]. Building-specific indicators are particularly valuable for guiding design decisions, but studies highlight ongoing fragmentation in assessment frameworks and limited integration of energy and emissions metrics [7, 8]. Tools such as material passports and BIM-based lifecycle assessment models can help operationalise these indicators by improving data availability and traceability [9]. In this context, the transition from a linear to a CE represents

a fundamental shift in resource and waste management, requiring more integrated and lifecycle-oriented approaches to material and building information management.

In the traditional linear model, resources are extracted, transformed into products, and eventually discarded at the end of their useful life, often resulting in significant environmental impacts and resource depletion. In contrast, the CE aims to extend the lifecycle of materials and products through strategies such as reuse, repair, and recycling, thereby reducing waste generation and improving resource efficiency. This approach promotes a more sustainable and environmentally responsible system of production and consumption [6, 7].

BIM plays an important role in supporting this transition within the construction sector. By enabling collaborative digital workflows and integrating virtual design with project delivery processes, BIM can improve material planning, reduce design errors, and enhance coordination among project stakeholders. These capabilities contribute to more efficient material use and reduced construction waste through improved visualisation, clash detection, and planning [10, 11]. Although BIM adoption has grown globally alongside CE initiatives, research indicates that its specific applications for supporting circular strategies across the entire lifecycle of assets remain underexplored. Further research is needed to better understand how BIM can facilitate lifecycle-based circularity practices and strengthen resource efficiency in construction and asset management [10, 12]. Previous studies have focused on linking BIM to custom external databases that contain the CE indicator data required for assessment. More recent studies have explored the integration of CE indicators information within the BIM environment through semantic enrichment using a data dictionary in the buildingSMART Data Dictionary (bSDD). This approach leverages BIM's potential for information management and enables BIM to function as a central data repository throughout the project life cycle [13]. To this end, this study aims to explore country-specific BIM-CE synergy by focusing on the stakeholder perspectives. By conducting an exploratory approach, this study compares the CE indicators requirements for the BIM environment from the data obtained from three countries, Portugal, Serbia, and Romania, and presents the constraints for CE adoption and BIM's potential to accelerate the shift.

2 Materials and Methods

This research examined stakeholder perspectives and current practices related to the integration of CE indicators into BIM environments by analysing stakeholder data needs, workflows, and implementation barriers. An international survey was conducted in multiple languages (Portuguese, Italian, English, Turkish, Serbian, and Romanian) to capture diverse perspectives on CE–BIM integration. The online questionnaire consisted of 31 questions across five sections addressing respondent profiles, stakeholder roles, expectations and constraints related to CE-BIM integration, and the incorporation of CE indicators into BIM workflows. Targeting professionals across the AECO value chain – including designers, engineers, contractors, policymakers, and digital solution providers – the survey collected quantitative data via a five-point Likert scale, as well as multiple-choice and open-ended responses.

Although responses were collected internationally, only Portugal, Romania, and Serbia were considered at this stage, due to a relevant number of responses, with 31, 34,

and 19 respondents, respectively. The data were analysed using descriptive statistics, cross-tabulation, and thematic analysis to identify trends in CE–BIM maturity, stakeholder needs, and key implementation barriers, which informed the development of a policy-oriented framework for the harmonised integration of CE indicators within BIM environments. Although the survey is international, this study focuses on Portugal, Romania, and Serbia due to higher response rates. The results are exploratory and not fully representative of the European AECO sector. Differences in sample size and national BIM and CE maturity may affect comparability. Future research should include more countries and stakeholder groups for broader analysis.

3 Results and Discussion

Most respondents were aged 35–44 (46%), male (62%), and held either a university (54%) or postgraduate degree (56%). The majority had over 10 years of experience in the AECO sector (74%) and worked primarily in architectural design (36%) or engineering consultancy firms (31%). BIM use was mainly at a basic level (viewer or simple model use) (34%) or intermediate level (modelling and coordination) (36%), while the use of CE strategies was typically intermediate (occasional) (46%) or basic (rare) (24%). The ranking of the relevance (from very relevant to not relevant) of various CE indicators to their practice is represented in Fig. 1. Overall, the comparison indicates that while all three countries recognise the importance of CE indicators, Portugal and Serbia display clearer prioritisation patterns, whereas Romania reflects a more heterogeneous perspective. These differences may be associated with variations in policy frameworks, digital maturity, and industry awareness related to CE-BIM integration across the studied contexts.

In Portugal, respondents rated material circularity (e.g., circularity score/MCI), recyclable/recycled content, and reusable content as highly relevant indicators, with a large share of responses concentrated in the "very relevant" and "relevant" categories. Waste-related metrics and durability indicators also received moderate-to-high relevance ratings, suggesting that Portuguese stakeholders prioritise indicators linked to resource efficiency and lifecycle performance. In contrast, indicators such as hazardous materials, toxicity-related metrics, and material traceability were more frequently evaluated as only somewhat or slightly relevant, indicating lower prioritisation in current BIM-based workflows. These findings suggest that the Portuguese AECO sector is particularly focused on the potential for material recovery and lifecycle optimisation as core components of CE implementation.

Responders in Romania show a more distributed response pattern across the relevance scale, indicating a less consolidated perception of CE indicators within BIM processes. Several indicators, including material circularity, reusable content, and waste metrics, received mixed evaluations ranging from "relevant" to "slightly relevant," reflecting varying levels of awareness or implementation of maturity. However, indicators such as design for disassembly, durability/service life, and resource-efficiency strategies are relatively more relevant than other categories, highlighting the growing recognition of lifecycle-oriented design approaches.

In Serbia, the results reveal a stronger concentration of responses in the "very relevant" and "relevant" categories across most indicators, particularly for material circularity, recycled content, and waste metrics. This suggests a relatively strong alignment between CE objectives and BIM data needs among Serbian stakeholders.

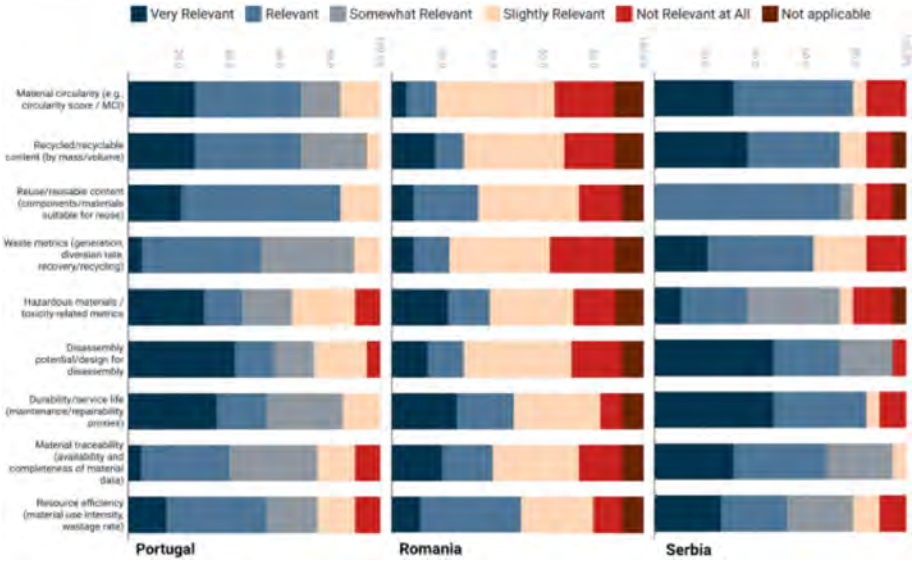

Fig. 1. Relevance of CE indicators to the work of respondents.

CE indicators are most frequently assessed using BIM during the Concept & Early Design and Production & Construction stages, indicating that BIM is primarily applied to support design decisions, material planning, and construction coordination, as seen in Fig. 2. Indicators such as material circularity, recycled content, and resource efficiency are therefore more commonly evaluated in the earlier project phases. In contrast, considerably fewer assessments occur during Use, Operation & Maintenance and End-of-Life, suggesting that BIM is still rarely used to support lifecycle-based circular management, including durability monitoring, disassembly planning, or material recovery.

In Portugal, the results indicate that CE indicators are predominantly assessed during the Concept & Early Design stage, particularly for indicators related to material circularity, recycled content, and resource efficiency. The Production & Construction stage also shows some use of BIM for evaluating indicators such as waste generation and hazardous materials, reflecting BIM's role in construction planning and coordination. However, assessments during Use, Operation & Maintenance and End-of-Life remain relatively limited, particularly for indicators such as disassembly potential, durability, and material traceability. This pattern suggests that while circular considerations are increasingly introduced during design, BIM-supported lifecycle monitoring and end-of-life planning are still not widely integrated into professional practice.

In Romania, CE indicators appear to be assessed more consistently across multiple lifecycle stages compared with the other countries. Both Concept & Early Design

and Production & Construction stages show strong representation for most indicators, including material circularity, reuse potential, waste metrics, and resource efficiency. Additionally, Romania displays comparatively higher levels of assessment during the Use, Operation & Maintenance stage, particularly for durability, service life, and material traceability, indicating a growing awareness of lifecycle-based circular management. Although End-of-Life assessments remain less frequent, the results suggest a relatively higher maturity in integrating CE considerations within BIM workflows.

In Serbia, the assessment of CE indicators using BIM is generally less frequent and more uneven across lifecycle stages. While some evaluations occur during Concept & Early Design, particularly for indicators related to recycled content and material circularity, the overall distribution suggests limited systematic integration within BIM processes. Assessments during Production & Construction and Use & Operation stages are comparatively lower, and the figure shows a higher proportion of responses associated with End-of-Life or Not Applicable categories, especially for indicators such as disassembly potential and hazardous materials. This pattern suggests that BIM adoption for CE evaluation remains at an early stage, with significant opportunities to strengthen lifecycle data integration and circular performance assessment.

Among the three countries, Romania shows the most balanced distribution of assessments across lifecycle stages, Portugal demonstrates moderate integration mainly concentrated in early phases, and Serbia presents lower levels of BIM-supported CE assessment and a higher proportion of responses indicating that indicators are not yet applied.

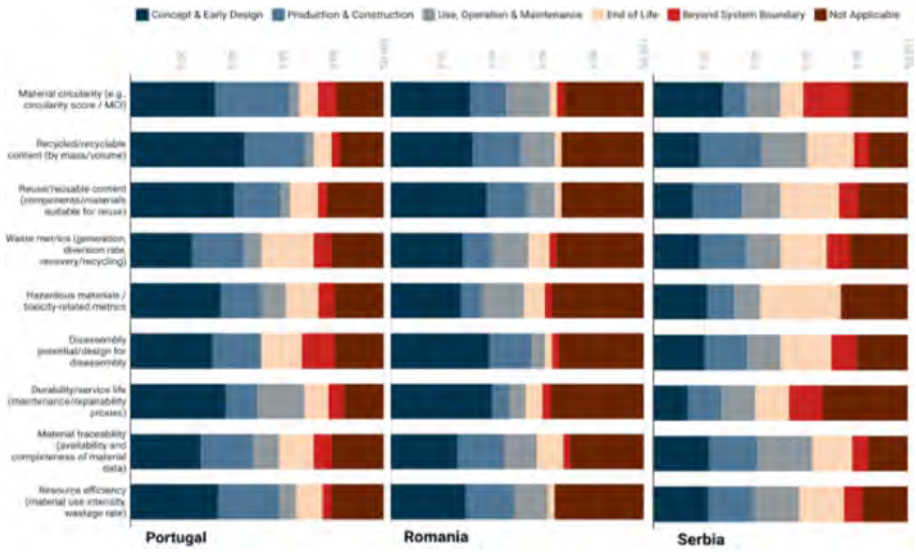

Fig. 2. Stages at which CE indicators are assessed using BIM.

Table 1 maps the key constraints affecting CE adoption onto the BIM capabilities that can most directly address them. It should be noted that these correspondences are

not arbitrary: they emerge from the survey findings, in which stakeholders identified both the barriers they face and the BIM functionalities they consider most relevant to their work. The rationale for each link is therefore grounded in the empirical data and further supported by the existing literature.

Table 1. Top 5 constraints in CE adoption and contribution to CE goals**.**

Constraints in CE adoption	Expected BIM contribution to CE goals – rationale
Lack of skills	Resource and cost optimisation through 4D/5D BIM: 4D scheduling and 5D cost modelling enable non-specialist stakeholders to visualise material flows and lifecycle costs, reducing the impact of skill gaps on CE-informed decision-making.
Cost constraints / Lack of reliable data	Reduction of rework through clash detection: BIM-based collision detection minimises costly on-site errors and supports more accurate quantity take-offs, thereby reducing material waste and associated costs.
Unclear regulatory guidance	Waste reduction through improved planning: BIM enables detailed simulation of construction sequences and material use, supporting compliance-oriented waste management plans even in contexts with fragmented regulatory frameworks.
Lack of standardised BIM data structures	Material quantity accuracy: structured BIM object libraries and IFC-based data schemas improve the consistency and comparability of material data, laying the groundwork for CE indicator reporting.
Lack of (inter)national CE indicator definitions	Material/product data management (EPDs, certificates, etc.) and support for material reuse and recycling: BIM can host and link EPD records, material passports, and circularity certificates, enabling traceability even in the absence of unified indicator definitions.

Moreover, as stakeholder perceptions indicate that BIM is primarily used during the early design stage, strengthening BIM use is needed to support a lifecycle-oriented approach to foster circular transition. This can be achieved by developing a comprehensive policy framework that not only bridges synergies among lifecycle stages but also encourages BIM's contribution to CE constraints. Therefore, future work, based on these findings, is a policy-oriented framework that can be developed to support harmonised CE data practices and promote scalable CE-BIM integration across projects and governance levels. The European Commission [2] identifies three key policy domains, such as improving operational energy performance, accelerating low-carbon material adoption, and enhancing circularity, all of which depend on accessible and structured building-level data. To this end, the policy framework to accelerate CE-BIM integration

through various lifecycle stages directly supports these priorities by enabling traceable, verifiable and interoperable CE-indicator datasets.

4 Conclusion and Final Remarks

This study investigated stakeholder practices, data requirements, and implementation barriers related to CE indicator integration into BIM environments by analysing stakeholder practices, data requirements, and implementation barriers across the AECO sector. The survey results reveal that, although stakeholders recognise the importance of CE indicators, particularly durability, recyclability, reusability, and material circularity, their systematic use in BIM workflows remains limited, often occurring only when required by specific project demands or regulations. The findings also show notable differences among the analysed countries, with Portugal and Serbia demonstrating clearer prioritisation of CE indicators, while Romania reflects more heterogeneous perceptions. Furthermore, the results highlight that CE indicators are predominantly assessed during the concept and early design stages, where BIM is most frequently used to support material selection and design decisions. In contrast, the application of BIM for circularity monitoring during operation, maintenance, and end-of-life stages remains relatively underdeveloped, indicating a gap in lifecycle-wide CE data integration.

Overall, the study confirms that BIM has strong potential to support the operationalisation of CE indicators. However, this potential can only be fully realised through improved data standardisation, interoperability, and governance frameworks. The stakeholder feedback emphasises the need for harmonised data structures, better integration of material information (e.g., material passports and digital building logbooks), and clearer regulatory guidance to ensure consistent CE monitoring across project phases. Based on these insights, the paper highlights the need for a policy-oriented framework to support scalable CE-BIM integration through lifecycle stages, across projects and governance levels. By aligning digital construction practices with CE objectives, such frameworks can support public authorities, industry organisations, and standardisation bodies in strengthening lifecycle data management and accelerating the transition toward a more circular, resource-efficient, and climate-neutral built environment.

Towards Circular Architecture. The Role of Digital Twin for the Quantification and Valorization of Waste Management

Emma Nivesse[1,2], Isabelle De Smet[1], Nicolas Youssef[2], David Laplume[1], and Sesil Koutra[1(✉)]

[1] Faculty of Architecture and Urban Planning, University of Mons, Mons, Belgium
sesil.koutra@umons.ac.be
[2] Junia, Université Catholique de Lille, LITL, F-59000 Lille, France

Abstract. As a key urban innovation and a cornerstone of sustainable initiatives, Digital Twins (DT) serve as enabling instruments for data-informed, evidence-based transitions, connecting the social, ecological, and spatial dimensions of urban transitions, aligning with European ambitions ranging from promoting energy efficiency to the 2050 decarbonization roadmap. Moving from linear to circular design models, the study fosters adaptive solutions for developing dynamic, learning-oriented circular approaches to construction waste management. Along with a scientific and replicable decision-support tool, the study promotes closed-loop systems in spatial transformations and stark contrasts to the traditional economic models of "take-make-dispose" technocratic solutions and architectural conceptions. The research develops a systematic review of tools for both building-level renovation and district-scale regeneration, mapping reusable resources, quantifying waste, and reducing new material extraction. The research will conclude by determining its applicability in site-specific locations and complex environments through evaluations of the impacts of design interventions and the promotion of mutual understanding of its utility. By bridging the gaps in technical modeling, the collaborative DT processes will leverage sustainability and co-develop and test actionable insights in real-time settings, not only as technological demonstrators but also as participatory instruments for inclusive urban transformations.

Keywords: Circular Economy · Digital Twin · Architecture · Waste management · Decision-support tool

1 Introduction

Construction is one of the major contributors to global waste, accounting for more than 30% of worldwide generation, over 40% of resource use, and 25% of global waste, leading to unsustainable models and emerging alarming situations amid complex, growing environmental challenges. Integrating efficient waste management practices is pivotal to advancing sustainable practices in the construction sector. The built environment is responsible for more than 40% of raw material extraction, and more than one- third of this extraction occurs within European borders [1].

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 1350–1357, 2026.
https://doi.org/10.1007/978-3-032-34930-9_157

Moving from traditional models of "take-make-dispose" models towards green transformative shifts and reuse, recycling, and circular models seems imperative to face challenges related to natural depletion, energy consumption, or soil artificialization due to massive urbanization pressures [2]. Proposed by Ellen MacArthur Foundation [3] as a catalyst for the reduction of the building carbon footprint, while promoting efficient strategies for cost, and resources' optimized use [4], Circular Economy (CE) has been increasingly studied as a promising and sustainable concept as opposed to the linear approaches [5], whereas its potential applications in various processes of life cycle (production, consumption, distribution), and its principles of material recycling, and reuse are commonly acknowledged, being closely aligned with the United Nations Sustainable Development Goals (SDGs) in an integrated and transformative framework and promote innovative design strategies supporting resource reutilization and realignment and sustainability. In recent years, the concept of circularity has gained rising scientific and policy interest with the adoption of the First Circular Action Plan in 2019, and continued being institutionalized through European engagements, as the new Circular Economy Action (CEAP) (2020), or Green Deal towards the 2050 decarbonization pathway ([6, 7]). In fact, the transition from 'linear' to 'circular' strategies poses a range of new challenges for designers, requiring the acquisition of specific knowledge, resources, and management skills, as well as the development of novel methods, that operate within closed-loop flows and consider the entire project lifecycle.

Recent research, e.g. ([5, 8]), has been conducted to conceptualize circular design and identify knowledge gaps in construction standards, and still, developments are in an infant stage with significant technological uncertainty. Current trends and standalone and siloed tools have been developed to support circular design and the required skills for designers, with limited, nevertheless, empirical investigation and case-study evidence [9], which have led to fragmented practices and communication inability due to the absence of unified, clarified policy structures or misinterpretations, creating a lack of effectiveness. The study aims to bridge learning outcomes on standardized grounds and promote digitalized tools for practitioners of cleaner production with standardized ontologies and common language, guiding decision-making processes towards greener and resilient practices by exploring the 'digital twinning' strengths and potential in environmental engagements, and restructuring the narrative of current construction models and their disastrous environmental effects.

Circular economy is an umbrella term that encompasses synthetic processes and relevant principles for the use and reuse of materials, operating at different scales of implementation. The concept draws on interdisciplinary roadmaps documented in grey and scientific literature that combine diverse viewpoints from industrial and academic stakeholders. Some of them describe the concept in single conceptualized frameworks, whereas others explore the interconnectivity of its dimensions in more holistic view - points of a "restorative", resilient, and long-lasting architectural and urban design and an instrument for sustainable development practices ([9, 10]).

Construction-intensive activities intensify soil artificialization, leading to major contributions to environmental degradation through excessive waste management and exacerbating serious ecological imbalances. To understand the distribution of the circular economy in scientific research, a selected sample of 1,597 scientific publications from

the Lens.org database was analyzed. To focus the results on the circular economy and related topics, these publications were selected based on the occurrence of the keywords "circular economy" and "architecture". The sample publications were chosen based on their publication year, from 2010 to 2026, because of their increasing mention in the literature since the 2010s ([11, 12]). To specify the sample, a field of study was chosen: waste management, engineering, circular economy, and architecture. To ensure comprehensive cluster outcomes, a minimum benchmark of five (5) occurrences was set. Figure 1 shows clusters in different colors, with node sizes representing keyword co- occurrence and lines representing affinity between them.

The circular economy is linked to many topics through scientific research. Its scope of application is broad and continues to expand. The co-occurrence of keywords in scientific research indicates that research density is higher around circular economy, sustainability, waste management, life cycle analysis, and recycling. The connections between keywords reveal links across disciplines, and the distribution of the cluster demonstrates the movement of scientific research. The main concepts emerging from this cluster are Building Information Modeling (BIM), digital twins, blockchain, and Industry 4.0 with weaker connections between architecture and this cluster.

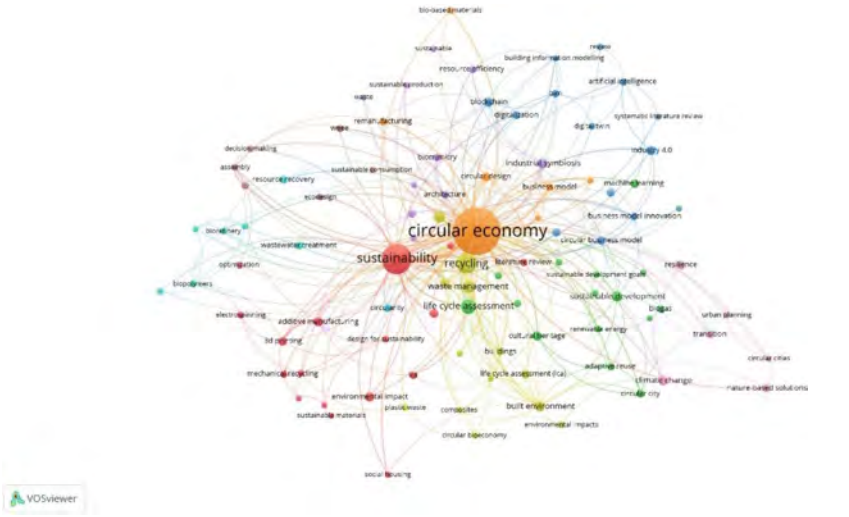

Fig. 1. Bibliometric analysis from Lens.org database, of the scientific research about circular economy and architecture in Europe from 2010 to 2026.

2 Tools. Addressing Gaps and Challenges

To support and enable circular design, a range of tools and methods has been identified and documented in the grey and academic literature; a systematic literature roadmap is provided in this section to identify innovations and relevant gaps. From the same lens, recent research on the conceptualization of the circular economy has systematically

identified significant gaps arising from the lack of unified approaches, leading to misalignments, misunderstandings, and misinterpretations ([13, 14]). Most studies address the transferability of knowledge and common agreements across different methods and tools, and neglect the social implications, behavioral adaptations, and consumer-centric lifestyles, adopting systemic views of a circular mindset, while others focus on waste management and demolition waste [15].

The study revealed complementary difficulties in adapting "design personas," the need for innovative collaboration schemes and relevant competencies, and the need to assess and anticipate plausible environmental impacts and societal adoption challenges in advance. Digital highways synchronize data bidirectionally and bridge data and interoperability gaps on "what-if" scenarios, translating simulation insights into real-world applications in connected ecosystems. Kozminska [17] et al. explored architectural cases in circular design processes, by highlighting innovative standards and the need for interdisciplinarity due to the perplexing nature of stakeholders, emphasizing the role of architects as 'orchestrators' of the process as pivotal to coherent designs

Waste recovery takes place at various levels, depending on the possibility; it starts with prevention, followed by reuse, recycling, and energy recovery. Considering the **project lifecycle criteria** each tool offers a different approach to waste management categorized into nine criteria: tracking, quantifying, mapping, advising, modeling, interconnecting, analyzing, managing, and preventing (Table 1).

Table 1. Objective of the tool for waste management and circular economy in the construction industry

Tool objective	Description
Track	Waste flow tracking
Quantify	Waste quantification and inventory creation
Map	Location of deposits, waste recovery operators and materials
Advise	Inform stakeholders about methods for recovering construction waste
Model	Integrate construction waste into a 3D model
Interconnect	Facilitate exchange between stakeholders about suitable and easily accessible reusable materials
Analyze	Construction data, including its life cycle, performance at the scale of material and building
Manage	Management of construction waste on site, facilitating waste collection
Prevent	Prediction and anticipation of construction waste to reduce its quantity

Existing tools for waste management in the construction industry can be organized with these objectives to expose their roles in the recovery process. The study of a sample of 10 tools that are more often used or mentioned in the construction industry seems to demonstrate their broad scope.

Table 2. Sample of 10 tools used in the recovery of waste in the construction industry

Tools	Track	Quantify	Map	Ad-vise	Model	Intercon-nect	Analyze	Manage	Prevent
Track waste	X	X							
BAMB Materials Passports	X								
TOTEM					X		X		X
DEMOCLES						X		X	X
SimaPro							X		
VALOBIM		X	X						
RREUSE				X					
Opalis						X			
Level(s)							X		
OpenLCA							X		

Table 2 shows a disparity in the purposes of the tools in existing literature, presented with fragmented regard. Each of them is generally part of a post-production waste approach, seeking to manage what happens to waste, while only few of them target the first stage of recovery: prevention, as the case of TOTEM (Belgium) that analyzes the life cycle of a project from the design phase. Version 2020 of the method behind TOTEM was used in the study of Lam et al. (2022) [18].

At first glance, the industry appears well-equipped with tools and methods, but stakeholders face complex, too numerous, and siloed tools. As they are often costly, difficult to use, and time-consuming, it has become difficult for contractors and architects to incorporate them into their thinking. Furthermore, these tools are mainly intended for large-scale projects and large-scale companies. Along with the development of circular economy strategies, digitalization has been identified in diverse studies as an enabler of these practices, yet it is characterized by a significant lack of theoretical or technical background, a fragmented approach, and limited synergies that hinder the feasibility of circular models.

The concept of Digital Twin (DT) dates back to 2002, when industrial designers at the University of Michigan introduced it as a virtual representation of physical assets, aimed at design optimization, the integration of circular standards, and real-time monitoring and material flow [19]. It has progressively emerged as a key enabling technology that addresses design complexities in decision-making processes and is a promising strategy for reducing costs, facilitating innovation, and supporting the green transition, considering the combined information from multiple sources and scales in real-time ecosystems to improve efficiency and time savingsWhen combined with BIM, it enables material and knowledge flows throughout construction and waste management, facilitating the dynamics of automated processes in real-time ecosystems of architectural projects. In

several endeavors and exemplary cases, DT enabled architectural performance through the evaluation of waste volumes and quality, the identification of reuse scenarios aligned with customer preferences, and the distribution of resources, exploring the operational option of DT integration to advance circular economic practices [20]. Despite the multiple assets on DT use, multiple barriers hinder the lack of transparency and traceability with fragmented and underused data and the need for intersections among different sectors, including the barriers of advanced skills and relevant training [21].

3 Discussion

Moving from linear to circular architectural conceptualizations fosters multilevel innovation and adaptive solutions in real-time ecosystems by optimizing time, costs, and resource use and distribution. In this study, a systematic review of existing tools for construction and demolition waste identified significant gaps in communication and collaboration, and the need for more inclusive designs that promote closed-loop systems and holistic support mechanisms, by adding new knowledge to the existing literature.

Moreover, each tool has advantages but also disadvantages that can hinder the development of waste recovery. These drawbacks result in tools that are time-consuming, costly and sometimes expensive, difficult to learn, difficult to apply in the field, often requiring high-performance equipment, and lacking educational value and awareness. BIM-related tools are developing, but small companies do not systematically model their projects, which can be an obstacle to the use of waste recovery software. As an example, some tools are developing into application, to facilitate their use in site to the most stakeholders as possible (for example the tools ValoDépôt, BatiTri, Cycle Zero in France). Developing these types of tools could promote waste recovery among stakeholders who find it difficult to implement, such as small construction companies.

Other factors come into play in waste recovery, such as the location of construction sites and their proximity to sorting and storage facilities, as well as the size of the sites, which, when too small, does not promote waste recovery because of the low rentability for the companies.

4 Perspectives and Future Work

Digital advancements the conceptualization, design, and implementation of architectural projects optimize visualization, data generation, and the development of synergies throughout the project lifecycle, thereby improving communication skills and collaborative schemes among the involved stakeholders. In the next steps of the study, to meet research objectives, empirical studies on benchmarking approaches (France and Belgium) will be conducted to provide avenues for further investigation that emerge from the current discussion. Empirical evidence will be collected towards an in-depth understanding of the DT ecosystem to demonstrate its feasibility and constraints in real-time architectural projects of different scales.. This will help reveal the potential of digitalization as well as its limitations related to technical patterns, participation instruments, and learning processes.

It seems relevant to consider key stakeholders and self-builders such as small construction companies, small design offices, and even, for example, individuals wishing to build and recycle their waste, who also have a role to play in the recovery of construction waste at their scale. The next phase of the study aims to develop a tool that best addresses the existing drawbacks, evaluating the possibilities and limitations of a comprehensive, holistic tool, such as a digital twin or a simpler and more accessible tool for the stakeholders concerned. While considering that these different tools will not be geared towards the same types of projects or stakeholders.

Various tools could be implemented, such as educational sheets for construction workers and self-builders, training sessions for construction companies and their staff, or applications that are easy to bring to the construction site and simpler to use. Waste recovery should target transport-related waste such as packaging, implementation-related waste such as losses, cuttings, and cleaning inherent to the construction site, and demolition and building dismantling waste.

Even though efficient tools exist today, there is a real gap between the birth of innovation and its adoption. Companies do not easily position themselves as leaders but prefer to follow what has already been done. This creates a gap between the creation of a tool and its application. In addition, project size comes into consideration, as tools are less often used in smaller projects.

An Automated BIM-LCA Framework to Environmental Decision-Making in the Structural Design

Danielle Freitas(✉) and Helena Gervásio

ISISE, University of Coimbra, Coimbra, Portugal
danielle.freitas@uc.pt

Abstract. Climate change challenges the construction sector to develop solutions that balance functional performance with reduced environmental impact. Despite growing interest in sustainability during the design phase, its integration into project workflows remains limited, largely due to the difficulties of linking environmental information to digital models, such as interoperability constraints, risks of data loss, and the time-consuming nature of traditional impact assessment processes. Therefore, this study proposes an approach that integrates Life Cycle Assessment (LCA) with Building Information Modelling (BIM), applied to steel and composite structures. Through an application designed to generate parametrized structural models, designers can define materials and attributes that already include embedded LCA data, allowing immediate access to environmental indicators. The tool supports BIM model exportation with detailed 3D geometry and LCA values, providing quantity take-off and impact analyses directly within the BIM platforms. The results show significant improvements in modelling speed, information automation, and decision-making support, contributing to a more efficient, integrated, and sustainability-oriented design process.

Keywords: Life Cycle Assessment · BIM · Steel and Composite Structures · Sustainable Design · Digital Workflows

1 Introduction

The construction industry is widely recognized as one of the largest contributors to natural resource consumption and greenhouse gas emissions. The sector is responsible for approximately 37% of global CO_2 emissions related to energy and industrial processes, with building construction and materials manufacturing accounting for approximately 11% of this total [1]. Within this context, steel and composite construction offers important advantages such as faster execution, architectural flexibility, and high steel recycling rates [2–5]. However, these benefits do not eliminate their environmental burden, as steel production is highly energy-intensive and concentrates a substantial share of carbon emissions in the early stages of a building's life cycle, before the operational phase begins [3, 6].

In response, it is essential to integrate sustainability and efficiency into the design and planning stages of civil construction. Digital technologies, such BIM, offer a promising approach, as they allow decisions to be anticipated and alternatives to be evaluated in the early phases of the project [7–10]. One of the main advantages of BIM is its ability to assign detailed parameters to each element of the model, which allows for additional analyses related to costs, energy performance, and environmental impacts.

LCA approach is considered one of the most robust and widely recognized methods for quantifying the environmental impacts of products and building systems [11]. The application of LCA in BIM models has been recommended because it enables analyses that are closer to the project reality and promotes greater integration among design disciplines [12]. In addition, from a practical perspective, designers still face difficulties in creating parametric families and managing reliable technical data, both of which require considerable time and specialized knowledge [13]. As a result, issues related to model detail, data standardization, software compatibility, and the correct linkage of environmental parameters continue to limit the effective integration of BIM and LCA [14–16].

Given this scenario, this study proposes a solution for the automated generation of BIM elements for steel and composite structural systems, integrating construction and environmental data to support LCA at early design stages. The approach is intended to reduce modeling time, standardize information, and enable the incorporation of sustainability criteria into design project workflows.

2 Materials and Methods

The proposed approach consists of developing a tool to automate the generation of steel and composite building systems organized as macrocomponents. The methodology is structured as an integrated workflow comprising three complementary components: a web-based interface for user input and plugin distribution, an LCA calculation procedure, and a developed Revit plugin.

The overall workflow of the web-based interface system is illustrated in Fig. 1, which is structured into three main parts: **(i)** input data, **(ii)** assessment of embodied life cycle impacts, and **(iii)** outputs.

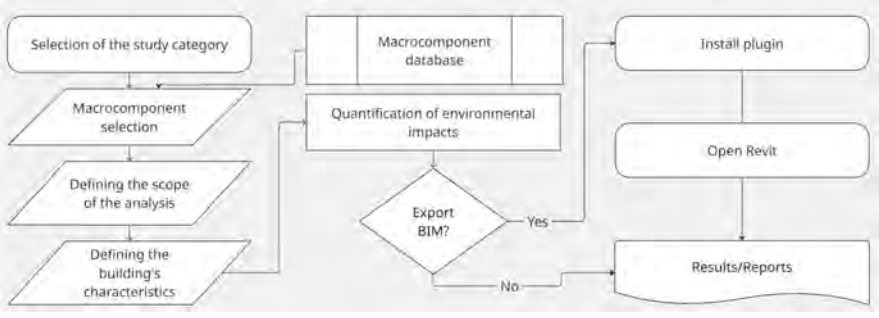

Fig. 1. Workflow tool.

Users can perform an LCA either at the level of an individual building component or at the level of building type, including single-family, multi-family, institutional, industrial, and commercial buildings. After selecting the assessment mode by category, the user selects the specific macrocomponent to be analyzed. The macrocomponents were classified using a UniFormat system [17] and their detailed structure is shown in Fig. 2.

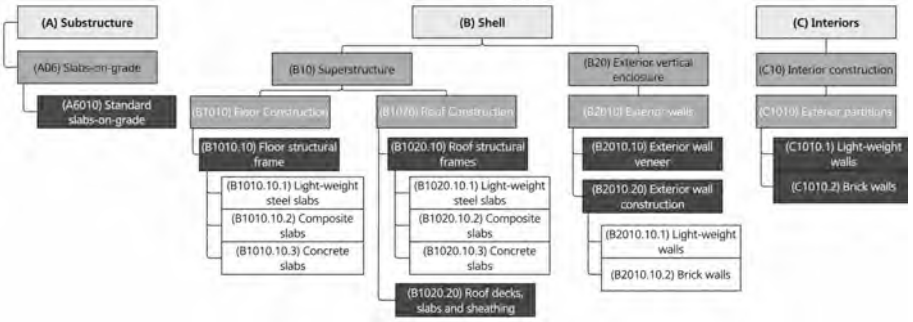

Fig. 2. Macrocomponent classification.

The user can define a set of attributes, including constituent materials, insulation type and thickness, and the LCA scenarios to be considered. The insulation materials available for selection include rock wool, expanded polystyrene (EPS), extruded polystyrene (XPS), glass wool, polyurethane (PUR), polyethylene (PE), cork, wood fibers, and external thermal insulation composite systems (ETICS). Materials are retrieved from a previously structured library that assigns to each material its density, recycling rate (RR%), and potential end-of-life scenarios. This material library is linked to an Excel-based LCA databse developed from Life Cycle Inventory (LCI) datasets derived from the Ecoinvent database [18], following the methodological framework described by [19]. The database was structured to include the environmental data required for the materials and life-cycle modules considered in the study, in accordance with ISO 14040:2006, ISO 14044:2006, EN 15804:2012, and EN 15978:2011.

Based on the input data, the tool performs the LCA calculation using a predefined functional unit of **1 m² of macrocomponent over a 50-year lifespan**. The generated results allow the user to visualize not only climate change impacts in **kg CO_2-equivalent**, but also additional environmental indicators relevant to a broader assessment, such as environmental impacts (GWP-total, GWP-fossil, etc), resource use (PERE, PERT, etc), output flows, and waste categories (HWD, NHWD and RWD). Once the calculations are completed, the application presents the results according to the selected scope, allowing the user to consider **A1–A3** (product stage), **C1–C4 and D** (end-of-life and beyond system boundary), or the full **A–D life cycle**.

Based on these inputs, the plugin reads the information provided through the web-based interface and automatically instantiates the corresponding Revit family, assigning the parameters to the model. The plugin was developed using Dynamo visual programming and enables the instant generation of parametric families based on a set of previously developed parametric families representing the building components considered

in the study. These families were created and structured based on technical datasheets of real national construction systems, ensuring that their geometry, material composition, and constructive characteristics reflect representative solutions used in practice. They were then organized according to the classification adopted in the methodology, allowing the plugin to associate each selected macrocomponent with its corresponding geometry, material composition, and relevant attributes for subsequent LCA processing.

3 Results

The proposed tool was tested using all macrocomponents implemented in the system, considering a functional unit of 1 m^2 for each element. Figure 3 illustrates the different types of macrocomponents available within the tool.

Fig. 3. Macrocomponents types.

The validation process involved selecting the various insulation materials available in the database, as well as defining the corresponding construction parameters and LCA scopes. Figure 4 presents the web-based interface where the selection and definition of macro-component characteristics are performed.

After calculation, the tool enables an "Export BIM" function that allows users to download the "BuildingsLCA" plugin [20]. The generated macrocomponents can be imported into Revit as RFA format, already containing both construction attributes and the associated environmental results.

These data are embedded as family type parameters, enabling direct access, filtering, and quantification within the BIM environment. Once loaded into Revit, each macro-component provides a detailed geometric representation, its constituent materials, and the corresponding LCA indicators, allowing designers to model the element while simultaneously accessing the environmental information integrated into the BIM object. The values are presented as parameters within the Model Properties of each macrocomponent family and are organized alphabetically according to the LCA scope analyzed to facilitate interpretation by designers. Using these parameters, it becomes possible to develop

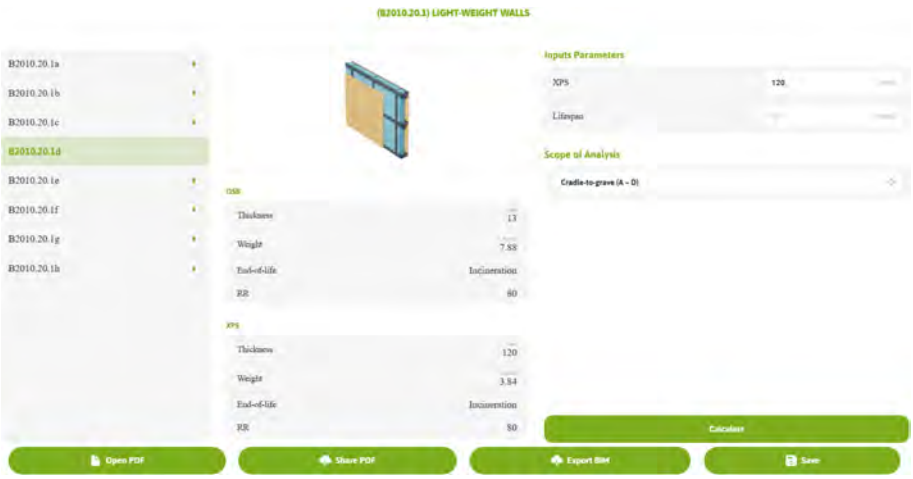

Fig. 4. Definition of the attributes of macrocomponent B2010.20.1 for LCA calculation.

BIM projects and, at the end of the design process, obtain their overall environmental impact.

The LCA values obtained using the tool were validated by comparing the automated results generated by the tool with the reference calculations previously developed in the Excel-based LCA database. For the validation, the same material quantities, input parameters, life-cycle scenarios, and environmental indicators were considered. The consistency between the two sets of results confirmed that the tool correctly retrieves the environmental data, associates them with the corresponding material quantities, and applies the calculation procedure as intended.

4 Discussion

The proposed workflow was tested across all macrocomponents included in the tool. In all cases, the tool successfully generated the corresponding BIM objects, performed the LCA calculations according to the selected scope, and exported the components to Revit with both construction and environmental parameters embedded.

However, due to the complexity of these construction systems, the slab and roof macrocomponents are exported as Structural Framing Beam families, which must be applied within Revit's Structural Framing System. This approach is necessary because the floor categories in Revit do not allow the insertion of detailed steel structural elements, being limited to a 2D graphical representation. Similarly, macrocomponents representing lightweight construction solutions are exported as Curtain Wall system families.

Despite these implementation constraints, the results indicate that the developed tool substantially reduces the time required for the initial generation of detailed parametric families. In the tested workflow, the comparison focused specifically on the initial modelling stage, namely the creation and parameterization of complex BIM families. While the manual creation of a family of this type, level of detail and data information can take

several hours, the automated workflow enables the equivalent family to be generated and imported into Revit in approximately 10 min, representing a significant reduction in initial modelling time. This comparison refers specifically to the generation of the parametric family and does not include subsequent operations such as model verification, re-importing after design changes, or minor manual adjustments.

5 Conclusions

Considering the limited expertise of many designers in developing detailed BIM objects, as well as the challenges associated with integrating BIM elements with LCA studies, the developed tool presents a promising solution. The system allows for the parametric configuration of different types of building systems. Exporting enables the creation of families applicable to Revit architectural models with a significant level of detail, including 3D steel structures, which facilitates visualization, coordination, and quantity takeoff.

Obtaining LCA results for building elements is simple and immediate. The parameters are integrated into the properties of the created families, allowing environmental analyses to be carried out more efficiently and directly within the BIM environment. Therefore, beyond improving modeling efficiency, the solution also can promote circular economy principles into early design stages by embedding material, recyclability, and end-of-life information into BIM objects. This is particularly relevant for steel construction, where recycling, disassembly, and component reuse represent important pathways to reduce embodied environmental impacts.

Despite its flexibility and user-friendly workflow, some limitations remain. Whenever it is necessary to add a new material or change the thickness of the thermal insulation, the configuration must be recreated in the tool and exported again to Revit. Furthermore, converting macrocomponents into Revit system families rather than loadable conventional families proved to be a practical solution, but may introduce additional complexity for designers mainly due to the inherent restrictions of the software when handling this type of family. Nevertheless, the tool also demonstrated its ability to significantly reduce the time required to model complex families.

For future work, it is considered relevant to explore extending the system to automatically generate complete building models with predefined dimensions and construction elements, instead of exporting only individual objects. Additionally, integrating graphical visualizations and comparative LCA reports directly into the tool interface would facilitate interpretation and decision-making. Expanding the system to include other classification systems and integrating it with national or regional environmental databases adapted to different countries would further enhance the tool's potential for international applicability.

Abstract. The circular built environment is characterized by dynamic building lifecycles, driven by heterogeneous material flows, iterative operational conditions, and multiple stakeholders. These requirements closely align with advances in emerging agentic Artificial Intelligence (AI) systems, enabling autonomous task decomposition, multi-tool reasoning, and feedback-driven adaptation. Despite rapid progress in autonomous multi-agent systems and digital twin (DT) intelligence, the integration of agentic AI into the circular built environment remains in its early stages. This study proposes an automated Level of Development (LoD) maturity assessment framework to evaluate the readiness of agentic AI workflows for circular construction applications. A two-phase systematic literature review was conducted to construct three research domains representing (1) agentic AI in the built environment, (2) circular construction, and (3) BIM/DT-based lifecycle digitalization. Cross-domain mapping revealed strong coupling between circularity and AI-enabled BIM/DT research, a developing trend between agentic AI and digitalization, and a limited intersection between agentic AI and circularity. The maturity classifications were mapped onto a LoD 100–500 scale, ranging from single-agent systems to autonomous frameworks. Initial maturity scores were generated using a large language model based on a six-dimensional (D1–D6) agentic maturity rubric covering agency structure, tool integration, reasoning depth, adaptivity, autonomy, and environmental data resolution. The outputs were assessed using an LLM-assisted consistency-checking procedure across rubric dimensions. The proposed framework provides a scalable approach to assess the readiness of agentic AI systems for the development of autonomous circular construction workflows

1 Introduction

Generative artificial intelligence (GenAI), particularly through large language models (LLMs), has initiated a new phase of transformation in architecture, engineering, and construction (AEC) through access to information, decision support, and workflow automation [1]. This transformation signifies not only the emergence of new tools but also the restructuring of knowledge-intensive, multi-stakeholder, and interdisciplinary construction processes. However, the use of these technologies in AEC carries significant limitations. Productions that are insufficiently grounded in domain knowledge can lead to problems such as hallucinations, contextual disconnection, unjustified decision-making, and outdated information [2]. These problems become more critical in BIM-based environments where structured data, classification systems, standards, and lifecycle-based decision approaches require co-working.

Research into reliable GenAI in the AEC is increasingly evolving toward retrieval-augmented generation (RAG) and agentic AI. RAG aims to improve factual accuracy and contextual appropriateness by grounding LLM outputs in external, validated information sources for information retrieval [3–5]. For the execution of more complex workflows, agentic AI enables task breakdown, tool handling, multi-agent coordination, memory management, and structured reasoning [1, 6]. Despite this progress, the use of agentic AI in circular construction remains limited and fragmented. Effective management of such processes requires AI systems capable of interpreting different data sources, evaluating decision alternatives, and operating adaptively throughout the lifecycle. BIM-DTs stand out as fundamental digital infrastructure that stores and updates circular construction information such as reuse of building components, material composition, component history, performance data, operational status, and end-of-life management [7].

Current research in agentic AI is concentrated in operational monitoring, DT simulation, smart building management, and auditing [8–10]. This shows a significant research gap that requires higher-level digital intelligence capable of interpreting data in context and translating it into lifecycle decisions. This study aims to address this gap by providing a Level of Development (LoD)-based maturity framework to evaluate the current maturity of agentic AI in circular construction. For this, the interdependencies among the agentic AI, circular economy, and BIM fields were examined. The results map the binary relationships between the fields and reinterpret the LoD concept through a maturity lens, enabling the co-reading of BIM data reliability and AI autonomy.

2 Method

The research has a threefold methodology including pairwise domain mapping across key research fields, LoD-based maturity classification through a lifecycle approach, and agentic AI maturity evaluation using a multidimensional rubric. The pairwise domain literature mapping is based on comparing dependencies of three emerging research domains within the built environment: (1) Agentic AI in construction; (2) Circular construction systems; (3) BIM-based digitalization using DTs. The proposed maturity evaluation framework, applied to the literature findings, aims to identify (i) how agentic AI systems interact with digital building data infrastructures and (ii) to what extent they support circular construction workflows.

2.1 Pairwise Domain Mapping

A pairwise domain mapping strategy was employed to analyze the relationships between the three domains: (1) Circular construction and AI-enabled BIM-DT; (2) Agentic AI and BIM-DT**;** and (3) Agentic AI and circular construction. These domains were compared to examine research developments across different levels of AI autonomy in digital infrastructure. The study first evaluated the two dominant pairwise relationships observed in the literature. The relationship between agentic AI and circular construction was found to be very limited and therefore treated as exploratory.

The literature dataset was compiled through systematic searches of Scopus, Web of Science, and IEEE Xplore. After screening and eligibility assessment, two subsets were extracted from the literature corpus. The first subset included 25 studies [11–35] where circular construction practices are operationalized through lifecycle digitalization platforms. These studies mainly focus on material tracking, lifecycle assessment, material passports, reuse planning, and deconstruction modeling. The second subset comprised 12 publications [36–47] focusing on autonomous AI systems characterized by capabilities of task decomposition, tool integration, multi-agent coordination, and adaptive reasoning.

This study reinterpreted the traditional geometric-based LoD scale as a dual maturity framework, linking BIM data reliability and agentic AI autonomy within circular construction workflows [48]. The Agentic LoD (ALoD) categories were interpreted across three circular construction lifecycle phases: early concept and design estimation, coordination and deconstruction planning, and autonomous material recovery and end-of-life management. The lifecycle phases are defined in Fig. 1 based on the combined progression of BIM data reliability and AI autonomy, and the maturity levels used to classify the review results are summarised in Table 1.

2.2 Agentic Maturity Rubric Evaluation

The technological maturity of the identified systems in emerging domains was evaluated using a six-dimensional agentic maturity rubric (D1-D6). The dimensions reflected the transition from traditional AI decision-support systems toward autonomous AI agents capable of operating across digital environments [1]. Using a six-dimensional agentic maturity rubric, each review finding was evaluated with LLM classification using a four-point scale (0–3), where 0 indicates the lowest or conceptual capability and 3 represents advanced implementations involving adaptive behavior, multi-agent coordination, or dynamic interaction with external digital environments.

The six-dimensional rubric used for study-level coding is presented in Table 2. For each finding, the dimensional scores were averaged to calculate the mean values. The mean values were then mapped to the ALoD maturity levels defined in Table 1 to position each finding in terms of technical agentic capability and its potential role in lifecycle-based circular construction workflows.

Table 1. Agentic LoD maturity levels and lifecycle interpretation

Maturity level	Label	ALoD	Interpretation
0	No agentic capability	Below ALoD	Review, conceptual mapping, and evidence of digitalization without an autonomous system.
1	Analytical decision-support systems	ALoD 100–200	Single model, DSS, basic tool-supported analysis; human is the primary decision-maker
2	Coordinated computational workflows	ALoD 300	Integrated BIM/DT/robotics workflow supporting structured automation, reuse assessment, and deconstruction planning.
3	Advanced agentic autonomy	ALoD 400–500	High integration with adaptive, robotic, DT-enabled, self-managed execution for autonomous management.

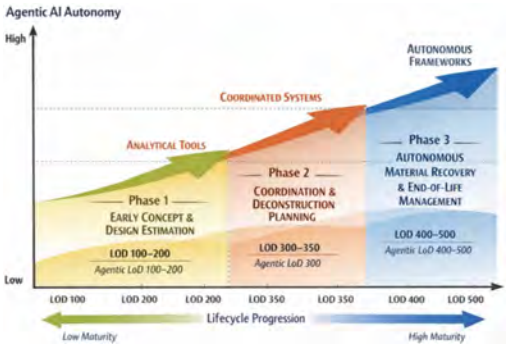

Fig. 1. BIM-AI maturity framework lifecycle diagram

Table 2. Six-dimensional agentic maturity rubric

Dimension	0	1	2	3
D1 Agency structure	No agent	Single analytical model	Coordinated workflow	Multi-agent, self-organizing agency
D2 Tool integration	No digital tool integration	Standalone model or software	BIM/DT, platform, robotics integration	Multi-tool, API, cloud integration
D3 Reasoning depth	Descriptive, review-level	Classification estimation	Rule-based planning, optimization	Iterative autonomous reasoning
D4 Adaptivity	Static, conceptual	Fixed data-driven model	Optimisation, scenario-responsive	Real-time feedback-driven adaptation
D5 Autonomy	No autonomous capability	Human in decision support	Automated workflow or execution	Autonomous, self-managed execution
D6 Environmental data resolution	Generic, conceptual	Document, survey, and generic data	BIM, material, building-level data	Sensor, reality-capture, robotic, DT, as-built data

3 Results and Discussion

3.1 Pairwise Domain Relationship Mapping Results

In the pairwise domain mapping analysis, the strongest relationship observed in the literature was between circular construction and AI-enabled BIM/DT infrastructures**.** Within this subset, studies demonstrated that digital material passports and lifecycle data platforms can support circular decision-making throughout the building lifecycle, particularly for reuse planning strategies [11, 19]. Contributions highlighted the integration of BIM with advanced digital technologies such as blockchain, IoT, and AI-supported analytics to improve transparency and traceability in supply chains [12, 14, 17]. Most contributions have remained focused on information structuring, assessment, and decision support rather than autonomous execution.

The second relationship concerned the integration of agentic AI systems within digital construction environments. Most studies fell into digital lifecycle infrastructure, focusing on broader construction automation problems. This confirms the central gap addressed by the proposed framework: while agentic AI research has advanced automation capabilities, the two trajectories have not yet been systematically integrated.

3.2 Agentic Maturity Assessment Results

The technological maturity of the identified systems was evaluated using the six-dimensional agentic maturity *rubric* presented in Table 2. The complete study-level coding matrix for all 37 analyzed publications is presented in Table 3. Accordingly, among the 37 analyzed publications, 11 studies were classified as having no agentic capability, corresponding to 29.7% of the corpus, while 10 studies were classified as analytical decision-support systems, representing 27.0%. The largest group consisted of 13 studies classified as coordinated computational workflows, corresponding to 35.1%. Only three studies, 8.1% of the corpus, reached the level of advanced agentic autonomy.

Table 3. Maturity level results of Agentic AI use through the analyzed publications

4 Conclusion

The fundamental technological components for circular construction are largely available in terms of BIM and DTs, providing structured data infrastructure, and agentic AI, providing task decomposition and autonomous decision-making logic. This study offers three key contributions. First, it systematically reveals the relationships among circular construction, BIM, DT infrastructure, and agentic AI through binary domain mapping. Second, it examines the current level of agentic AI development using a multidimensional evaluation rubric encompassing agent structure, tool integration, reasoning depth, adaptivity, autonomy, and environmental data resolution. Third, it demonstrates that

circular construction workflows require different levels of AI support across lifecycle phases, each corresponding to increasing levels of BIM data reliability and AI autonomy.

The pairwise domain results revealed that an integrated approach to supporting circular lifecycle processes remains limited due to a lack of conceptual alignment between AI autonomy and BIM data reliability. Most agentic AI implementations are currently applied to operational construction processes rather than lifecycle-oriented decision-making, and increasing levels of AI autonomy remain only indirectly connected to circular construction strategies. This highlights a structural gap between digitally enabled circular construction infrastructures and emerging agentic AI technologies.

This study is limited to a maturity assessment based on a review. Future research can extend the framework through expert review, stakeholder-driven criteria mapping, and application within operational circular construction workflows.

Ground Penetrating Radar for Circularity: Identifying Reusable Building Components Through Non-destructive Testing

Ourania Patsia(✉) and Alexandre Novo

Screening Eagle Technologies, 29004 Málaga, Spain
ourania.patsia@screeningeagle.com

Abstract. Construction and demolition activities generate significant amounts of waste, contributing to environmental degradation and reduction of raw materials. A promising solution to these issues is the reuse of building components. Promoting the reuse of building components through advanced detection and characterization methods can help address these challenges and support circular economy practices in the construction sector. This work explores the use of Ground Penetrating Radar (GPR) as a detection tool for identifying hidden materials in existing concrete-based and timber-based buildings that could be re-used in new constructions or for repairing/renovating old ones. In addition to detecting hidden components, GPR can also be used for material characteriza-tion. The effectiveness of GPR was determined by scanning different case studies of buildings that will be demolished. Data processing and interpretation were performed to demonstrate the components and information that can be identified with GPR, enhanced by automated interpretation techniques and augmented reality (AR) visualization. As demonstrated in this study, structural components (e.g., rebars, studs), insulation layers and other internal components can be detected in addition to voids and qualitative information regarding moisture content and deterioration. These findings demonstrate the potential of GPR to enhance material recovery and reuse strategies in building deconstruc-tion. This research is conducted as part of the SUM4Re project which aims to promote circularity in construction by creating material banks using different scanning techniques and innovative data-driven approaches to identify reusable materials in end-of-life buildings.

Keywords: non-destructive testing · ground-penetrating radar (GPR) · circular construction · sustainability

1 Introduction

Construction and demolition waste is among the largest waste streams globally, creating serious environmental, social, and economic challenges. Valuable materials such as concrete and wood are often discarded rather than recycled, resulting to the continued extraction of raw resources. The production of new materials as well as the disposal of existing ones contribute substantially to greenhouse gas emissions and environmental degradation. These challenges can be tackled by instead identifying reusable resources within

existing buildings, promoting material recovery and reuse, and also circular economy practices that reduce waste and support more sustainable constructions.

SUM4Re is an initiative co-funded by the European Commission under the Horizon Europe research and innovation programme. The SUM4Re project seeks to reduce waste and accelerate the transition to circular economy models within the construction sector. Its primary objective is to develop comprehensive methodologies for identifying and characterizing materials, including hidden components, in end-of-life buildings, enabling valuable materials or components to be recovered and reused in new construction projects or renovation works. Different scanning technologies are investigated for identifying different materials. The project will also develop artificial intelligence (AI)-supported algorithms to enhance the interpretation of data collected through advanced scanning technologies. Ultimately, digital material banks will be established to ensure the traceability and efficient management of recovered materials and components [1].

Ground penetrating radar (GPR) is one of the investigated scanning techniques for the purposes of the SUM4Re project. GPR has become one of the most versatile and widely used methods in non-destructive testing (NDT). Its capability to investigate subsurface features without causing damage makes it highly valuable across numerous industries. It is commonly used for the inspection of concrete structures, assessment of bridge integrity, detection of underground utilities, evaluation of road conditions, archaeological exploration, and geological investigations, among many other uses [2]. Specifically for concrete structures, it is commonly used for detecting structural components such as rebars and post-tensioning cables, conduits, and others, as well as give information regarding the concrete condition.

Fundamentally, GPR is used to characterize subsurface materials, distinguish between different layers, identify buried objects and detect other anomalies. Its expanding use is largely due to its key advantages: it is non-invasive, allows for fast data collection, and provides high spatial resolution. The operating principle of GPR involves transmitting electromagnetic (EM) waves into a target material, such as soil, or concrete, through a transmitting antenna. As these waves propagate through the medium, they are partially reflected at interfaces where materials exhibit contrasting dielectric properties. The receiving antenna captures these reflected signals, and their amplitude and travel time reveal information about the depth and characteristics of subsurface features [3].

Although applications in concrete and soil are more prevalent, research and commercial usage of GPR for wood and timber structures are steadily increasing. It has been utilized for monitoring the internal condition of tree trunks, evaluating wooden utility poles, and examining other timber structures. Typical uses in wood assessment include detecting internal cracks, knots, moisture variations, and evaluating the overall condition of the wood [4–6].

This paper demonstrates the effectivity of repurposing GPR technology for the aims of material recovery and shows what information can be extracted with GPR regarding hidden components but also material characterization. This is shown with two case studies with different materials and structure, which present two out of three pilot sites for the SUM4Re project; a reinforced concrete structure in Spain and a timber-based building in Norway.

2 Methodology

2.1 Pilot Sites

The first pilot site comprises of two buildings located in San Sebastián, in the Basque Country of Spain: the Anoeta railway station and the Jolastokieta building. Originally, the building in Jolastokieta was an industrial facility where elevators were manufactured but in recent years, the building is abandoned. The floors are constructed from concrete slabs topped with a mortar layer and embedded steel rebars. In contrast, the walls are composed of brick and concrete and do not contain internal reinforcement. At present, the building stands empty, and several exposed external steel beams are visible on site. A photograph of this site can be seen in Fig. 1a.

Fig. 1. a. Jolastokieta building, Spanish pilot and b. Residential timber building, Nordic pilot

The second pilot site is located in Longyearbyen, Svalbard, Norway which is widely recognized as the world's northernmost inhabited settlement. This site consists of a two-storey residential building primarily constructed from timber. The structure is supported by foundation piles embedded in the permafrost layer, which historically has provided ground stability. The external walls are composed of multiple layers, including exterior cladding, asphalt panels, insulation materials, and fibreboard. The floor system is predominantly wooden and incorporates insulation and heating elements, while tiled finishes are present in areas such as the bathroom. Figure 1b shows an image of the exterior of the building.

Extreme weather conditions and the impacts of climate change on the permafrost have led to ground instability, compromising the building's structural support. This instability is one of the key reasons why this building, along with others of a similar type, has been selected for demolition. Given the site's remote Arctic location, transporting construction materials is both logistically challenging and costly, making material circularity and reuse from buildings about to be demolished particularly important [7].

2.2 System Used

For conducting the GPR scans, the Proceq GP8800 high-frequency system was selected. This is a step-frequency continuous-wave (SFCW) system with a modulated frequency range of 400–6000 MHz and its high frequency allows for resolving relatively small features. It has a maximum penetration depth of 65 cm which was sufficient for the investigated structures which have small thickness.

The transmitting and receiving antennas are in the same case and measures a total size of 8.9 x 8.9 x 7.6 cm making it compact, easy to transport and use in the field but also ideal for tight spaces. It is designed to operate in direct contact with the surface of the structure being scanned with its primary application being concrete scanning. Figure 2 shows an image of the sensor.

Fig. 2. The Proceq GPR GP8800 sensor with some of its features annotated

2.3 Data Collection and Processing

The data acquisition performed was similar to both sites. Grid scans of 60 x 60 cm were performed at different parts of the buildings, both in walls and floors. In a grid scan, measurement lines were collected at both x and y directions with spacing $\Delta x = \Delta y =$ 5 cm between lines. For scanning each area with accurate positioning, a grid paper was used which has marked the 0,0 origin and the parallel lines at each direction with 5 cm spacing. For each A-scan, a time window of 16 ns was recorded with 655 samples. The scans were performed with the antenna being in direct contact with the structure surface.

It is common after data collection to perform certain processing of the GPR data that will result in easier and more accurate interpretations. For all collected datasets, the following filter sequence was applied:

- Time zero correction: This is a vertical shift of the data to a certain sample such as the 0 m to represent the ground surface which is necessary for correct depth estimation.
- Noise cancellation: Frequency filter used for removing certain types of noise (e.g. from Wi-Fi or cell phones) from the data.
- Background removal: Reduces noise that appears as horizontal stripes in the data but also the strong direct wave response that might mask other objects.
- Gain: Signals are getting weaker with increasing depth making certain responses not visible. This filter is used to amplify the signal amplitudes and make these responses visible.

3 Results

3.1 Case Study 1: Spanish Pilot

Before starting the interpretation, it is important to set the dielectric constant value. This is a material electrical property which is necessary for accurate depth estimations. In this case, this was calibrated using a process called hyperbola fitting [8] and by utilizing the hyperbolic responses from the rebars. Across all scans, the dielectric was between 9 and 12 which are characteristic of wet concrete (dry concrete is typically between 5–8).

As expected, the reinforcing mesh embedded within the concrete floor slab was clearly detected and mapped, along with other linear features that may correspond to additional reinforcement elements or embedded pipes. An example is shown in Fig. 3 where in Fig. 3a, the scanned area along with the grid paper can be seen and in Fig. 3b, the GPR slice at ~18 cm depth in which the rebar mesh can be seen. In certain areas, small irregularly shaped anomalies were also identified, which could potentially indicate the presence of voids. Overall, the concrete slab exhibited a high moisture content. This assessment is supported by the high dielectric values, as well as by visible surface conditions observed on site. Therefore, the concrete in this case study is considered deteriorated. Figure 3c shows the B-scan for line 23, where the hyperbolas from the rebars can be seen in the data along with the high dielectric values calculated which show the condition in the vicinity of each rebar.

3.2 Case Study 2: Nordic Pilot

Similarly, the dielectric value was calibrated for the scans in the Nordic pilot. However in this case since hyperbolas were not present in the data, this was performed by utilizing the backwall response from the wall/floor and their known thickness. This resulted in dielectric values between 2 and 3 across all scans which are bulk values for the wall/floor as a whole and not separate for each constituent material.

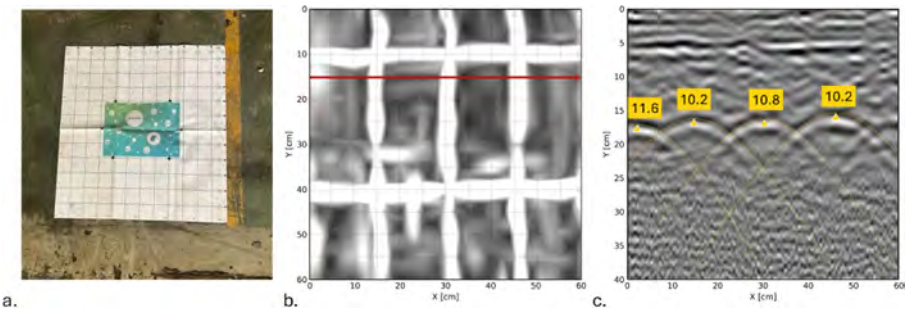

Fig. 3. a. Floor slab scanning location from Spanish pilot, b. Depth slice at ~18 cm depth showing the reinforcing mesh with rebars at both directions and line 23 highlighted and c. B-scan of line 23 showing the detected hyperbolic responses from rebars and the high dielectric values at the vicinity of each

From the GPR data over the floors, the heating elements, the vertical wooden beams (with hyperbolic responses) along with the insulation layer could be identified but also the interfaces between the insulation/cavity and insulation/fibre board (recorded as flat horizontal responses). The heating elements can be seen in the depth slice of Fig. 4a, where the data have are visualized on the scanning location utilizing the augmented reality (AR) feature directly on-site. Different responses from the heating elements and layers can be seen in the example B-scan data in Fig. 4b.

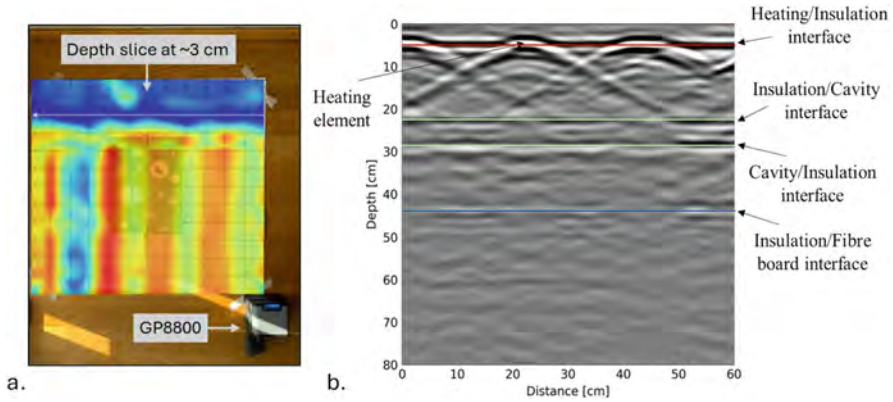

Fig. 4. a. Projected depth slice on the floor slab using the AR feature which shows the heating elements and b. Example B-scan from the floor data showing the different responses recorded

In the wall data, the vertical and horizontal wooden studs, insulation layers, and other similar layer interfaces could be identified. An example is provided in Fig. 5a where the vertical wooden stud is shown directly at the scanning location by projecting the data with the AR tool. In Fig. 5b, the hyperbola from the stud and the flat responses from the layer interfaces are also highlighted. Cabling or mesh within the wall was also identified as a sequence of hyperbolas in the same depth, as shown in Fig. 5c. Most walls seemed in a good condition with no anomalies detected, especially in the internal walls. However, certain external walls showed significant clutter which indicates the presence of higher moisture and/or voids in the wall structure such as the example displayed in Fig. 5d. Thus, based on the GPR data is speculated that this area is likely deteriorated.

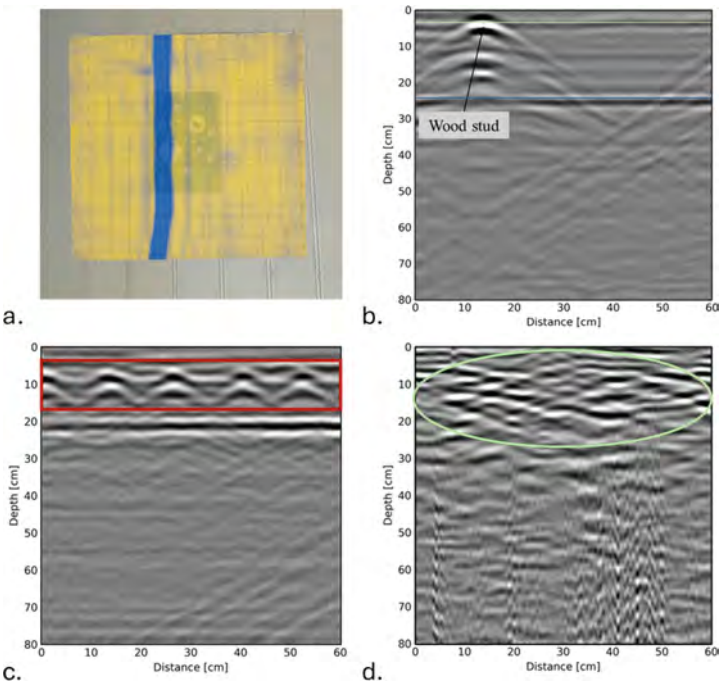

Fig. 5. a. Depth slice showing the vertical wooden stud inside the wall, b. B-scan example showing flat responses and hyperbola from wooden stud, c. Potential cabling or mesh in the wall response and d. Significant clutter in the data from external building walls

4 Conclusions

One of the primary GPR applications is the identification of embedded elements in concrete, such as reinforcing bars and post-tensioning cables, while also providing insight into the state of the surrounding concrete, including moisture content. For the Spanish pilot site, the objective of the GPR survey is to detect and characterize metallic reinforcement bars embedded within concrete slabs, while also assessing the condition of the concrete, including moisture levels and the potential presence of voids. This was achieved as shown by the results of the Spanish pilot with this information supporting selective cutting or deconstruction strategies, facilitating the recovery of steel reinforcement and the potential reuse of concrete elements.

The Nordic pilot results showed that for timber structures, GPR can be used to detect concealed components such as wooden studs and insulation layers, as well as to identify moisture accumulation but also internal voids. Additional reusable elements, such as metallic and non-metallic utilities, heating elements, and internal cabling typically embedded within walls and floors can also be located. More broadly, GPR is capable of scanning a wide range of construction materials, distinguishing between layers, and identifying embedded features, making it applicable beyond concrete and timber alone. Therefore, its applicability to different materials and structures along with different types of information that GPR can provide, ease of data collection and non-destructive

nature make GPR an efficient technique for selective deconstruction and useful reusable material identification.

A Framework for Digital and Sustainable Classroom Management: Non-Intrusive CO_2-Based Occupancy Estimation for Demand-Controlled Ventilation

Graziano Salvalai(✉), Roberto Villa, and Manuela Grecchi

Politecnico di Milano, Milano 20133, Italy
graziano.salvalai@polimi.it

Abstract. Classrooms often present low Indoor Air Quality (IAQ) conditions, including in mechanically ventilated educational buildings where Constant Air Volume (CAV) HVAC systems operate on fixed schedules that do not account for real-time occupancy. This rigidity creates a critical trade-off: inadequate IAQ during peak usage and unnecessary energy consumption during low-occupancy periods. Addressing this issue requires accurate, real-time occupancy data, which is often unavailable due to cost or privacy constraints. This study analyses and validates a non-intrusive method for estimating real-time occupant counts using CO_2 concentration data. Measurements were collected in two adjacent classrooms with similar HVAC configurations during a long-term monitoring campaign in which indoor CO_2 levels were continuously recorded. A CO_2 mass-balance model was developed to incorporate sensor data and the constant air exchange rate of the HVAC system, enabling dynamic estimation of occupant-generated CO_2 and, consequently, occupant count. Model outputs were validated against scheduled occupancy data obtained from surveys. Results indicate that the method predicts occupancy patterns with an accuracy of approximately ±5%. With appropriate sensor placement, spatial occupancy distribution can also be inferred. Continuous monitoring revealed frequent CO_2 peaks above recommended thresholds during teaching hours, underscoring the limitations of static ventilation strategies in educational environments. The CO_2-based estimation model effectively captured these events, offering a cost-efficient and privacy-preserving proxy for real-time occupancy.

1 Introduction and Related Works

The built environment plays a pivotal role in both climate change mitigation and human well-being. Buildings account for a substantial share of global final energy consumption and associated greenhouse gas emissions, largely due to heating, cooling, and ventilation demands. In educational buildings, where the number of occupants per unit area

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 1383–1390, 2026.
https://doi.org/10.1007/978-3-032-34930-9_161

can be up to four times higher than in typical office spaces [1], Indoor Air Quality (IAQ) becomes a central concern [2, 3]. Carbon dioxide (CO_2) concentration is widely adopted as a proxy indicator for ventilation adequacy [4]. A CO_2 concentration of 1000 ppm is the de facto standard threshold for acceptable IAQ [5]; exceeding this limit, or reaching levels above 1500–2000 ppm, is linked to reduced cognitive performance and increased discomfort among students [6]. Maintaining adequate IAQ while limiting energy use is therefore a dual objective. In many existing university buildings, mechanical ventilation is provided by Air Handling Units (AHUs) in Constant Air Volume (CAV) mode, operated according to fixed schedules, independently of real occupancy. This creates structural inefficiencies since fixed airflow rates may be insufficient during peak occupancy, leading to a low level of IAQ, while supplying excess air during partial vacancy causes unnecessary energy consumption. Transitioning to adaptive control strategies, such as Demand-Controlled Ventilation (DCV), can yield substantial savings without compromising comfort [7, 8]. Implementing DCV requires reliable real-time occupancy data [9]. Existing occupancy estimation approaches generally fall into direct sensing, indirect environmental sensing, and data-driven methods. While direct sensing techniques (e.g., cameras, optical sensors) provide high accuracy, they suffer from high costs, and severe privacy concerns in educational contexts [10, 11]. Data-driven approaches require extensive labelled datasets and exhibit limited transferability [12]. Consequently, CO_2-based occupancy estimation offers a low-cost, non-intrusive alternative [13]. Since humans produce CO_2 proportionally to their metabolic activity, transient mass-balance formulations can be exploited to dynamically infer occupant counts [14]. This correlation heavily depends on the available volume per student and the ventilation rate [15]. Within a digital building management framework, this approach functions as a virtual sensor [16]. Despite its potential, CO_2-based estimation becomes highly complex under active mechanical ventilation, as the controlled introduction of outdoor air alters indoor CO_2 independently of human presence [10, 11]. If the exact amount of mechanical ventilation is not factored into the mass-balance equations, the model will systematically underestimate the occupant count. Furthermore, baseline outdoor CO_2 concentrations fluctuate daily [4, 17]; assuming a static outdoor baseline of 420 ppm introduces significant calculation errors. To address these gaps, this study proposes and validates a non-intrusive occupancy estimation framework based on transient CO_2 mass-balance modelling applied to mechanically ventilated university classrooms. The main objectives are: i) develop a model capable of estimating real-time occupant count, switching autonomously between mass-balance models based on the operational state of the AHU, ii) validate the model against scheduled occupancy data collected during a long-term monitoring campaign.

2 Methodology

The proposed methodology, schematized in Fig. 1, is based on a transient mass-balance equation describing indoor CO_2 concentration dynamics.

The model relies on three assumptions. These comprise i) reasonably well-mixed indoor air, ii) constant mechanical ventilation rates during operation, and iii) human respiration as the predominant CO_2 source. Standard metabolic rates define this human

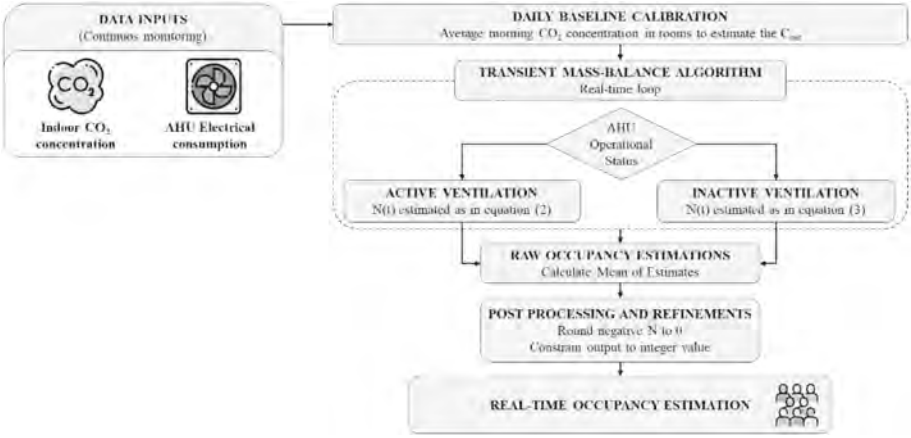

Fig. 1. Methodology framework for a non-intrusive CO_2-based occupancy estimation

generation. The general mass-balance differential equation (1) governs the temporal evolution of indoor CO_2 concentration [11].

$$\frac{dC(t)}{dt} = \frac{N(t) \bullet g}{V} - \frac{Q}{V} \bullet (C(t) - C_{out}) \tag{1}$$

where N(t) represents the number of occupants at time t. The parameter g defines the per-capita CO_2 generation rate, which in this study is set to 0.0052 L/s/person [15]. V denotes the room volume. Q indicates the ventilation airflow rate. C(t) and C_{out} represent the indoor and outdoor CO_2 concentrations, respectively. Discrete-time implementations apply Δt as the sensor sampling interval. $C_{initial}$ and C_{final} signify the indoor CO_2 concentrations at the beginning and end of each time step. The algorithm dynamically recalibrates C_{out} daily to ensure accurate estimations. This baseline derives from averaging the indoor CO_2 concentration measured during the pre-occupancy flushing period. This period spans from the morning activation of the air handling unit until 08.30. The system applies a default outdoor value if it detects no activation within this window. The algorithm adapts the occupant count calculation to the operational state of the mechanical ventilation. The electrical current drawn by the air handling unit continuously indicates this operational state. The system discretises the time series according to Δt. Equation (2) integrates the mechanical extraction of CO_2 over Δt during active ventilation periods.

$$N = \frac{Q}{g \bullet \left(1 - e^{-\frac{Q}{V}\Delta t}\right)} \bullet \left(C_{final} - C_{out} - (C_{initial} - C_{out}) \bullet e^{-\frac{Q}{V}\Delta t}\right) \tag{2}$$

Inactive ventilation periods assume Q equals zero. Equation (3) attributes all CO_2 variation exclusively to occupant generation under these inactive conditions.

$$N = \frac{\left(C_{final} - C_{initial}\right) \bullet V}{g \bullet \Delta t} \tag{3}$$

The algorithm rounds any negative values for N to zero to account for sensor noise. The final output is constrained to integer values. Large spatial volumes can introduce potential inaccuracies. The methodology limits these errors by averaging independent estimates. These estimates originate from the sensors positioned in the front and rear zones.

3 Case Study and Monitoring Setup

The experimental approach was validated during the DIGITMAN project [18–20], using two representative classrooms at the Politecnico di Milano, Lecco Campus. Designated as Classroom A and Classroom B. Both rooms feature a clear height of 3.8 m. Classroom A accommodates 200 seats within 373.02 m^2 and 1,417.48 m^3. It includes a north-facing curtain wall and a west-facing ribbon window. Classroom B provides 100 seats across 170.71 m^2 and 648.70 m^3. This room features a fully glazed western facade with two electrically operated casement windows. Dedicated CAV systems serve both rooms to maintain regulatory air exchange and thermo-hygrometric control. Classroom A receives 11,000 m^3/h of supply air. Classroom B receives 7,200 m^3/h.

The monitored classrooms are accessible on weekdays from 07:00 to 19:00 for fixed lectures and unstructured study. Mechanical ventilation operated daily from 07:00 to 18:00. A distributed sensor network monitored indoor conditions starting in March 2024. Two sensors per room measured carbon dioxide concentrations and other indoor parameters. These devices were suspended 3.0 m high in the front and rear zones (Fig. 2). Measurements were transmitted to a cloud platform at one-minute intervals. The system concurrently logged electrical current, energy consumption, and external weather conditions. Table 1 details the physical characteristics of the classroom and the technical specifications of the sensors employed in the study.

Table 1. Summary of experimental setup and sensor technical specifications

Category	Parameter	Unit	Value/Specification
Classroom A	Volume (V)	m^3	1,417.48
	AHU airflow (Q)	m^3/h	11,000
Classroom B	Volume (V)	m^3	648.70
	AHU airflow (Q)	m^3/h	7,200
Sensors	Air Temperature	°C	Operational range: - 40 to 80 °C Accuracy: ± 0.1 °C
	Relative Humidity	%	Operational range: 0 to 100% Accuracy: ± 1.5%
	CO_2 concentration	ppm	Operational range: 0 to 5000 ppm Accuracy: < (± 50 ppm +3%)

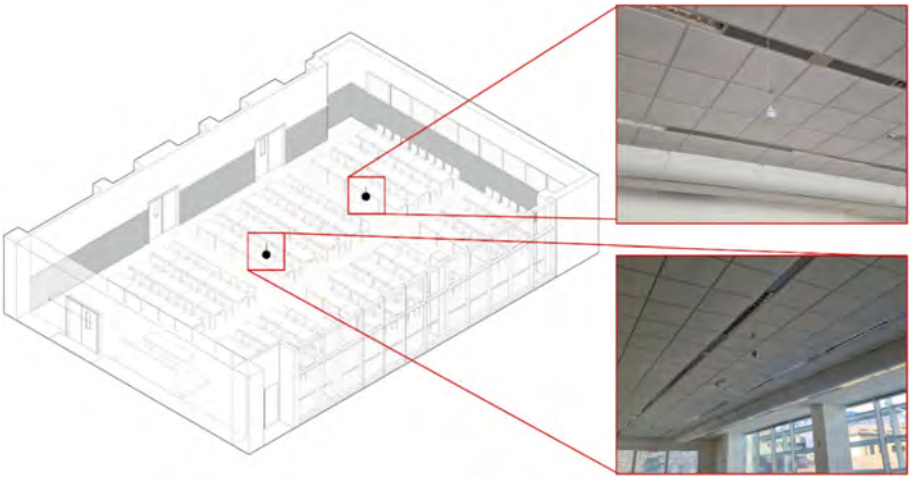

Fig. 2. CO_2 Sensor positioning in Classroom A; similar layout is used in Classroom B

4 Results and Discussion

Continuous monitoring demonstrated the inadequacy of static schedules for predicting ventilation requirements (Fig. 3). Unscheduled occupancy occurred frequently. Attendance during scheduled lectures rarely reached nominal capacity. This discrepancy caused significant over-ventilation. A CO_2-based mass-balance model captured these dynamic occupancy fluctuations accurately. Model predictions were compared against manual survey data. These observations were recorded at approximately hourly intervals during representative operational days. Occasional higher-frequency checks supplemented these routine measurements. The performance was assessed using the Mean Absolute Error (MAE).

Under steady-state conditions, the model achieved an average predictive accuracy of approximately ±5% with a MAE of ±3 occupants. This performance established the model as a reliable proxy. Current CAV systems operate inefficiently compared to established IAQ standards (Fig. 4) [5]. Classroom B supplies 7,200 m^3/h instead of the required 4,000 m^3/h. This causes a structural over-ventilation of 44%. Classroom A supplies 11,000 m^3/h, which exceeds its 8,000 m^3/h normative threshold.

Implementing demand-controlled ventilation with this virtual sensor provides substantial energy conservation. The power consumption of air handling unit fans is proportional to the cube of the airflow rate (Eq. 4).

$$P_2 = P_1 \bullet \left(\frac{Q_2}{Q_1}\right)^3 \tag{4}$$

Adjusting airflow to actual occupancy significantly decreases fan power consumption. Operating in Variable Air Volume mode reduces air velocities across the integrated heat exchanger. This reduction increases contact time and enhances both thermal and latent heat recovery. Several parameters influence the accuracy of the estimation model.

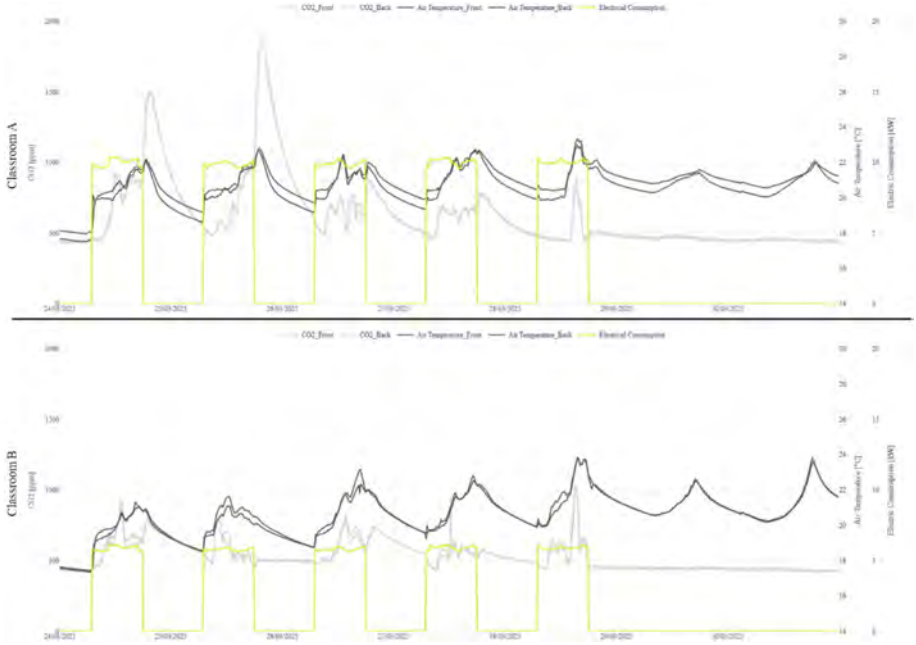

Fig. 3. Monitoring results during a representative week. Up: results for Classroom A; down: results for Classroom B

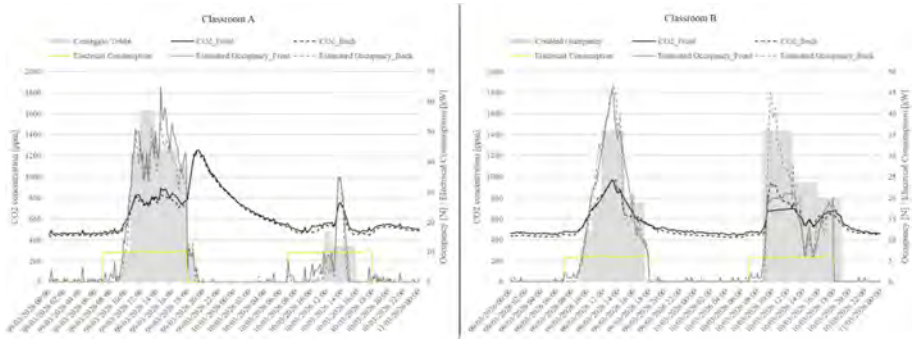

Fig. 4. Comparison of predicted occupancy (grey lines) compared with measured occupancy (light grey area) across two days. Left: results for Classroom A; right: results for Classroom B

These factors include i) the per-capita carbon dioxide generation rate, ii) the assumption of well-mixed air, and iii) the dynamic recalibration of the outdoor baseline. Variations in metabolic activity can introduce deviations in the generation rate. Dual-zone sensors effectively mitigate errors from local concentration gradients. Dynamic outdoor baseline recalibration prevents systematic errors associated with assumed static concentrations.

5 Conclusion

This study validated a non-intrusive, privacy-preserving framework for real-time occupancy estimation. The method employs CO_2 sensors in mechanically ventilated university spaces. The proposed model achieves an accuracy of $\pm 5\%$ without the costs or privacy risks of optical sensors. Results indicate current CAV operations cause a structural energy waste of at least 44%. Over-ventilation during periods of low occupancy causes this inefficiency. An occupancy-based demand-controlled ventilation strategy ensures healthy indoor air quality. This approach complies with regulations while reducing the building carbon footprint through lower fan power. The mass-balance model assumes constant mechanical ventilation. This assumption excludes transient natural ventilation events like window or door openings. System accuracy depends on precise spatial sensor placement. Appropriate positioning remains necessary to capture representative average concentrations in large volumes. Future work will i) integrate virtual sensors into Building Management Systems, ii) quantify thermal savings from optimised heat recovery, and iii) apply machine learning to adapt metabolic emission rates.

Abstract. Impregnation is a process within the discipline of wood preservation. Its purpose is to protect wood against all kinds of biotic and abiotic pests in various applications in the most economical way, using appropriate impregnation agents and methods to ensure optimal and long-lasting durability. This study aimed to impregnate Scots pine wood samples used in the impregnation industry with carbon nanotubes prepared at different concentrations (2% and 3%) using the full-cell method and to standardize these processes. For this purpose, the impregnation process was carried out with the specified tree species woods using impregnants of different concentrations by varying the pre-vacuum time and value (5 and 10 min and 60 cmHg vacuum), pressure time and values (10 and 20 min and 4, 6, and 8 atm pressure), and keeping the final vacuum time and value (5 min and 60 cmHg vacuum) constant. The retention (adhesion, kg/m^3) values, water uptake rates, and compression strength parallel to the grain of the impregnated wood samples were determined. These data were modeled with artificial neural networks. In this context, the impregnation material concentration, pre-vacuum time, pressure value and time were used as input information; and the retention amounts, water uptake rate, and compression strength parallel to grain were entered as outputs. The mean absolute percentage error (MAPE) for all models obtained was below 1%. As a result, models that can predict the intermediate values of the study with very high accuracy were obtained. It was concluded that ANN applications can be used with extremely high reliability and accuracy in such applications within the wood preservation discipline.

1 Introduction

Numerous studies have reported the application of artificial neural networks (ANNs) in the wood and timber industry for modeling production processes and predicting material properties. In this context, ANN models have been successfully applied to estimate drying rates in kiln-drying processes of lumber, demonstrating higher prediction accuracy

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 1391–1398, 2026.
https://doi.org/10.1007/978-3-032-34930-9_162

compared to traditional modeling [1]. Similarly, ANN-based data fusion methods have been utilized in moisture content sensing systems for timber, improving the reliability and precision of moisture measurements [2]. In studies focusing on wood material classification, artificial neural networks have been combined with image-based analysis techniques for veneer classification, and the integration of evolutionary feature selection methods has been shown to significantly enhance classification performance [3].

ANN models have also provided important contributions to process optimization and quality control in manufacturing environments. For instance, artificial neural networks have been employed to predict and control surface roughness in CNC turning operations, successfully modeling the complex relationships between machining parameters and surface quality [4]. In addition, ANN applications in variable process control have demonstrated considerable advantages in monitoring and managing production performance in particleboard manufacturing (Esteban, Fernández, De Palacios, & Conde, 2009). In research investigating the mechanical properties of structural plywood panels, ANN models have been used to predict parameters such as modulus of rupture (MOR) and modulus of elasticity (MOE), and these models were found to provide higher predictive accuracy compared to multivariate regression approaches [5].

Furthermore, hybrid approaches combining neural networks with decision tree methods have been developed for the classification of wood veneer images, yielding promising results for material quality assessment [6]. In studies examining the mechanical performance of heat-treated wood, ANN models have also been applied to predict compressive strength, and these models have been shown to outperform multiple linear regression models in terms of predictive capability and reliability [7]. Collectively, these studies highlight the effectiveness of artificial neural networks as powerful tools for modeling production processes, predicting material properties, and supporting quality control applications in wood science and wood-based industries. The aim of this study was to investigate the effects of carbon nanotube–based impregnation parameters on the retention, water absorption behavior, and compressive strength parallel to the grain of *Pinus sylvestris* wood, and to develop artificial neural network models capable of accurately predicting these properties based on the applied treatment conditions.

2 Material and Method

2.1 Wood Species

Scots pine (*Pinus sylvestris*) wood samples, commonly used in the impregnation industry, were evaluated in this study.

2.2 Impregnation Agents

As the impregnation agent, nano-sized carbon nanotubes prepared at different concentrations (2% and 3%) using distilled water as the solvent were utilized.

2.3 Impregnation Conditions

The full-cell process was applied as the impregnation method. Scots pine wood samples were impregnated using solutions with different concentrations by varying the pre-vacuum duration and level (5 and 10 min at 60 cmHg vacuum), pressure duration and levels (10 and 20 min at 4, 6, and 8 atm pressure), and final vacuum duration and level (5 min at 60 cmHg vacuum). Following the treatment, retention values were determined.

2.4 Retention Amount

The retention amount of the experimental samples (R, kg/m^3) was calculated using Eq. (1) given below.

$$R\left(kg/m^3\right) = (G \times C)/V \times 10 \tag{1}$$

In this formula: R = Retention amount (kg/m^3); G = $T_2 - T_1$, where G represents the amount of impregnating agent absorbed (g); T_1 = weight of the sample before impregnation (g); T_2 = weight of the sample after impregnation (g); C = solution concentration (%); V = sample volume (cm^3).

2.5 Water Absorption Ratio (WAR)

Samples measuring of 3 × 3 × 1.5 cm were used to calculate the water absorption ratio (WAR). The impregnated samples were dried in an oven at 103 ± 2 °C until they reached a constant weight, and their oven-dry weights and dimensions were determined. Subsequently, the samples were placed in a certain amount of water with a weight applied on top to keep them fully submerged. During the immersion period of 336 h (2 weeks—the final measurement time according to the standard), the amount of water absorbed and the dimensional changes of both experimental and control samples were measured. For this purpose, at the end of each measurement period, the samples were removed from the water, the excess surface water was wiped off, and measurements were taken with the same precision. Using the initial oven-dry weight values, the water absorption ratio (WAR, %) was calculated separately for each experimental and control sample. WAR was calculated according to Eq. (2).

$$WAR(\%) = \left(\frac{M_2 - M_0}{M_0}\right) \times 100 \tag{2}$$

M_0: Initial oven-dry weight (g); M_2: Weight of the sample removed from water after each measurement period (g).

2.6 Compressive Strength Parallel to Grain

The compressive strength tests were conducted in the laboratories of the Department of Forest Industrial Engineering, Faculty of Forestry, Karadeniz Technical University, using universal testing machines in accordance with the TS-2595 (1977) standard. The

test samples were prepared with dimensions of 20 × 20 × 30 mm and conditioned at 20 °C and 65% relative humidity. After conditioning, the samples were air-dried, and their width and thickness were measured before testing. These measurements were performed from the middle section of each specimen using a micrometer with a precision of ±1 mm. During the test, a uniform loading rate was applied to the specimens' cross-sections so that they could be crushed within 2 min. The load was continuously applied until the specimen failed, and the maximum load value at the moment of failure was recorded from the machine dial. By measuring the force at failure (F_{max}), the compressive strength parallel to the grain ($\sigma_{B//}$) was calculated using Eq. (3) given below.

$$\sigma_{B//} = \frac{F_{\max}}{a \times b}\left(\frac{N}{mm^2}\right) \tag{3}$$

Fmax: Force at the moment of failure (N); a: Side length of the cross-section of the sample (mm); b: Side length of the cross-section of the sample (mm)

2.7 Modeling with Artificial Neural Networks

The modeling process was carried out by creating an ".m file" code in the MATLAB software environment. In the models, which had a feedforward network architecture and consisted of a single hidden layer, the backpropagation learning algorithm was used as the training algorithm. In addition, the Levenberg–Marquardt (LM) and Scaled Conjugate Gradient (SCG) algorithms were selected as optimization algorithms. For each model, two different optimization algorithms and fifteen different hidden neuron numbers (5–20) were compared in order to determine the most suitable network architecture. The learning rate and momentum coefficient were both set to 0.5, the maximum number of iterations was 1500, the validation check number was 500, and the target error value was determined as 1×10^{-5}. The performance of the obtained models was evaluated using the mean squared error (MSE), mean absolute percentage error (MAPE), and the coefficient of determination (R^2) Eqs. 4–6, respectively

$$MSE = \frac{1}{n}\sum_{i=1}^{n}(e_i - p_i)^2 \tag{4}$$

$$MAPE(\%) = \frac{1}{n}\sum\left|\frac{e_i - p_i}{e_i}\right| \times 100 \tag{5}$$

$$R^2 = 1 - \frac{\sum_{i=1}^{n}(e_i - p_i)^2}{\sum_{i=1}^{n}(e_i - \overline{e})^2} \tag{6}$$

In the equations, n represents the number of data points, e_i represents the actual value, $\overline{e}$ represents the mean of the actual values, and p_i represents the predicted value generated by the model.

3 Results and Discussion

The ANN model data table for the samples impregnated with carbon nanotubes is presented in Table 1.

Table 1. The test results for the samples impregnated with carbon nanotubes

Pre-vacuum time (min)	Pressure time (min)	Pressure level (atm)	Impregnation concentration (%)	Retention (kg/m^3)	Water absorption ratio (%)	Compressive strength parallel to grain (N/mm^2)
5	10	4	2	13.07	90.45	552.46
5	10	6	2	13.25	90	556.31
5	10	8	2	13.4	90.56	550.03
5	20	4	2	13.5	89.95	550.45
5	20	6	2	13.56	89.9	551.3
5	20	8	2	13.65	89.88	549.67
10	10	4	2	13.69	87.56	556.08
10	10	6	2	13.87	87.5	559.93
10	10	8	2	14.02	87.41	553.65
10	20	4	2	14.12	87.3	554.07
10	20	6	2	14.18	86.83	554.92
10	20	8	2	14.27	86.5	553.29
5	10	4	3	19.09	88.22	559.23
5	10	6	3	19.27	87.77	563.08
5	10	8	3	19.42	87.33	556.8
5	20	4	3	19.52	87.72	557.22
5	20	6	3	19.58	87.67	558.07
5	20	8	3	19.67	87.65	556.44
10	10	4	3	19.18	85.33	562.85
10	10	6	3	19.36	85.27	566.7
10	10	8	3	19.51	85.18	560.42
10	20	4	3	19.61	85.07	560.84
10	20	6	3	19.67	84.6	561.69
10	20	8	3	19.76	84.27	560.06

Overall, higher impregnation concentration, longer pre-vacuum duration, and higher pressure levels tend to increase the retention amount while reducing the water absorption ratio. In terms of mechanical properties, although no substantial changes were observed in the compressive strength parallel to the grain, slight improvements were detected under certain treatment combinations. These findings indicate that carbon nanotube impregnation plays a particularly significant role in influencing retention and water

absorption behavior, while its effect on mechanical properties appears to be more limited but generally positive.

Performance of the Best Selected ANN Model for Carbon Nanotube–Impregnated was presented in Table 2.

Table 2. Performance of the Best Selected ANN Model for Carbon Nanotube–Impregnated

Tested Parameter	Performance	Training	Validation	Test	Overall
Retention	MSE	0.000935	0.02313	0.005586	0.004369
	MAPE	0.170894	112.859	0.484938	0.276872
	R	0.999944	1	1	0.99977
Water Absorption Ratio	MSE	0.000343	0.3121	0.202339	0.064591
	MAPE	0.017053	0.641358	0.531378	0.111939
	R	0.99995	1	1	0.990726
Compressive Strength Parallel to Grain	MSE	0.006131	0.292559	0.046989	0.047553
	MAPE	0.010664	0.119484	0.047894	0.022834
	R	0.999827	1	1	0.998881

The performance results indicate that the artificial neural network model achieved very high prediction accuracy for all investigated properties. The coefficient of determination (R) values are extremely close to 1, both in the training phase and in the validation and test datasets, demonstrating a strong agreement between predicted and experimental values. In particular, the overall R values of 0.999 for retention, 0.990 for water absorption ratio, and 0.998 for compressive strength parallel to grain confirm that the model has a very high predictive capability. Similarly, the MSE values obtained for the three parameters are quite low, indicating minimal deviation between predicted and observed values. Among the tested properties, the retention model shows the lowest overall error values, suggesting that the ANN model is particularly effective in predicting retention behavior. Although slightly higher error values were observed in the validation phase for water absorption ratio and compressive strength, the overall performance metrics still demonstrate a strong predictive performance. The MAPE values further support the accuracy of the models, as the overall percentage errors remain at very low levels. These results collectively suggest that the developed ANN model can reliably estimate retention, water absorption ratio, and compressive strength parallel to grain in carbon nanotube–impregnated wood samples, making it a powerful predictive tool for evaluating impregnation performance and related wood properties.

Although the ANN models showed high predictive accuracy, the present study was based on a limited and relatively homogeneous dataset. Therefore, model generalizability to different wood species, broader impregnation conditions, and varying environmental conditions should be interpreted cautiously. Future studies should test the model with larger datasets and compare its performance with alternative modeling approaches.

4 Conclusion

In conclusion, the results of this study demonstrate that impregnation parameters and carbon nanotube concentration significantly influence the retention capacity, water absorption behavior, and to a lesser extent the mechanical performance of *Pinus sylvestris* wood. Increasing impregnation concentration, pressure level, and treatment duration generally enhanced retention values, indicating more effective penetration of the impregnating agent into the wood structure. At the same time, higher retention levels were associated with reduced water absorption, suggesting that carbon nanotube impregnation contributes to improved dimensional stability by partially limiting water uptake. Although the compressive strength parallel to the grain did not exhibit large variations among treatment conditions, slight improvements were observed in several parameter combinations, indicating that the treatment does not adversely affect the mechanical integrity of the wood. Furthermore, the artificial neural network models developed in this study showed very high predictive performance, with extremely high determination coefficients and low error values, confirming that ANN-based approaches can successfully estimate retention, water absorption, and compressive strength based on processing parameters. Overall, the findings highlight the potential of combining carbon nanotube impregnation and ANN-based modeling as an effective strategy for predicting and optimizing the performance of impregnated wood materials.

Abstract. Historical urban nodes are complex heritage environments shaped not only by physical traces but also by sensory and emotional layers emerging from embodied user experiences. Within the scope of a TÜBİTAK-supported international project, this study reinterprets the sensory heritage of the Bedesten in Trabzon, Turkey, by analyzing concepts and sketches produced by participants through seeing, hearing, smelling, tasting, and touching using an AI-assisted model. Integrating Pallasmaa's multisensory architecture with Merleau-Ponty's philosophy of embodied perception, the study emphasizes sensory–emotional sustainability. Sketches (visual impression and conceptual) and textual emotion expressions were combined to construct a multimodal emotional resonance map. Processed through an unsupervised Self-Organizing Map (SOM), these data generate a spatial emotional topology. The proposed Model–Concept Protocol (MCP) organizes multimodal sensory data and offers a framework for digitally interpreting the emotional identity of historical urban environments, supporting sensory heritage documentation and the long-term sustainability of heritage assets

Keywords: Sensory Heritage · Emotional Sustainability · Multimodal Analysis · Artificial Intelligence and SOM · MCP (Model-Concept Protocol)

1 Introduction

Urban space is a complex phenomenon shaped by sensory and emotional interactions, which are essential to understand cities as unique fields of knowledge (Durmuş Öztürk & Çıraklı, 2023). Senses and emotions are very influential in the way people perceive urban spaces and therefore are very important in the formation of the spatial experience. Historical urban nodes are characterized not only by their physical features but also by the sensory and emotional experiences generated through embodied interactions.

This study was supported by Scientific and Technological Research Council of Türkiye (TUBITAK) under Grant Number 223K212. The authors thank TUBITAK for their support.

In architectural discourse, the multisensory character of spatial experience is increasingly acknowledged as a crucial factor in the perception and memory of environments (Pallasmaa, 2005; Böhme, 2017). However, heritage studies often focus on material conservation and the visual, ignoring the sensory and affective layers that contribute to the experienced dimension of historic places. Recent advances in digital technologies and artificial intelligence open up new possibilities for the integration of experiential data in architectural analysis. The paper proposes an MCP-oriented modeling approach for studying emotional transformations in sensory heritage environments. The Bedesten in Trabzon, Turkey in a TÜBİTAK supported urban route: The model-concept protocol (MCP) and self-organizing map (SOM) modeling for the analysis of sensory heritage and emotional dynamics of historical urban nodes.

2 Conceptual Framework of Sensory Heritage Modeling

Urban historic continuity is maintained not only through physical structures, but also through multi-sensory interactions and emotional responses that are elicited in spatial contexts by users. The importance of sensory perception and spatial atmosphere for the creation of human experience has been long recognized in architectural theory (Pallasmaa, 2005), but heritage documentation practices have mostly been confined to visual and material attributes. Consequently, it is challenging to systematically document and interpret the complex sensory and affective layers that constitute the lived experience of historic environments. Recent studies have pointed to the limitations of object-centred heritage archives and their visual bias in representing embodied and multisensory experiences (Hou et al., 2022). Such a limitation emphasizes the need for computational methods and defined protocols to interpret multimodal sensory data.

2.1 Sensory Heritage and Multimodal Spatial Emotion Modeling

Sensory architecture is a primary medium in the intergenerational transmission of collective memory, but it is troubled in urban settings with histories of rupture. This has prompted interest in sensory–emotional sustainability, focusing on the documentation of the experiential dimensions of urban heritage. The merging of experience and technology is essential to the creation of knowledge as cities evolve. Heritage contributes to local identity and sustainability. As suggested by research, the emotional resonance in digital heritage environments relies on well-structured multimodal configurations (Zhang & Du, 2025). New research opportunities arise with advances in technology and data-driven analysis methods (Picon, 2010; Carpo, 2017). Spatial emotion modeling studies user-space relations and discovers patterns from computational data. Affective computing, and more broadly, artificial intelligence tools, offer a better way to explore emotional experiences (Picard, 2000). Multimodal machine learning enables the combination of different data types (Baltrušaitis et al., 2017). The study uses sketches and textual emotion expressions in a multimodal data set analyzed by Self Organizing Map (SOM) to produce a spatial emotional topology that emphasizes the axes of emotional transformation.

2.2 Why a Protocol? The Need for MCP

Historical spaces are intricate systems influenced by sensory perceptions and embodied experiences. Conventional cultural heritage research has primarily emphasized visual and material elements, neglecting sensory and emotional aspects. This study introduces the Model–Concept Protocol (MCP) as a framework for organizing and interpreting sensory data in urban settings. By incorporating sketches and textual emotional expressions, MCP facilitates AI-supported analysis of the physical and experiential characteristics of historical spaces.

3 Methodological Framework

3.1 Research Context: Bedesten as a Historical Urban Node

Trabzon's Bedesten is an important commercial and social center, serving as a covered bazaar for precious goods and a gathering place for diverse social groups. Its architectural significance comes from its function in the historical trade network of Trabzon (Tuluk & Üstün, 2007). It is strategically located in the bazaar district and linked to caravanserais and markets, and it is an example of Ottoman urbanism that encourages economic activity and social interaction (Cerasi, 1999). Originally a part of key trade routes, it has moved from a busy commercial centre to a place of cultural heritage and tourism, showing changes in the collective memory of the city (Lowry, 2010). This paper explores the Bedesten as a historical urban node where the interactions of its users produce sensory and emotional experiences.

3.2 Data Structure and Preprocessing

The study examines the user experiences at Trabzon Bedesten by employing a dataset of multi-layered sensory data obtained from textual emotional expressions and sketches of 24 architecture students. The analysis was performed with text preprocessing by applying natural language processing (NLP) techniques, including text cleaning and TF-IDF transformation for numerical feature representation. Each student took part in a 45–60 min sensory exploration session and produced 48 sketches and documented associated sensory and emotional experiences. The project was funded by TÜBİTAK (223 K212) and voluntary participation and anonymization of data during processing were guaranteed.

$$TFIDF(t,d) = TF(t,d) \times \log\left(\frac{N}{DF(t)}\right) \tag{1}$$

The visual data sketches were digitized and image processing techniques were used to extract features. The included image features were edge density, shape distribution, and line orientation parameters. All the data obtained after the preprocessing were converted into digital feature vectors and a suitable data structure was generated for analysis.

3.3 Multimodal Modeling Architecture

The research uses a multimodal data modeling approach to analyze different types of data within a unified framework. This improves the analysis by integrating different sensory layers of spatial experience. It utilizes an artificial intelligence technology with a two-dimensional array structure.

$$X = \left[X_{text}, X_{image}\right] \tag{2}$$

3.4 Sensory Vector Space

For the analysis of multidimensional array data a common representation of all data types is important and it is given by the sensory vector space approach. The framework offers a common context for diverse data types about spatial experiences. As shown in Eq. (3), the differences of two samples of sensory data are intended to estimate the similarities of different user experiences.

$$d(x, y) = \sqrt{\sum_{i=1}^{n} (x_i - y_i)^2} \tag{3}$$

The study used textual and visual data from participants to produce sensory vectors. It classified textual data into five sensory categories—sight, hearing, smell, touch and taste—and linked emotional concepts to them. Visual sketches were divided and categorized according to the main sensory references. Frequency counts revealed the presence of all sensory and emotional categories in the responses of participants, which were subsequently normalized and transformed into numerical vectors for multimodal processing in a shared feature space.

3.5 Self-Organizing Map Implementation

We applied a classifying method of sensory data pattern based on the Self-Organizing Map (SOM) of unsupervised learning. The SOM model is an artificial neural network that maps high-dimensional data onto a two-dimensional map, with each neuron represented by a weight vector.

$$w_j = \left[w_{j1}, w_{j2}, \ldots, w_{jn}\right] \tag{4}$$

The nearest neuron (Best Matching Unit – BMU) was determined for each data sample, and weights were calculated as shown in Eq. (6) and used to position similar data samples close to each other on the map. x, w_j, $\alpha(t)$ and $h_{cj}(t)$ represent input vector, neuron weight vector, learning coefficient, neighborhood function respectively.

$$BMU = argmin_j \parallel x - w_j \parallel \tag{5}$$

$$w_j(t+1) = w_j(t) + \alpha(t) \cdot h_{cj}(t) \cdot \left(x - w_j(t)\right) \tag{6}$$

The SOM model was a hexagonal map of 10 × 10, with 1000 training iterations and an initial learning rate of 0.5, which is decreased over time. It used a Gaussian neighborhood function. Weights were randomly initialized. The evaluation metrics show a Quantization Error of 0.083 and a Topographic Error of 0.021, which mean that the clustering and the topology preservation were effective.

3.6 Model–Concept Protocol Structure

In the study, the Model–Concept Protocol (MCP) was employed to systematically analyze multimodal sensory data. The framework comprises three layers: conceptual expressions of participants related to space, sketches or visual representations, and the application layers for artificial intelligence and data mining methods (Fig. 1).

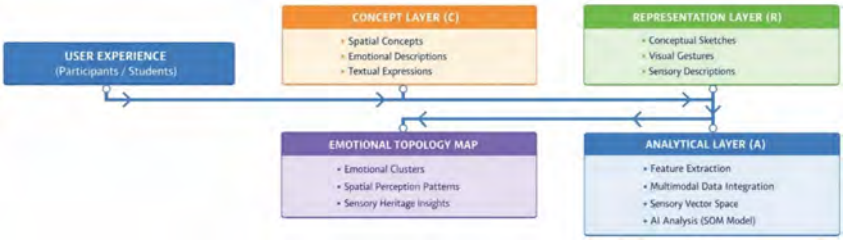

Fig. 1. Model-Concept Protocol Structure

4 Findings: Emotional Topology of the Bedesten

The analysis was done by the Self-Organizing Map (SOM) model to show the emotional clusters of the participants related to the Bedesten. Sensory and emotional perceptions are grouped around specific patterns based on participant experiences (Fig. 2). The sensory vector is computed using specific equations as X = [124, 30, 130, 155, 39 | 84, 13, 66, 64, 25]. The strongest sensory intensities are smell, touch and sight. Sum of sensory frequency was 478. The normalized sensory vector was calculated as Sn = [0.259, 0.063, 0.272, 0.324, 0.082]. Moreover, the total emotional frequency was calculated to be 252, which resulted in a normalized emotional vector En = [0.333, 0.052, 0.262, 0.254, 0.099]. The sensory-emotional topology of the SOM analysis is shown in further visualization in Fig. 2. Additional visualizations of the U-Matrix output and maps of neuron hit distribution in Appendix A (A1, A2, A3) increase the transparency of the method by visualizing the boundaries between clusters and the density of the data across the SOM structure (Fig. 3).

The Bedesten experience is one of touch, smell and sight with less emphasis on hearing and taste. The multimodal analysis on sensory data and sketches indicates a high correlation between senses and emotional responses with respect to the space. Tactile, visual and olfactory perceptions trigger emotions, showing a rich sensory environment created by stone textures and scents. The basic emotional concepts of "trace," "comfort,"

Fig. 2. Sensory Emotion Map

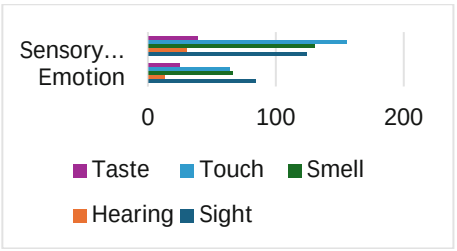

Fig. 3. Digitized sensory and emotions

"integration," "history," and "discovery" suggest that the Bedesten is an ambience that reinforces emotional links to the past. Our analysis with SOM shows the grouping of similar sensory-emotional patterns in the adjacent neurons, which indicates common perceptual experiences, and demonstrates the effectiveness of the SOM in mapping relationships in multimodal heritage data and recurring emotional patterns linked to the sensory features of the space (Fig. 4).

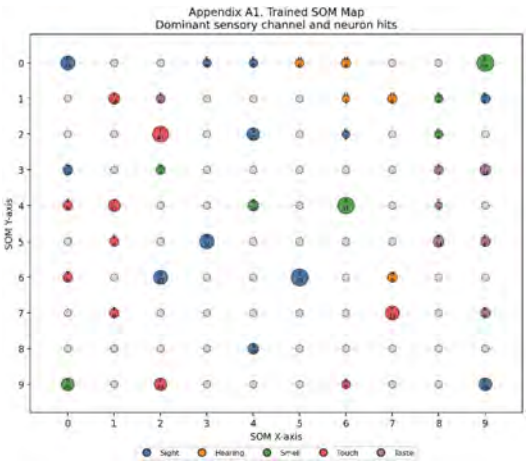

Fig. 4. Trained SOM Map

The U-Matrix visualization reveals the cluster structure of the dataset, showing the distance relationships between neighboring neurons. Areas of lower distances are groups of sensory-emotional observations with similar characteristics, and areas of higher distances are transitions between different perceptive groups. According to the description, the participants' experience is not identical, but is based on several main sensory-emotional themes. This is consistent with the idea of the Bedesten as a layered sensory heritage environment where different sensory channels trigger different emotional responses. The Hit Map shows the distribution of participant observations across the SOM neurons, indicating that some sensory-emotional patterns were commonly perceived by several participants. The clustering reveals the most salient topics in the

Bedesten environment and indicates the agreement among users about their perceptions of the space. On the other hand, neurons with a small number of hits correspond to unique or personal experiences. Taken together, the results confirm that the perception of sensory heritage in the Bedesten is the result of collective as well as individual experiences, reflecting the complex emotional engagement with historical urban environments (Fig. 5).

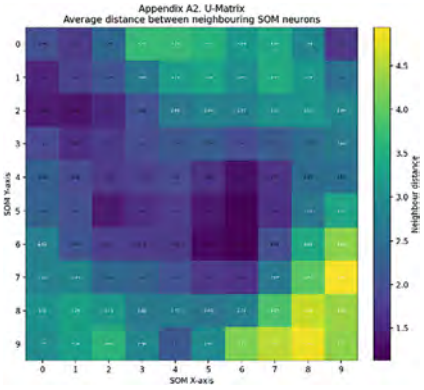

Fig. 5. U Matrix

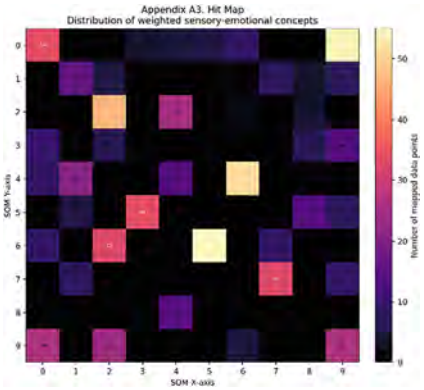

Fig. 6. Hit Map

The analysis of visual and concept sketches brings to light the role of sensory experiences and emotional responses in shaping user experiences, particularly in the context of the Bedesten. These conceptual sketches on the tactile and olfactory senses point to themes such as "trace," "internalization," and "comfort" where material texture and atmospheric qualities are of great importance. In this study, sensory frequencies were defined as sensory variables and conceptual expressions of participants were defined as emotional variables and evaluated by correlation analysis. The results indicate a significant relation between emotional responses and the senses of touch, smell and sight, which are identified as essential for the construction of spatial experiences. By contrast, hearing and taste were less correlated. The findings suggest that historical urban spaces, such as the Bedesten, do not only derive meaning from the visual architecture but also from the material textures and sensory atmospheres; therefore it is presented as a multilayered sensory heritage environment. A Pearson correlation analysis revealed moderate to strong positive correlations ($r = 0.61–0.83$, $p < 0.05$) between touch, smell and sight and the key emotional concepts of comfort and discovery. The correlation matrix also confirmed the central role of tactile, visual and olfactory perceptions in the emotional experiences of the Bedesten.

5 Discussion and Conclusions

We present the Model-Concept Protocol (MCP), a framework to organize sensory-emotional data from user experiences for artificial intelligence (AI) analysis. Using the Trabzon Bedesten as a case study, the framework leverages textual and sketch data produced by participants to build a multimodal representation of sensory interactions. The

main conclusions are that the sustainability of historical environments depends on the physical structures as well as their emotional atmospheres created by user experiences. The research calls for a methodological change in architectural and cultural heritage research through the lens of sensory heritage and emotional sustainability, allowing AI-supported documentation and experiential analysis. The MCP framework conceptualizes historical environments as dynamic emotional landscapes to help document sensory heritage, strengthen attachment to place, and guide adaptive reuse, thereby contributing to heritage continuity, cultural sustainability, circularity and United Nations Sustainable Development Goal 11 (Sustainable Cities and Communities).

Abstract. Digitalisation is increasingly acknowledged as a critical enabler of the circular economy, supporting the shift from linear production models toward sustainable, closed-loop systems. While its implications for manufacturing and supply chains have been widely examined, its specific role in advancing the energy transition and strengthening the resilience of the built environment remains underexplored. The interaction between digital tools, circular strategies, and energy and material flows in buildings is particularly relevant given the sector's centrality to decarbonisation and climate-neutrality goals.

Emerging digital instruments, such as Digital Product Passports (DPPs), Building Renovation Passports (BRP), and Digital Building Logbooks (DBLs), provide lifecycle and product data to support circular practices, including resource efficiency, operational optimisation, and renovation planning. However, adoption is constrained by limited interoperability, fragmented data governance, and inconsistent policy frameworks.

This study conducts a comparative policy analysis of selected European digital policy initiatives, focusing on their relevance to circular renovation, integration with digital tools, and impact on energy performance. It provides a structured synthesis of policy instruments, a classification of digital tools, and a conceptual framework to assess alignment and fragmentation between policy objectives and implementation. The paper highlights interoperability challenges and outlines pathways to integrate digital infrastructures with renovation strategies to support EU energy transition goals.

Keywords: Digitalisation · Circular Economy · Energy Transition · Building Renovation Passport · Digital Building Logbook

1 Introduction

The building sector accounts for approximately 50% of resource extraction and consumption, over 30% of EU waste, 40% of energy use, and 36% of energy-related greenhouse gas emissions. Key materials such as cement, iron, and steel are major sources of emissions. Given this environmental footprint, transforming the sector is central to European climate and resource efficiency policies (Bragança et al. 2024).

There is an urgent need to move beyond the linear "business-as-usual" model by applying circular economy (CE) principles to reduce resource consumption and lifecycle impacts (Executive Agency for Small and Medium sized Enterprises. et al. 2021).

The CE model promotes decarbonising the construction sector by reducing waste and resource extraction through narrowing, slowing, and closing resource loops (Çetin et al. 2021) (Keles et al. 2025). These approaches are increasingly seen as essential for a sustainable, low-carbon built environment (Sáez-de-Guinoa et al. 2022).

Despite growing policy focus, the links among EU frameworks, digital tools, and circular renovation remain underexplored.

This paper addresses this gap through a qualitative comparative policy analysis of European initiatives and a review of digital building information systems. Policy frameworks were selected based on relevance to circular economy objectives, integration with digital tools, and impact on energy performance. Digital tools were identified through a structured review of ScienceDirect (2022–2026), yielding 221 articles; after screening for relevance and scope, 52 studies were retained. The structured literature review informs the classification of digital tools presented in Sect. 2, which in turn provides the analytical basis for the comparative policy analysis. Together, these components feed into the proposed conceptual framework linking policy drivers, digital tools, and circular renovation practices. The study is positioned as a conceptual and policy analysis contribution, without primary empirical data.

2 EU Policy Frameworks Supporting Circular Renovation

The EU has introduced several policy initiatives that link circular-economy principles, sustainability, and digitalisation, collectively establishing a framework that connects circular-economy objectives to building renovation and data systems. However, their contributions differ significantly in regulatory strength, scope, and capacity to support digital and circular renovation practices. Frameworks were prioritised based on their binding regulatory force, explicit provisions for digital tools, and direct relevance to building renovation.

To strengthen the comparative analysis, policy frameworks were systematically assessed across six analytical dimensions: (i) scope, (ii) regulatory force, (iii) implementation maturity, (iv) level of integration with digital building tools, (v) interoperability provisions, and (vi) relevance to circular renovation. This framework enables a structured comparison of how different policies contribute to the digitalisation–circularity nexus in the built environment.

2.1 Comparative Overview of EU Policy Frameworks

The analysed policies reflect a multi-level governance structure spanning strategic, building-, and product-level instruments.

At the strategic level, the Circular Economy Action Plans (2015, 2020) define overarching objectives for resource efficiency and material circularity. However, as non-binding frameworks, they provide only indirect support for digitalisation and circular renovation.

Building-level policies show stronger implementation capacity. The Renovation Wave promotes large-scale renovation under the European Green Deal, emphasising lifecycle thinking and energy performance. The recast Energy Performance of Buildings Directive (EPBD) operationalises these objectives through binding requirements and supports digital tools such as DBLs and interoperable data systems, strengthening lifecycle data management.

At the product level, the revised Construction Products Regulation (CPR) introduces binding requirements for product transparency and sustainability, supporting structured digital information. In contrast, the Level(s) framework provides a voluntary methodology for lifecycle-based assessment, contributing to harmonisation but with limited direct impact.

Emerging initiatives, such as the EU Digital Building Logbook framework, aim to consolidate lifecycle data but remain under development with unresolved standardisation challenges (Hwang et al. 2025). Table 1 compares these frameworks across analytical dimensions, highlighting differences in regulatory strength, maturity, and capacity to support digitalisation and circular renovation.

Table 1. Key EU Policy Frameworks supporting Circular Economy

Policy	Scope	Regulatory Force	Implementation Maturity	Digital Integration	Interoperability Provisions	Relevance to Circular Renovation
Circular Economy Action Plan(2015, 2020)	Cross-sector	Strategic (non-binding)	High	Indirect	Limited	Indirect
Circular Economy Act	Cross-sector	Binding (expected)	Emerging	Moderate	Under development	Medium
Renovation Wave	Buildings	Strategic	Medium–High	Indirect	Limited	High
EPBD recast (2024)	Buildings	Binding (Directive)	High	Strong (DBLs, BRP, EPC)	Moderate	High
Level(s) Framework	Buildings	Voluntary	Medium	Indirect	Limited	Medium
CPR revision (2024)	Products	Binding (Regulation)	Medium	Moderate (DPP link)	Partial	Medium–High
EU Digital Building Logbook Initiative	Buildings	Emerging framework	Developing	Strong	Under development	High

The comparison shows that binding instruments, particularly the EPBD and CPR, play a central role in operationalising digital and circular objectives, while strategic and

voluntary frameworks provide direction but limited enforcement. This uneven distribution of regulatory force contributes to differences in implementation and impacts the effectiveness of digital tools across system levels.

2.2 From Policy to Practice: Digital Tools and System Integration

According to researchers (Antikainen et al. 2018) digitalisation accelerates the transition to a circular economy by closing material loops through precise product data and optimising processes to minimise waste and reduce transaction costs. These tools facilitate the exchange of building and product information across the lifecycle, enabling more informed renovation decisions and supporting circular construction practices.

The comparative analysis shows that policy frameworks operate at complementary system levels, shaping the development and deployment of digital tools throughout the building lifecycle.

At the building level, policies such as the EPBD and Renovation Wave enable tools including BIM, Digital Twins, DBLs, and BRPs. These tools support lifecycle data management, renovation planning, and performance optimisation. BIM enables structured digital modelling and circular design strategies, while Digital Twins extend these capabilities through real-time monitoring (Çetin et al. 2022; Hwang et al. 2025). DBLs function as central repositories that integrate materials, components, and renovation history, supporting informed, circular decision-making (Alonso et al. 2023).

At the product and material level, policies such as the CPR underpin DPPs and Material Passports, which provide structured data on product composition, environmental performance, and lifecycle characteristics. These tools enhance material transparency and traceability, enabling circular construction practices.

Table 2 summarises these tools and their contributions to circular economy and energy transition objectives, illustrating how policy frameworks are translated into operational digital mechanisms.

Despite their complementary roles, the integration of these tools across system levels remains limited. A functional division emerges in which building-level tools focus on energy performance and renovation planning, while product-level tools address material transparency. However, these domains are not fully aligned. DBLs are intended to centralise building information but depend on compatible product-level data, while DPPs provide detailed product information without clear integration pathways into building-level systems. This fragmentation limits the ability to connect material data with renovation decision-making processes.

Table 2. Digital tools' contribution to the circular economy.

Digital Tool	Description	Contribution to Circular Economy	Contribution to Energy Transition
Building Level Tools			
. digital modelling and operational tools			
Building Information Modelling (BIM)	Digital representation of the physical and functional characteristics of a building	Enables lifecycle material tracking, design for disassembly, and circular design strategies	Supports energy modelling, renovation planning, and building performance analysis
Digital Twins	Real-time digital replicas of physical buildings using sensor and operational data	Enable monitoring of building components and predictive maintenance, extending asset life	Optimise building operations and energy performance
. data repositories			
Digital Building Logbooks (DBL)	Digital repositories containing structured information about buildings across their lifecycle	Store information on materials, components, and renovation history, facilitating reuse and recycling	Integrate energy performance data and renovation pathways
. planning instruments			
Building Renovation Passports (BRP)	Long-term renovation roadmaps for individual buildings	Support stepwise renovation strategies that can incorporate circular construction principles together with DBLs	Guide energy renovation pathways towards highly efficient buildings
Material/ Product Level Tools			
. data repositories			
Digital Product Passport (DPP)	Digital record containing structured information about a product's composition, origin, environmental performance, and lifecycle characteristics	Improves material transparency and traceability, enabling repair, reuse, recycling, and secondary material markets	Provides data on product energy performance and lifecycle carbon emissions, supporting energy-efficient and low-carbon products
Material Passports	Databases documenting the composition and characteristics of materials used in buildings	Improve traceability of materials and enable reuse, recycling, and recovery at the end of life	Support lifecycle assessment and embodied carbon analysis

3 Policy, Digitalisation and Circular Renovation

The proposed framework builds on the policy and tool analysis in Sect. 2 as an original synthesis. Rather than depicting a linear link between policy drivers, digital tools, and renovation outcomes, it serves as a diagnostic structure for assessing their alignment. In particular, it helps identify mismatches between policy objectives, digital system development, and their practical application in circular renovation processes.

Figure 1 illustrates the conceptual framework linking European policy drivers, digital building information systems, and circular renovation practices. By improving data transparency and interoperability, these systems facilitate resource efficiency, material reuse, and energy performance optimisation, contributing to broader energy transition objectives. The framework is normative, proposing an integrated model derived from the policy and digital tool reviews in Sect. 2, making explicit the causal relationships between them.

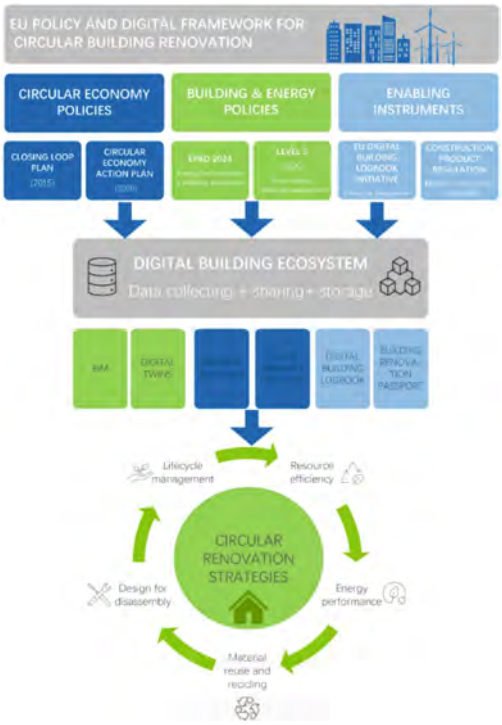

Fig. 1. EU Policy and Digital Framework for Circular Building Renovation, authors' own

The framework comprises three interconnected layers. The first, EU Policy Drivers, includes the Circular Economy Action Plans, the EPBD recast, the CPR revision, and the Renovation Wave, which define the mandates shaping the built environment. The second, Digital Enablers, encompasses the building- and product-level tools reviewed in Sect. 2 (BIM, Digital Twins, DBLs, BRPs, DPPs, and Material Passports), acting as the interface between policy objectives and renovation activities. The third, Circular Renovation Outcomes, includes key sustainability results such as resource efficiency, material traceability, improved energy performance, and reduced embodied carbon.

By structuring the interaction between policy, digital tools, and outcomes, the framework highlights that gaps in circular renovation are not only technological but systemic. Misalignments between building- and product-level policies lead to fragmented digital ecosystems, limiting the effectiveness of data-driven renovation strategies.

EU efforts to improve energy efficiency, circularity, and resource management support targets of a 55% reduction in greenhouse gas emissions by 2030 and climate neutrality by 2050. Achieving this transition requires systemic innovation, with digital tools enabling efficient processes and transparent access to product and resource data within integrated ecosystems (Cagno et al. 2021).

4 Discussion

The proposed framework contributes to the literature by integrating policy analysis and digital tool assessment within a single analytical structure. While previous studies have examined digitalisation as an enabler of the circular economy or analysed EU policy instruments for energy renovation (Hwang et al. 2025)limited attention has been given to how misalignments between these domains affect circular renovation outcomes. By explicitly linking policy levels with digital system functions, this framework provides a basis for identifying structural barriers to implementation.

The proposed framework integrates policy analysis and digital tool assessment within a unified structure, linking policy levels with digital system functions to identify structural barriers to circular renovation. Digital tools such as BIM, Digital Twins, Digital and Material Passports, DBLs, and BRPs support lifecycle data management and decision-making (Keles et al. 2025), their implementation remains fragmented due to limited interoperability, low digital maturity, and a lack of standardisation.

From the comparison between policy frameworks and tool functionalities, four key interoperability gaps emerge: (i) the absence of a common data schema linking BIM outputs to DBL repositories, reflecting fragmentation between modelling tools and data storage systems; (ii) the separation of DPPs and Material Passports under distinct regulatory tracks, limiting integration; (iii) the lack of standardised data exchange formats for BRPs across Member States, indicating uneven implementation maturity; and (iv) the absence of defined integration pathways between Digital Twins and DBLs.

These gaps highlight misalignments between policy objectives and digital infrastructures, reinforcing the need for coordinated standardisation to support circularity and the energy transition of the built environment.

5 Conclusions

This paper examined the role of digitalisation in supporting the transition towards a circular and climate-neutral built environment, focusing on the interaction between EU policy frameworks and digital building information systems. The analysis shows that digital tools—such as BIM, Digital Twins, DBLs, BRPs, and DPPs—have strong potential to enhance lifecycle data management, material traceability, and performance monitoring, thereby supporting circular renovation processes.

However, the findings also indicate that, while policy support is evolving, it remains fragmented across governance levels and instruments, limiting effective implementation. Interoperability emerges as the central bottleneck, with persistent gaps in data standards, system integration, and coordination between tools and policy frameworks.

Addressing these challenges will require coordinated efforts in standardisation, digital infrastructure, and regulatory alignment to enable digital tools to effectively support circularity and the energy transition in the built environment

Abstract. Finite element (FE) simulations offer a scalable framework to explore parameter variations such as slenderness, confinement conditions, and loading scenarios that cannot be tested experimentally in a systematic or economically feasible manner. This study investigates the ability of several constitutive material models to approximate the uniaxial compressive behaviour of rammed earth (RE). Stress-strain curves from unconfined compression tests on cylindrical RE specimens serve as the basis for model calibration and validation. Two RE materials with distinctly different stiffness characteristics were chosen to assess whether the selected models can capture varying material behaviour. Material models commonly used in geotechnical and structural analysis, such as Drucker-Prager, Menetrey-William and Concrete Coupled Damage-Plasticity are implemented and compared across four FE software environments: ANSYS Workbench, COMSOL Multiphysics, SOFiSTiK, and PLAXIS. All investigated models successfully reproduced the compressive strength. The models implemented in ANSYS Workbench and COMSOL Multiphysics additionally provided a good approximation of the nonlinear material behaviour and the overall stiffness response.

Keywords: Earthen Materials · Finite Element Analysis · Material Models · Unconfined Compressive Strength Test · Numerical Approximation

1 Introduction

In recent years, earthen construction has experienced increasing standardisation. In Germany, a normative framework was developed for earthen blocks (DIN 18945 [1]) and the structural design of earthen masonry (DIN 18940 [2]). In addition, a design guideline for rammed earth walls is currently under development [3]. However, compared to

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 1415–1423, 2026.
https://doi.org/10.1007/978-3-032-34930-9_165

conventional construction materials such as reinforced concrete, earthen materials still lack a comparable empirical foundation. To address this deficit efficiently, upcoming parameter studies must be strategically designed to minimise the required experimental effort while maximising knowledge gain. This requires the development and calibration of reliable and precise material models capable of accurately reproducing the mechanical behaviour of earthen materials. Robust numerical models enable virtual testing, support the targeted planning of laboratory campaigns, and ultimately contribute to establishing earth as a dependable material for load-bearing structural applications.

As a first step towards this goal, this paper investigates the numerical modelling of the uniaxial load-bearing behaviour of unstabilised rammed earth (RE). Several constitutive material models commonly used in geotechnical and structural analysis such as Drucker-Prager (DP), and the Concrete Coupled Damage-Plasticity (CDP) model are implemented and compared across four finite element (FE) software environments. The study includes FE software used in both academic research (ANSYS Workbench [4], COMSOL Multiphysics [5]) and engineering practice (SOFiSTiK [6], PLAXIS [7]). The numerical simulations are calibrated and validated against experimental results from unconfined compressive strength tests on cylindrical rammed earth specimens.

2 Methodology

2.1 Basis for Numerical Studies - Unconfined Compressive Strength Tests

Two RE mixtures produced by different manufacturers were analysed, hereafter referred to as STL-1 and STL-2. The grain size distribution of both materials is reported in Baier et al. [3]. The manufacturing moisture content was set to 8.6 M-% for STL-1 and 8.1 M-% for STL-2, determined using the Drop Test defined in NZS 4298 [8]. Cylinders with a diameter d of 100 mm and a height H of 200 mm corresponding to an aspect ratio of $H/d = 2.0$ were chosen. Three specimens of each material were compacted using an automatic proctor machine and a compaction energy of 0.6 MJ/m^3. The material was placed in three layers. The specimens were dried under standard environmental conditions for mineral-based materials at 20 ± 2 °C and a relative humidity of 65 ± 5%. Mass equilibrium, defined as a maximum weight variation of 0.1 wt.-% within 24 h, was reached after four weeks. To achieve a uniform stress distribution during testing, the specimen surfaces were levelled using a 2–5 mm layer of gypsum.

The unconfined compression tests were conducted on a hydraulic testing machine at a constant displacement rate of 1.5 mm/min. In accordance with DIN 18945 [1], failure occurred within 30–90 s. Axial strain was recorded using three clip-on extensometers with a gauge length of 100 mm (see Fig. 1). The strain gauges were positioned in the mid-section of the test specimen to minimise the effect of lateral constraint.

The stress-strain curves, compressive strength f_c, ultimate strength f_u, and corresponding strains ε_c, ε_u are presented in Fig. 1. A linear elastic material behaviour up to $f_c/3$ was assumed, and the Young's modulus E_{33} was derived as secant modulus from the stress-strain curve. Although the grain size distributions of the two mixtures are quite similar, f_c and E_{33} differ. STL-2 exhibits lower stiffness than STL-1, with E_{33}/f_c

ratios of 424 and 1095, respectively. Both materials are therefore included in the numerical simulations, allowing the ability of the selected models to capture varying stiffness characteristics to be assessed.

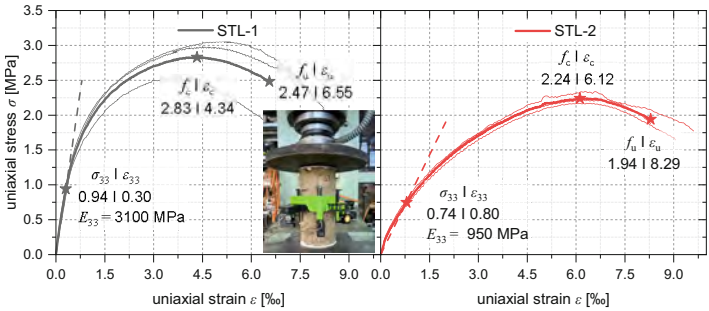

Fig. 1. Stress-strain curves of STL-1 and STL-2 including a picture of the experimental set up – thin curves represent measurements, thick curves the mean value.

2.2 Numerical Approach

To ensure comparability between different modelling environments, all FE programs were first benchmarked using a linear-elastic material model. Identical geometry, boundary conditions, loading scheme, and discretisation were applied in all software environments. No significant deviations in the resulting stress-strain response were observed, confirming numerical consistency.

The specimen was idealised as a cube with an edge length of 100 mm. The height corresponds to the experimental gauge length, enabling direct comparison of axial strain between numerical and experimental results. Stress was computed as the sum of vertical reaction forces divided by the cross-sectional area. Strain was computed from the displacement w_z of the top surface divided by the model height. To isolate constitutive effects and minimise computational cost, simulations were primarily performed using a single solid element. Large-deformation formulations were activated in all programs. In addition, a conventionally discretised mesh was analysed and subjected to a classical mesh convergence study. As both approaches produced identical stress-strain responses, the single-element model was adopted for subsequent parameter studies. A scheme of the mechanical model, including support (u_z, u_x, u_y) and displacement w_z, is shown in Fig. 2. The elastic behaviour was defined by the Young's modulus E_{33} reported in Fig. 1 and a Poisson's ratio of $\nu = 0.1$ according to [9].

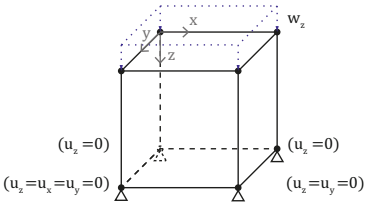

Fig. 2. Modelled load and support scheme of single solid element.

3 Results

3.1 Comparison of Numerical and Experimental Stress-Strain Curves

The numerical derived stress-strain curves are compared with the experimental results in Fig. 3. The following sections briefly describe the material models implemented in the respective FE software including input parameters and a brief evaluation. Where appropriate, deviations between experimental and numerical results were assessed using the Root Mean Square Error (RMSE).

3.2 ANSYS

Within the scope of this study, three different nonlinear material modelling approaches were evaluated using ANSYS Workbench [4]: Menetrey-Willam (MW) according to [10, 11], Drucker-Prager Concrete (DP-HSD) based on [12], as well as a Multilinear (ML) approach, where multiple stress-strain points from the test data were implemented. For the MW and the DP-HSD material model, a linear softening law was introduced. Elastic behaviour was assumed up to $f_c/3$. Beyond this threshold, plasticity was activated according to the respective constitutive material formulation. The input parameters of the material models MW and DP-HSD are listed in Table 1. The material models DP-HSD and MW offer the advantage that many of the required parameters can be derived directly from the experimental stress-strain curves. (Fig. 1). The tensile strength f_t was approximated based on results by [13]. The biaxial compressive strength f_{bc} was set in line with [14]. The material models require the input of plastic strain ε_{pl} rather than total strain ε when defining nonlinear material behaviour. The plastic strain ε_{pl} can be calculated using Eq. (1).

$$\varepsilon_{pl,i} = \varepsilon_i - \varepsilon_{el,i} = \varepsilon_i - \frac{\sigma_i}{E_{33}} \tag{1}$$

As shown in Fig. 3, both MW and DP-HSD result in a very good approximation of the experimental data of both RE mixtures with RMSE ≤ 0.05. The MW formulation showed slightly better convergence behaviour in the post peak area.

The ML material model demonstrates that the material behaviour up to f_c can also be approximated purely based on the experimental stress-strain relationship without a physically motivated constitutive formulation. For simple numerical analyses, such an approach may already provide a sufficient representation of the material response.

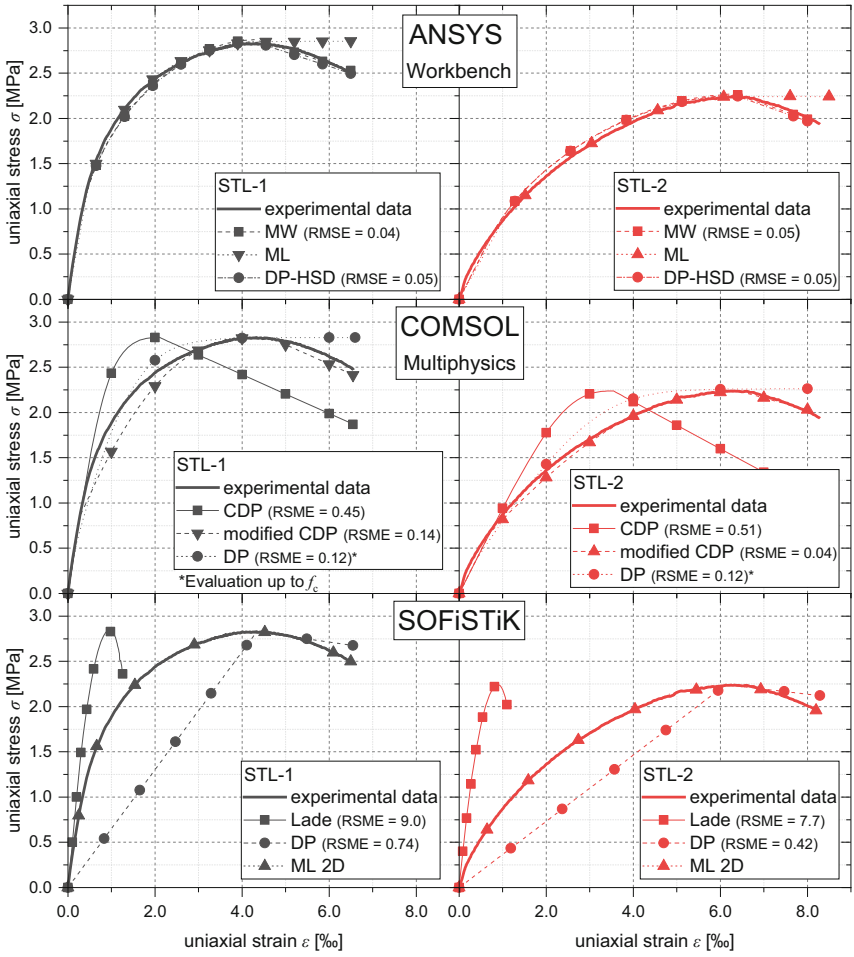

Fig. 3. Comparison of numerical and experimental stress-strain curves using the following material models: Menetrey-William (MW), Drucker-Prager (DP-HSD & DP), Concrete Coupled Damage-Plasticity (CDP), Lade and Multilinear (ML) approach.

Table 1. ANSYS [4]: parameter sets for material models MW and DP-HSD

f_c	f_u	$\varepsilon_{pl,c}$	$\varepsilon_{pl,u}$	f_{bc}	f_t	ε_t	$\sigma_{t,u}/f_t$	dilatancy
see Fig. 1 & Eq. (1)				$1.2 \cdot f_c$	$0.11 \cdot f_c$	3‰	1%	MW: $\psi = 30°$
								DP: $\delta_t = \delta_c = 1.0$

3.3 COMSOL Multiphysics

Two material models were chosen for the aim of this study: Soil plasticity model with Drucker-Prager (DP) criterion [12] and Concrete Coupled Damage-Plasticity (CDP) [15,

16]. The fitted parameters are listed in Table 2, and the resulting stress-strain curves are plotted in Fig. 3. For the DP material model based on the material parameters initial cohesion c_0, the friction angle φ and the dilatation angle ψ, the following hardening function with relation to the equivalent plastic strain ε_{pe} is proposed:

$$c_h = c_0 \cdot \left(1 + \varepsilon_{pe}\right) + 10 \cdot c_0 \cdot \left(1 - e^{-1000 \cdot \varepsilon_{pe}}\right) \tag{2}$$

For the CDP model, the compressive strength f_c was taken from the experimental evaluation (see Fig. 1). Furthermore, the default settings $1.13 \cdot f_c$ and $0.3 \cdot f_c$ were used for the biaxial compressive strength f_{bc} and the compressive yield stress σ_{cy}, respectively. For the post-peak behaviour, a dependency of the compressive fracture energy from the strain limit ε_{fc} was chosen. The CDP model was initially modelled using the default hardening parameters defined by [15]. In a second step, the hardening parameters were calibrated based on the stress-strain response (modified CDP).

All three material models successfully represent the uniaxial compressive strength. The upper limit for linear elastic response of both CDP models corresponds approximately to σ_{33}, whereas in the DP model the plastic response starts earlier due to c_0 and φ. Compared to the CDP, the modified CDP and the DP simulate the uniaxial material behaviour much better. Particularly, the modified CDP provides a good approximation of ε_c. Since no softening response has been added to the DP model, only the modified CDP shows satisfactory results for the post-peak behaviour.

Table 2. COMSOL [5]: parameter sets (STL-1 | STL-2) for material models DP and CDP.

DP	c_0 [kPa]	φ [°]	ψ [°]		
	68 | 60	30 | 25	30 | 25		
CDP	ε_{fc} [mm/mm]	H_p	A_h	B_h	C_h
	1E-4	0.01	0.08	0.003	2
Modified CDP	1E-4 | 1.75E-4	0.001 | 0.08	0.0065 | 0.007	0.006 | 0.0065	0.2

3.4 SOFiSTiK

Within the scope of this study, two elastoplastic constitutive models were employed for simulations using a single solid element: the Drucker-Prager (DP) model based on [12] and the Lade model according to [17]. For the implementation of the DP model a friction angle $\boldsymbol{\varphi}$ of 30° was assumed. The cohesion $\boldsymbol{c}$ was determined according to [18] using Eq. 3. However, nonlinear hardening or softening behaviour is not explicitly considered in the material model. Therefore, the secant modulus E at the compressive strength was adopted instead of the experimentally determined Young's modulus E_{33}. This allows the modelling approach to reproduce f_c and ε_c correctly.

$$f_c = 2 \cdot c \cdot \tan\left(45 + \varphi/2\right) \tag{3}$$

The modelling approach according to Lade [17] uses a three-dimensional failure criterion that was proposed for soils. The formulation involves only three independent material parameters and is expressed in terms of the first and third stress invariants of the stress tensor. For the implementation in SOFiSTiK [6], the input parameters were determined according to the equations provided in [17]. To activate the nonlinear material behaviour within the model, the experimentally determined Young's modulus E_{33} had to be intentionally overestimated**.** Consequently, although the model reproduces the compressive strength and exhibits a nonlinear stress-strain response, the overall stiffness is significantly higher than observed in the experimental data. Additionally, a two-dimensional single plane element with a multilinear stress-strain curve (ML 2D) was investigated, using several stress-strain points from the test data. In analogy to the modelling approach used for the solid element, the single plane element was supported without additional constraints to avoid unintended boundary effects. For simple two-dimensional applications, this approach can adequately represent the material behaviour (Table 3).

Table 3. SOFiSTiK [6]**:** parameter sets (STL-1 | STL-2) for material models DP and Lade.

DP	E	ν	f_t	$\varepsilon_{pl,u}$	φ	φ_u	c	c_u	ψ
	652 | 366 MPa	s. section 2.2 & 3.1			30°		816 | 647 MPa	713 | 560 MPa	0°
Lade	E	ν	f_t		η_1		η_2	m	
	5000 MPa	s. section 2.2 & 3.1			5391 | 4282		$0.1 \cdot \eta_1$	1.0	

3.5 PLAXIS

The modelling approach described in Sect. 2.2 could not be implemented in PLAXIS [7]. Therefore, no comparison is provided here. However, PLAXIS [7] offers an option for calibrating material models using the integrated "SoilTest" tool. This tool allows to calibrate a selected material based on various experimental data, such as uniaxial, triaxial, oedometer tests and others. Against this background, PLAXIS [7] should still be considered as an option for FE analyses of earthen construction elements.

4 Discussion and Conclusion

In this study, several material models implemented in different FE software environments were applied to numerically reproduce the stress-strain curves of two RE materials obtained from uniaxial compression tests. Where possible, input parameters were derived from the experimental data; otherwise, they were assumed based on literature or fitted. Deviations between numerically and experimentally determined stress-strain curves were quantified using the Root Mean Square Error (RMSE).

In ANSYS Workbench [4], all selected material models yielded a very good approximation for both materials (RMSE ≤ 0.05), with most input parameters derivable directly from the experimental data without calibration.

In COMSOL Multiphysics [5], the DP model provided a good approximation of the material behaviour up to f_c (RMSE $= 0.12$), while requiring significantly different input parameters compared to ANSYS. The CDP model likewise resulted in a satisfactory approximation of the material behaviour, upon modification of the internally defined hardening parameters (RMSE of 0.14 for STL-1 and 0.04 for STL-2).

In SOFISTIK [6], a two-dimensional ML approach analogous to that used in ANSYS enabled a perfect approximation of the stress-strain curve. In the three-dimensional model, the compressive strength f_c was well reproduced by the selected material models. However, the DP model was limited in capturing the nonlinear material behaviour, and the calibrated parameters for the Lade model overestimated the stiffness of RE.

In PLAXIS [7], the intended modelling approach could not be implemented. However, the integrated calibration tool "SoilTest" offers a promising option for future FE analyses of earthen construction elements.

In summary, all investigated material models were able to reproduce the compressive strength f_c. The models implemented in ANSYS Workbench and COMSOL Multiphysics additionally captured the nonlinear material behaviour and overall stiffness response, demonstrating their suitability for approximating the uniaxial compressive behaviour of RE. However, since parameter sets were derived solely from uniaxial compression tests, the results cannot be considered generally applicable. Further tests are required to validate lateral deformation (ν) and volumetric (ψ) behaviour and to extend models to multiaxial stress states. The findings should therefore be understood as an indication of the approximation quality achievable with the selected models and the available test data, rather than a conclusive assessment of their general suitability.

Acknowledgments. The paper builds on the on-going efforts of the working group *Forschung* within the *Dachverband Lehm e.V.* to support research collaboration.

Abstract. The analysis and predictive capabilities of Machine Learning (ML) algorithms are becoming an increasingly invaluable asset in the research domains of heat transfer and building materials. Precision and high performance of such models are heavily reliant on the availability of substantial amounts of data for training and testing purposes. This study concentrates on reviewing available sources of experimental data and assesses compatibility implications with ML algorithm requirements. Focus is given on common building materials with temperature-dependent properties assessed against elevated temperatures or fire scenarios. The structure and consistency of the available information are discussed and compared with the fundamental training data requirements of ML algorithms, focusing on Artificial Neural Networks. The study concludes with a brief discussion on the financial and environmental benefits of data and material circularity and proposes methods of reusing available experimental results in cutting-edge Artificial Intelligence applications.

Keywords: building materials · data analysis · machine learning · information circularity

1 Introduction

1.1 Machine Learning as a Tool for Scientific Research

Machine Learning (ML), under the wider sphere of Artificial Intelligence (AI), is evolving into a valuable tool in scientific research, commercial production and industrial applications. It enables deeper understanding of data, reveals interconnections, supplements or surpasses the capabilities of existing statistical methods of analysis and creates opportunities for circularity and sustainable research and production.

Fully utilising the potential of such innovative tools relies on understanding and compliance with certain requirements. The algorithm architecture and choice of hyper-parameters are integral to developing a functional and effective model. The reliability and completeness of training and test data are fundamental to ensure underlying information patterns are captured with high levels of precision and confidence. Inherent biases by the model developers need to be filtered and isolated, while accessibility to the end user is essential to ensure uptake of the proposed models and their beneficial features.

This study focuses on the aspect of data availability and quality for training effective ML models. It outlines issues of available datasets, through the prism of building material properties, heat transfer and fire science. It discusses the opportunities created by ML in relation to information circularity and experimental data reuse and invites dialogue on approaches to enhance data depositories and accessibility of information.

1.2 Scientific Knowledge and Data Circularity

Circular Economy (CE) and its ability to "close the loop" on production processes is receiving notable attention due to striking a comfortable balance between economy, societal requirements and environmental consciousness [1]. Machine Learning is already contributing to the development of CE and it is suggested that reverse engineering the principles of circularity to advance ML itself is worth exploring [2]. The current mindset of singularity in information production/consumption is discouraging data sharing, reuse and leads to "fragmentation and lack of interoperability" in the heavily data-reliant field of Machine Learning [3].

Two aspects exacerbate the current difficulty in reusing scientific data in the context of information circularity and subsequently advancing ML. A lack of consistent methodology on recording how and with what purpose in mind datasets have been created hinders future attempts to access and reuse the stored information [4]. Secondly, the infrastructure that facilitates information circularity (at least in the context of reusing scientific data) needs to be enhanced. Data is currently stored in multiple decentralised repositories, behind varying types of access restrictions, making reuse either by researchers or automated information trawlers impractical [5]. Steps to alleviate the situation are being taken, in the form of official guidelines being drawn up (the European AI Act and the AI Right of Bills, for example). Further suggestions involve clearer guidance on data structuring and coherence by scientific journal publishers ahead of publication acceptance and clearer descriptions of dataset features and limitations by researchers who obtain the data in the first place, as well as more descriptive metadata and guidance both for discoverability by machines and organisation by annotator and editorial teams [6]. The core principles of data circularity and reuse are listed on Table 1.

Table 1. Information and data circularity requirements [5].

Requirement	Practical benefit
Findable	Adequately detailed and accurately labelled meta-data logged on a "searchable" depository to enable human or machine searchers to identify the required dataset.

(*continued*)

Table 1. (*continued*)

Requirement	Practical benefit
Accessible	Once found, the data should be easily accessible for free, through a universally accepted protocol.
Interoperable	Once retrieved, data should be in a universally acceptable "knowledge representation" format, including cross-referencing to other meta-data as required.
Reusable	Data being traceable to its source, with detailed descriptions of content, usage permissions and in line with universally accepted standards for the corresponding domain.

1.3 Scope and Contribution of This Study

The aim of the study is to identify representative sources of available experimental results that can be used for training ML algorithms while discussing opportunities on information circularity. It reviews previously published studies in the field of common building material properties exposed to fire and elevated temperatures, with special focus on concrete applications. This study also assesses the compatibility of such data against the fundamental training requirements of ML algorithms, focusing on Artificial Neural Networks (ANNs). This review is not exhaustive, and it concentrates on the most recent or representative publications available on online indexing platforms.

2 Methodology

The adopted research methodology follows the principles of meta-narrative literature review. The cornerstones of meta-narrative research comprise the initial research question setting; establishing the scoping and search strategy; a method of quality appraisal and data extraction; and finally, the stage of information analysis and narrative synthesis The initial paper selection process involved keyword and title review. Further filtering relied on assessment of abstract relevance, clarity and reproducibility of proposed methodology and finally relevance of conclusions [7].

The research objective for this work is distilled in the following question: "What are the features of the available experimental data of temperature-dependent material properties that can be used for training ANN models predicting thermal behaviour of building elements exposed to fire?". Parallel topics such as ML training data requirements and circularity of existing scientific knowledge are woven into the narrative by reviewing and discussing relevant scientific publications.

The scope of this study has been identified in previous paragraphs. The search strategy utilises online indexing platforms such as Scopus, IEEE, Google Scholar and Web of Science. Combinations of keywords such as "material properties, thermal behaviour, temperature-dependent properties, concrete, elevated temperatures, data circularity, Machine Learning data requirements" were used. The returned results were screened on their relevance and quality before including in the below review.

3 Results

3.1 Experimental Data Availability and Quality

A considerable volume of experimental and analytical research exists in relation to concrete temperature dependent properties when exposed to elevated temperatures [8]. For the purposes of this study 15 published papers have been selected and reviewed in detail. These feature both useful experimental results but also encourage discussion in relation to scientific knowledge and data circularity.

Studies have been focusing on different aspects and parameters of concrete specimen thermal behaviour. The impact of age, in conjunction with the concrete mix characteristics, and environmental conditions was investigated for temperatures up to 60 °C with a Japan developed tester for thermal conductivity [9]. Similarly, an electrical furnace was used to investigate the impact of aggregate type to the thermal conductivity and volumetric change of concrete when exposed to temperatures up to 600 °C [10]. Focusing on the impact of by-product admixtures, the hot wire method was utilised, for heating lightweight concrete specimens to 900 °C [11]. On the other hand, despite adequate details being provided for the fiber content and coarse aggregate mix design of samples, the experimental investigation scope varies considerably from being limited to 25 °C in one instance to extending to 1000 °C in others [12–15]. The experiment time (250 min) is reported only in one investigation of thermal behaviour of fly ash-based concrete for temperatures up to 550 °C with readings at 100 °C intervals [16]. Other studies focus on numerical investigation of cracked concrete or mixes containing asphalt, using experiments for validation but providing nominal information on temperatures developed or time required for the experiment [17, 18]. Although various numerical formulas are provided to describe the development of thermal conductivity, no experimental data is made available on any of the above studies.

A smaller proportion of studies (26% of the reviewed work) mention that experimental data can be made available upon specific request. Different experimental approaches were used to measure the thermal conductivity and specific heat of three samples of lightweight concrete at temperatures ranging from 20 to 1000 °C [19]. Others focused on the impact of fiber content in ultra-high-performance concrete, reviewing the thermal conductivity of samples at temperatures up to 850 °C [20]. The thermal conductivity, specific heat and thermal expansion of sleeving grout was subject of experimental investigation for temperatures up to 900 °C [21]. The influence of water content and levels of saturation were also reviewed analytically and experimentally for concrete samples heated up to 800 °C [22].

The compatibility and structure of the experimental data obtained through these works would need to be assessed against the fundamental requirements of Machine Learning models.

3.2 Machine Learning and Training Data Requirements

As seen in the previous paragraphs, experimental data on the temperature dependent material properties does exist. However, it is essential that the process of obtaining,

managing and preprocessing this data is assessed, before analysing and hopefully extracting useful conclusions [23]. The reason for such upfront scrutiny is that the quality of obtained information is detrimental to the quality of the ANN model predictions. Ensuring the provided training data is complete, balanced and accurate (both in terms of recorded features and target figures accuracy) is critical for the efficient operation of an ML model [24]. Gaps in the obtained data (either due to randomly missed/mistakenly noted observations, due to systematic recording errors or corruption in the process of storing, retrieving or preprocessing) can skew or significantly mislead the predictions made by an ANN [25, 26]. The presence of noisy data in the training dataset can be similarly impactful. Apart from potential degradation of predictive capabilities, noisy data elevates the complexity of the model leading to increased training times and computational costs [27]. Depending on the application, data of appropriate quality would conform with the criteria listed on Table 2.

Table 2. Machine Learning training and test data requirements.

Requirement	Qualitative explanation	Impact on Machine Learning model
Completeness	Data should not contain: • observations/entries with missing values. • features with missing titles or labels.	Missing observation values can create imbalances in the training data, affecting the quality of the ML predictions. Missing feature labels can lead to unexpected predictions due to erroneous consideration of training data sections.
Balance	A balanced amount of data should be available to represent each class or feature.	Unbalanced volumes of data lead to misrepresentation of data classes affecting the accuracy of the model.
Accuracy	Data should be free from systematic erroneous entries, noisy recordings and systematic outliers.	Although ML can quantify and filter out the impact of outliers, systematically erroneously recorded data, or noisy readings can skew the final predictions of the model. Such data also increases complexity of the model and reduces its predictive efficiency.
Consistency	Data entries should be presented consistently, avoiding variations in spelling, abbreviations, different languages, synonyms etc.	Data presentation inconsistencies can lead to unexpected editing results in the pre-processing phase and could create multiple data categories referring to the same entries or entry categories.
Volume	Adequate quantity of data should be available.	Scarcity of data could lead to unstable ML models, limited range of application or unreliable predictions [28].

Considering the influence of data quality on ML performance, this initial quality assessment should be tailored to the needs of the specific application. Different models have different requirements and tolerance towards quantity and quality of training data [24]. Regression is an example where data scarcity can lead to overfitting or model imbalances. When the available training data is riddled with the above weaknesses, strong domain prior knowledge is essential to understand, assess, interpret and accept or reconsider the generated ANN predictions [29]. A structured regime of recording data, ensuring quality criteria are met at the outset, could mitigate the risks of over recording (increased time, upfront costs) or under recording (data scarcity, noise, missing or skewed data or delays and associated data re-collection costs) [30].

4 Conclusions

This study concentrated on the implications of data availability and circularity when attempting to develop ML models predicting the thermal behaviour of concrete exposed to elevated temperatures. Developing these models necessitates a substantial amount of tabulated data. To ensure functionality, efficiency and reliability of the ML model, the data needs to be consistent, complete and balanced.

A significant number of experimental studies exist, reporting on the thermal behaviour of concrete exposed to fire or elevated temperatures. They report notable results and observations through schematics, diagrams and mathematical models.

However, this wealth of information and data is generally inaccessible for further use in Machine Learning research. The datasets are unavailable or difficult to access. There is also high variation in how and what data is recorded, necessitating convoluted pre-processing, performance or scope compromise or even rendering the intended research not possible.

It becomes apparent that action is needed to ensure that existing scientific knowledge becomes reusable in the context of building fire design and Machine Learning development. Possible actions would include, but not be limited to:

- Develop data sharing and storing protocols for fire testing results.
- Establish publicly available datasets drawing information from real time data collection sensors in existing buildings or lab experiments.
- Standardise the way data is recorded, labelled and enriched with meta-data.
- Obtain feedback through reviewing current fire research community needs and align data recording, reporting and sharing accordingly.

Considering that ML and AI in general are becoming indispensable tools in research, a general mindset shift might be necessary, where data curation and circulation become deliverables on their own. Future research could focus on preprocessing specific datasets, assessing existing knowledge gaps and establishing methodologies for effective use of existing knowledge. Standardinsing methods for tackling said gaps with bootstrapping techniques, FE modelling, and crossover review of existing experimental sets would be another essential future research avenue.

Abstract. By promoting a regenerative approach, the Circular Economy has been seen as a pathway to sustainable urban development. As a key component of urban circularity, urban metabolism examines the flows and stocks of resources within cities, including materials and energy. Increasingly, cities are applying this approach within a circular framework to identify opportunities to reduce resource dependence, improve efficiency, and guide more sustainable urban development. However, analyzing materials flows at the city level poses numerous challenges, including technical ones. Among the different categories of technical challenges, the lack of information/data is a relevant one. Understanding the correlations between this challenge at the urban level and challenges at the material and building scales is essential for identifying effective solutions to overcome them.

This study investigates how technical challenges, at the material and building levels, influence the analysis of material flows, particularly in terms of information and data, in urban systems. Furthermore, it explores how digital technologies, namely BIM and GIS, can be enablers and drivers to overcome these challenges. To this end, a desk research approach is employed to detect and map correlations between cross-level technical challenges in the built environment and to identify how digital technologies have been used to overcome the challenges. Finally, based on findings, a conceptual framework is proposed that identifies the use of BIM and GIS at the material and building levels to overcome technical challenges and how these results can be applied to material flow analysis at the urban level.

Keywords: Technical Challenges · Circular Economy · Urban Systems · BIM · GIS · Circular Strategies

1 Introduction

The transition towards circular and sustainable cities has intensified global interest in understanding the resource dynamics within the urban built environment. In this context, the Circular Economy (CE) has emerged as a central policy and research paradigm, advocating for regenerative cycles that minimize waste, retain material value, and decouple urban development from primary resource extraction [1].

Urban Metabolism (UM) constitutes a structural analytical lens through which cities can be examined as systems that consume inputs, including materials, energy, water, and food, and generate outputs in the form of products, waste, and emissions [2]. Among the different methods to analyze the metabolism of cities, Material Flow Analysis (MFA) enables systematic accounting of material inputs, stocks, and outputs within a defined urban system boundary, serving as a diagnostic tool for identifying material inefficiencies and monitoring progress towards circularity targets [3, 4]. Despite growing methodological advancements, the analysis of materials flows at the urban scale still faces technical challenges. Among these is the scarcity, fragmentation, and inconsistency of data describing material stocks and flows across different spatial and temporal scales [5]. These challenges are not isolated to the city scale but are deeply rooted in upstream deficiencies at the material and building levels, the scales at which the physical characterization of the built environment begins.

Digital technologies, particularly Building Information Modeling (BIM) and Geographic Information Systems (GIS), have been increasingly recognized as transformative enablers that bridge data gaps across scales [6]. Their integration represents a promising approach towards City Information Modeling (CIM), capable of supporting multi-scale urban data aggregation and analysis [6, 7]. However, barriers, including ontological misalignment, data granularity mismatches, and platform interoperability limitations, continue to impede their systematic use in urban MFA. This paper brings material, building, and urban scales information challenges into a single cross-scale framework and examines how BIM and GIS can support the upward translation of data needed for urban MFA.

2 Theoretical Background: Technical Challenges Across Scales

The built environment is characterized by an interconnected, scalable structure in which material properties, building components, and urban systems interact in complex, interdependent ways. Technical challenges manifest distinctly, yet correlatively, across these scales, with data and information deficiencies representing a critical cross-cutting constraint [8]. In this paper, the material scale refers to information associated with individual materials, products, and components, such as composition, technical properties, certification, traceability, and passport data. The building scale refers to information related to the aggregation, organization, and lifecycle tracking of those materials and components within assembled building artefacts, including stock indexing, as-built documentation, disassembly records, and building layers. The urban scale refers to information related to resource inputs, stocks, and outputs within defined urban boundaries. The distinction among scales is important because urban MFA depends not only on knowing what materials exist, but also on knowing where and how they are embedded within buildings.

Across the three scales of the built environment, lack of data and information constitutes one of the most persistent categories of technical challenges impeding CE implementation [8]. At the material scale, the most frequently reported barrier concerns data availability, accessibility, and accuracy, including unreliable data, outdated material passports, and limited information on salvaged components. These are followed by deficiencies in traceability and certification, which weaken the capacity to verify the quality

and performance of reused materials throughout the value chain. At the building scale, the challenge shifts from characterizing individual products to aggregating and tracking information in assembled artefacts. Key barriers include incomplete material stock indexing, absence of as-built documentation, insufficient tracking of reused materials across lifecycle phases, and lack of disassembly records. These limit the reuse of products elsewhere when buildings or components are dismantled. At the urban scale, barriers include limited data capabilities, insufficient integration across information sources, and restricted data availability for CE monitoring and planning [9]. Together, these challenges constrain the reliability, granularity, and temporal depth of urban MFA.

3 Methodology

This study adopts a desk-research approach grounded in a structured literature review and thematic synthesis. The analysis builds on previous review-oriented works addressing technical challenges to circular strategies in the built environment and the role of digital tools in supporting circularity and urban-scale material analysis [7, 8]. The first study [7], critically reviewed 19 papers, from a total of 75, from 2018 to 2025. By addressing the question: "*Is City Information Modeling currently defined and used in the context of Material Flow and Stock Analysis?*", the study aimed to understand the relationship between digital tools, namely City Information Modeling (CIM), and urban material analysis (MSA and MFA). The second study [8], on which this research is built, identifies and analyzes the primary technical barriers impeding the transition to a circular economy in the built environment, examining challenges across the urban, building, and material scales and exploring the potential of digitalization, design for disassembly, and BIM as enabling strategies to overcome them. The research approach of the present study was designed to: (i) identify and classify technical challenges related to data and information across the three scales; (ii) map correlations between challenges across scales in the lens of the analysis of the materials flows; and (iii) identify documented applications of BIM and GIS that respond to these challenges.

Building on these sources, the present paper conducted an interpretive cross-scale synthesis to propose a framework, constructed through iterative thematic synthesis, in which technical challenges were systematically mapped against documented applications of BIM and GIS technologies and organized into a hierarchical structure reflecting the scalar progression from material characterization to urban-level MFA. Challenge priorities were established based on frequency of mentions in the literature; they represent research relevance, not validated real-world priorities, and further validation is needed.

4 Cross-Scale Technical Challenges and Enablers in the Built Environment

Data and information deficiencies do not operate in isolation at each scale but exhibit a structural propagation pattern: gaps in material-level data, particularly regarding traceability, passport completeness, and quality documentation, cascade upward to constrain building-level material stock assessments, which in turn limit the reliability and resolution of urban-scale MFA inputs. This cross-scale propagation is further intensified

by the absence of standardized data schemas capable of ensuring semantic consistency across scales, a condition at the intersection of information deficiencies and the lack of technical standards that directly conditions the effectiveness of digital technology interventions. Similarly, at the urban scale, limited knowledge of UM methodologies and digital analytical tools constrains practitioners' capacity to deploy GIS-based platforms for spatiotemporal material flow mapping, even where underlying data are partially available. Table 1 maps these cross-scale correlations.

These literature-derived correlations indicate the principal points at which BIM and GIS may act as cross-scale enablers: at the material scale, through structured digital capture of material properties and passport data; at the building scale, through interoperable BIM models aggregating component-level information; and at the urban scale, through GIS-based platforms integrating building stock data for city-level flow analysis. As enablers, BIM and GIS address different but complementary dimensions of the cross-scale information problem: BIM supports structured representation and lifecycle tracking of materials and components, whereas GIS supports spatial aggregation, territorial analysis, and urban-scale interpretation.

At the material scale, BIM-based material passports offer a structured mechanism for encoding and updating material properties throughout the building lifecycle, directly addressing the data availability and traceability deficiencies. At the building scale, existing BIM models have been applied for material stock and material intensity assessment [9, 10], deconstruction planning, and selective demolition, supporting end-of-life material recovery and reuse strategies [11, 12]. At the urban scale, GIS has been extensively applied to address deficiencies in spatial resolution and temporal coverage. Applications include hotspot analysis to identify spatial concentrations of building material stocks, 4D GIS models to characterize urban building metabolism and construction and demolition waste flows, and integrated GIS–MFA–LCA frameworks to analyze the spatiotemporal dynamics of building stocks [13]. These studies collectively establish GIS as the primary tool for spatially aggregating and analyzing distributed material data at the city level, directly responding to the data integration and accessibility barriers identified at the urban scale.

The integration of BIM and GIS represents the most direct technological response to the cross-scale data propagation problem. Parezanović et al. (2025) [9] combined BIM models with GIS cadastral data to assess building material stocks, while Triantafyllidis et al. (2025) [10] demonstrated that linking georeferenced BIM models with GIS enhances spatial analysis capacities. The convergence of BIM and GIS capabilities through CIM frameworks represents a promising trajectory for cross-scale data integration. By enabling the translation of building-level material data into spatially referenced urban datasets, BIM–GIS integration holds the potential to substantially improve the granularity and consistency of urban MFA inputs [7]. An explicit articulation of this integration is proposed by Schiller et al. (2024) [6], who developed a materiality-based City Information Model (mCIM) applying MFA principles to construct a material cadastre map, positioning GIS as the urban-scale modeling framework and BIM as the source of detailed building-level material data.

Critically, the reviewed literature demonstrates that BIM and GIS are predominantly applied in isolation, with their integration remaining partial and rarely framed within a

Table 1. Cross-scale mapping of information/data technical challenges in the built environment.

Challenge/ category	Material Scale	Building Scale	Urban Scale
Data Availability and Accuracy	Unreliable material data; incomplete material passports; limited data on salvaged components	Lack of material stock indexing; absence of as-built documentation; inaccurate building component databases	Limited georeferenced building stock data; insufficient data for CE monitoring and planning
Traceability and Certification	Lack of certification for reused products; absence of component-level traceability across the value chain	Insufficient tracking of reused materials across lifecycle phases; absence of disassembly records	Limited provenance data for urban material flow attribution
Standardization	Absence of standardized material data schemas; incompatible material classification systems	Lack of open BIM data standards (e.g., IFC); inconsistent Level of Development (LOD) specifications	Absence of harmonized urban material accounting frameworks; incompatible spatial data standards
Spatial Resolution	Material-level spatial referencing largely absent; components not georeferenced	Building-level spatial data inconsistently captured; georeferencing dependent on GIS integration	Spatially inconsistent datasets; difficulty attributing material flows to specific urban zones or functions
Temporal Coverage	Limited longitudinal data on material performance and degradation over time	Lifecycle phase data fragmented; design-stage data rarely updated through construction and use phases	Temporally misaligned datasets; absence of dynamic stock inventories for urban monitoring
Interoperability	Incompatible material data formats; absence of machine-readable material passports	Lack of interoperability between BIM platforms; data exchange barriers across project stakeholders	Insufficient integration among urban data sources; limited BIM-to-GIS data translation capacity

Cross-scale propagation: data availability gaps cascade upward from material to building to urban scale, constraining MFA resolution at each level. Traceability gaps undermine flow accounting reliability. Absence of shared standards limits semantic interoperability. Spatial and temporal deficiencies at lower scales reduce disaggregation capacity in urban MFA.

unified cross-scale analytical structure [7]. This gap, compounded by the identified barriers to semantic interoperability and standardization, motivates the conceptual framework proposed in Sect. 5, which explicitly structures the roles of BIM and GIS across the material, building, and urban scales to support city-level MFA.

5 Proposed Conceptual Framework

The proposed conceptual framework explains how interventions at the material and building scales can improve the data foundations required for urban MFA, as shown in Fig. 1. The framework operates across three interdependent layers.

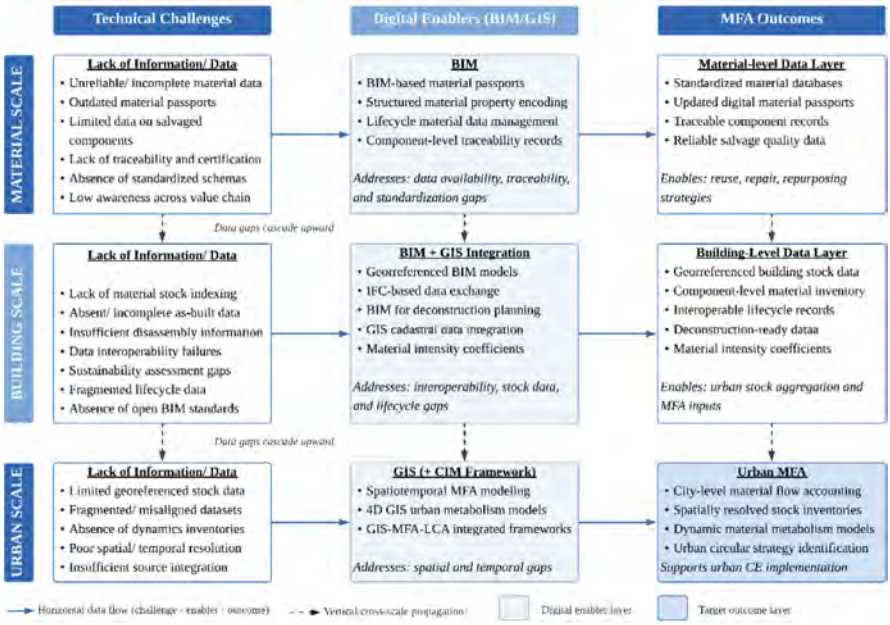

Fig. 1. Conceptual Framework: BIM and GIS as Cross-Scale Enablers for Urban Material Flow Analysis

At the material scale, BIM-embedded material passports and standardized product data libraries provide the foundational input data. At the building scale, BIM models enriched with material attributes, complemented by GIS-based spatial registration, enable characterization of the building stock. At the urban scale, spatially aggregated building stock data, processed through GIS-enabled MFA platforms, support city-level resource flow quantification and circular strategy identification.

This framework contributes to operationalizing CIM as a data infrastructure for urban circularity, emphasizing the importance of upward data flow from material characterization to urban analysis. Furthermore, the framework highlights that the resolution of urban-scale data challenges is conditional upon addressing their antecedent causes at lower scales.

6 Conclusions and Future Research Directions

This paper has discussed the cross-scale technical challenges that impact material flow analysis at the urban level, with particular focus on data and information deficiencies. Through a structured desk research approach, it has mapped correlations between challenges at the material, building, and urban scales, and identified how BIM and GIS technologies have been employed, individually and in integrated form, to address these challenges. The proposed conceptual framework offers a structured perspective on how digital technologies, when applied at lower scales, can generate upward data flows that enhance urban MFA capacity. By positioning BIM and GIS as cross-scale enablers within

a CE framework, the study underscores the need for integrated digital strategies that span from material characterization to city-level resource governance.

Several limitations should be acknowledged. First, the study is based on desk research and is therefore subject to publication bias and limited coverage of practitioner-driven or grey literature. Second, the relevance levels assigned to challenges are based on frequency of mention in the reviewed literature; they indicate prominence in research, not validated real-world priority. Third, the cross-scale correlations proposed in this paper are literature-informed analytical relationships and should not be interpreted as empirically confirmed causal links. Future research should focus on validating the relevance of challenges in real-world applications, developing and testing data pipelines that operationalize the proposed framework, including integrating material passport systems with BIM platforms and GIS-based urban stock databases. Comparative case studies across different urban contexts will be instrumental in refining the framework and assessing its transferability.

Explainable Anomaly Detection in Thermal Insulation Material Profiles: A Multi-Feature Case Study from Greece

Konstantinos Papachatzis(✉)

Aristotle University of Thessaloniki, 54124 Thessaloniki, Greece
knpapacha@civil.auth.gr

Abstract. This study proposes an explainable anomaly detection framework for identifying irregular thermal insulation materials across multiple key features, focusing on the Greek market. The analysis utilizes a dataset of 500 products sourced from technical leaflets, Environmental Product Declarations (EPDs), and market surveys, incorporating thermophysical, technical, environmental attributes, and retail prices. Initially, k-means, Gaussian Mixture Models (GMM), and Hierarchical Density-Based Spatial Clustering of Applications with Noise (HDBSCAN) were evaluated for identifying natural groupings within the dataset, yielding silhouette scores of 0.77, 0.77, and 0.79, respectively. HDBSCAN proved most effective at capturing the underlying density structure and actively isolating noise. Following HDBSCAN cluster assignment, GMM profiled the internal distributions of the pure clusters. A sensitivity analysis across three threshold scenarios (1%, 5%, and 10%) was then employed to rigorously evaluate the stability of the profiling findings. Finally, a decision-tree (DT) model extracted transparent, human-readable rules defining anomalous materials. The results highlight that thermal resistance, recommended application, price, and Global Warming Potential (GWP) critically drive anomalous behavior. From these, three actionable "if-then" rules are derived—identifying contextual niche failure, commercial discrepancy, and environmental deviation. Ultimately, by explicitly linking economic viability with lifecycle environmental impacts, this approach operates circular economy principles; it empowers stakeholders to move beyond basic material selection toward designing greener and competitive products.

Keywords: thermal insulation materials · anomaly detection · unsupervised clustering · explainable machine learning

1 Introduction

Globally, the building sector accounts for approximately 32% of energy demand and 34% of anthropogenic CO_2 emissions [1]. Furthermore, building and construction activities contribute to around 18% of emissions in the form of embodied carbon, primarily driven by the production of energy-intensive materials such as concrete and steel [1]. Beyond energy consumption and greenhouse gas emissions, the building sector is one of the most significant consumers of natural resources, generating approximately 35 billion tons of waste that ends up in landfills [2].

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 1440–1447, 2026.
https://doi.org/10.1007/978-3-032-34930-9_168

Therefore, achieving complete decarbonization in the building sector requires a rigorous whole life cycle assessment [3]. Moving another step forward from the concept of "green" to the concept of "sustainable" implies considering all three pillars of sustainability [4]. In this context, factors such as cost-optimal levels, thermal and visual comfort, aesthetics, and healthiness, among others, must be considered [5–7].

In the pursuit of sustainable new and retrofitted buildings, the envelope acts as the primary interface between the indoor and ambient environment, governing the building's response to external climatic stimuli. Consequently, thermal insulation is paramount, as its thermophysical properties directly dictate key performance aspects, notably hygrothermal behavior, fire safety, and acoustics.

1.1 Objectives

This study aligns with a prominent research direction focused on developing frameworks, decision-making tools, and methodologies for optimizing both insulation manufacturing and selection. Furthermore, it builds upon the author's previous work in this domain, which proposed two supervised machine learning (ML) models to predict the retail price of insulation materials within the Greek construction market [8]. These models were trained on a dataset of 500 commercial materials, utilizing their thermophysical, technical, and environmental attributes as predictors [8].

Using the same dataset, this study initially employs unsupervised clustering techniques to identify groups of insulation materials with similar sustainability profiles. Building on these clustering results, the second objective is to derive explainable rules for unseen materials by applying anomaly detection techniques.

2 Literature Review

Supervised ML methods have been widely applied in the research field of building materials to accurately predict numerous properties [9]. However, there is a scarcity of research applying unsupervised ML, particularly clustering techniques, to building materials.

Zhao et al. [10] employed Density-Based Spatial Clustering of Applications with Noise (DBSCAN) to dynamically choose appropriate reference values for key predictors of vacuum glass insulation performance. Alternatively, Wang et al. [11] conducted Agglomerative Hierarchical Clustering on daily time-series data representing the hygrothermal transfer from outside through an exterior wall. The goal was to create clusters of daily time series with similar trends to identify general patterns with better accuracy.

Moreover, Zia ul Haq and Ricciotti [12] utilized particle clustering analysis on Scanning Electron Microscopy images of geopolymer composite brick samples to gain insights into the underlying causes of compressive strength variation. On the other hand, Alami et al. [13] used k-means clustering on a dataset of thermal properties of palm and esparto-fiber reinforced concrete samples, aiming to segregate the data into homogeneous groups with shared thermal characteristics.

Focusing on unsupervised anomaly detection within the scope of the building sector, Fan et al. [14] proposed an autoencoder-based ensemble method for detecting anomalies in building energy data. In the same vein, Fahim et al. [15] introduced a time-series-to-image model to identify anomalous energy consumption in residential buildings.

3 Materials and Methods

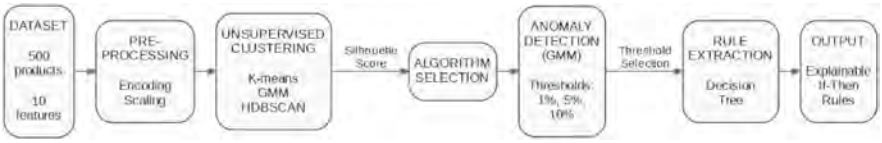

Fig. 1. Methodology flowchart.

3.1 Dataset Description and Preprocessing

This study utilizes a dataset comprising 500 commercial insulation materials sourced from the Greek construction market (Fig. 1) [8]. To comprehensively capture the materials' sustainability profiles—encompassing performance, utility, safety, environmental impact, and economic cost—ten key variables were selected: (1) recommended application, (2) thermal resistance [m^2K/W], (3) density [kg/m^3], (4) compressive strength [kPa], (5) fire resistance, (6) vapor diffusion coefficient, (7) waterproofness, (8) noise resistance, (9) cradle-to-grave (including Module D recycling benefits) GWP [$kgCO_2eq/m^2$], and (10) retail price (€/m^2).

The data were extracted from openly accessible official technical leaflets and EPDs. Concurrently, retail prices were acquired through a comprehensive market survey of construction material suppliers in Greece [8].

The initial dataset was compiled in Microsoft Excel and subsequently imported into a Python 3.14.0 environment for further data preprocessing [16]. Specifically, categorical features were encoded using One-Hot Encoding, while numerical variables were scaled to a range of 0 to 1 utilizing MinMax Scaling.

3.2 Clustering

To achieve the primary objective, three robust algorithms—k-means, GMM, and HDBSCAN—were employed to uncover the inherent natural groupings within the dataset [16]. The k-means algorithm is an iterative clustering method designed to partition a set of data points into a pre-specified number of clusters, k, by iteratively minimizing the within-cluster sum of squares [13].

Transitioning to the second algorithm, the GMM is a probabilistic clustering method that represents a dataset as a weighted sum of multiple Gaussian distributions. Each Gaussian component corresponds to a distinct cluster characterized by its own mean

and covariance matrix, thereby enabling the flexible modeling of clusters with varying shapes, sizes, and orientations [17].

Finally, HDBSCAN extends DBSCAN by constructing a density-based hierarchical structure and extracting the most persistent clusters. It calculates mutual-reachability distances to form a weighted graph [18], from which a minimum spanning tree is derived to build the cluster hierarchy. Clusters are ultimately identified based on their stability across varying density levels [19].

3.3 Anomaly Detection

Building upon the initial clustering results, a GMM was employed to meticulously profile the internal distribution of each identified cluster [16]. Unlike methods that merely calculate geometric centroids, the GMM characterizes each cluster probabilistically by estimating its mean vector (μ) and covariance matrix (Σ), thereby capturing the exact shape, spread, and orientation of the data [17].

Consequently, an anomaly score—derived from the log-likelihood—was calculated for each data point by evaluating its probability density within its assigned cluster's distribution. To rigorously assess the sensitivity of these findings, anomaly thresholds of 1%, 5%, and 10% were subsequently evaluated.

3.4 Rule Extraction

To extract explainable rules, an interpretable DT classifier—restricted to a maximum depth of 3 to prevent overfitting—was trained exclusively on the pure clustered instances, deliberately omitting HDBSCAN noise [16]. To counteract the severe class imbalance, a balanced class weight parameter is applied. By utilizing the original, unscaled material variables as inputs and the GMM-derived binary anomaly labels as targets, the DT generated transparent "if-then" rules that highlight the exact thresholds driving the anomalies.

4 Results

4.1 Clustering Interpretation

The clustering results indicate that all employed methods exhibit satisfactory performance when subjected to quantitative validation using the silhouette score. Both k-means and GMM suggest an optimal configuration of 24 clusters, yielding an identical silhouette score of 0.77. In contrast, HDBSCAN identifies 18 distinct clusters and achieves a marginally higher silhouette score of 0.79. However, it simultaneously isolates 43 materials into a "noise" cluster, classifying them as global anomalies. These global anomalies correspond to materials with limited representation within the dataset.

It is worth noting that HDBSCAN not only achieves a superior silhouette score, but it also actively isolates noise. This prevents the cluster contamination that typically occurs with the forced assignment mechanisms of k-means and GMM. Consequently, HDBSCAN was selected as the most robust and suitable clustering method for this study.

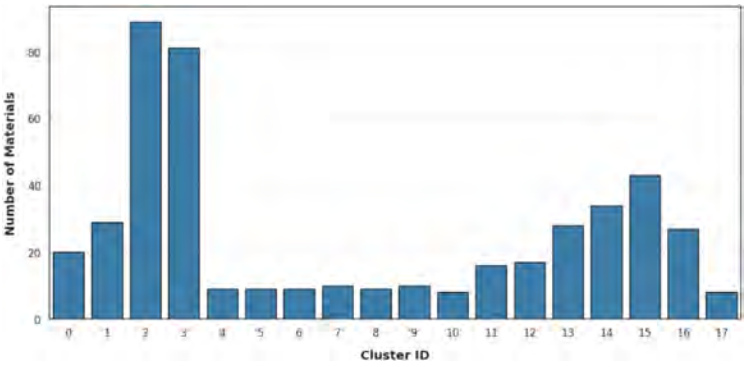

Fig. 2. Material distribution across the 18 clusters identified via HDBSCAN.

As illustrated by the GMM profiling of the HDBSCAN results (Fig. 2), the highly uneven cluster sizes underscore a heterogeneous market comprising both densely populated clusters of widely used materials and smaller clusters of niche products. Driven by the high-dimensional, density-based nature of HDBSCAN acting on one-hot encoded variables, materials within the same cluster exhibit strict uniformity in their base type, confirming they reflect true functional product families.

4.2 Sensitivity Analysis

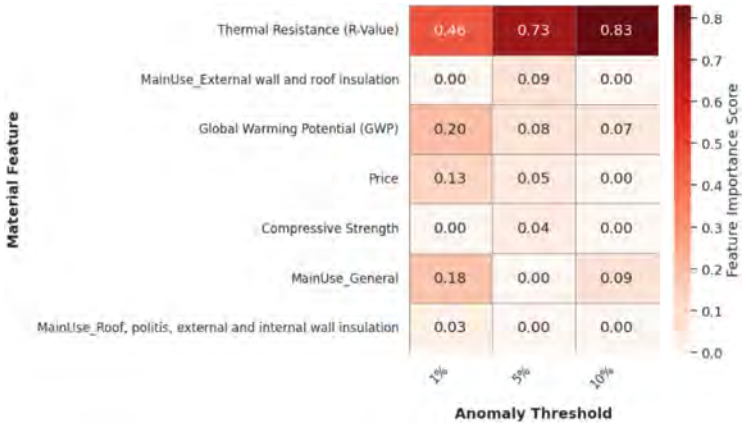

Fig. 3. Feature importance sensitivity across anomaly thresholds.

As illustrated in Fig. 3, thermal resistance emerges as the most critical feature in the profiling process across all three threshold scenarios. Importantly, GWP maintains a significant and consistent influence on the profiling results regardless of the scenario.

For the subsequent rule extraction phase, the 1% threshold scenario was selected; this stricter threshold effectively filters out vague performance variances to isolate genuine,

multidimensional market anomalies, thereby generating logical and actionable rules through the DT.

4.3 Anomaly Rules

As detailed in Table 1, the DT successfully derives three distinct anomaly rules, which are characterized as contextual niche failure, commercial discrepancy, and environmental deviation.

Table 1. Explainable rules defining contextual anomalies (1% threshold).

ID	Anomalous conditions (IF)	Physical and market interpretation
1	R-Value <= 0.93 AND Rec. appl. ≠ General AND Rec. appl. ≠ Roof / Pilotis / Wall	Contextual niche failure: Severe thermal underperformance restricted to highly unconventional or specialized application categories.
2	R-Value >0.93 AND GWP < = 41.04 AND Price <= 1.17	Commercial discrepancy: Relatively low pricing for materials exhibiting adequate thermal resistance and moderate environmental impact (potential dumping or mispricing).
3	R-Value >0.93 AND GWP > 41.04 AND GWP < = 43.70	Environmental deviation: Acceptable thermal performance compromised by an elevated, highly specific environmental footprint (GWP) relative to its peer cluster.

5 Discussion and Conclusions

The extracted explainable rules serve as valuable market-oriented decision-making tools that directly operate circular economy principles. By integrating a strict cradle-to-grave lifecycle perspective—capturing Module D recycling benefits within the GWP—alongside retail prices, the framework concurrently evaluates environmental and economic viability. Because these specific sustainability metrics significantly drive anomaly identification, the approach actively penalizes linear manufacturing profiles. Ultimately, it empowers stakeholders to move beyond basic material selection toward designing greener, competitive products that reduce environmental footprints, facilitate reuse, and maximize end-of-life recyclability.

However, several significant limitations must be acknowledged. First, the dataset is spatially and temporally constrained. Furthermore, the analysis does not account for other critical environmental and economic factors that influence material sustainability. Finally, the proposed approach is strictly data-driven; it identifies anomalies and extracts rules based solely on the patterns within the existing dataset, and thus should not be conflated with prescriptive rules designed to achieve predefined sustainability goals.

By integrating a broader range of features and exploring synergies with complementary methodologies, the proposed framework can be significantly enhanced. Furthermore, through regular data updates and the inclusion of new products via federated learning techniques, more effective and trustworthy anomaly rules can be extracted. Ultimately, these refined rules could serve as robust guidelines for the development and selection of more sustainable thermal insulation materials.

Abstract. The transition toward sustainable practices in the built environment must extend to the digital documentation of cultural heritage. Traditional Historic Building Information Modeling (HBIM) survey workflows frequently operate under reactive paradigms, identifying data gaps only during post-processing. This approach often results in redundant site visits, repeated equipment mobilization, and avoidable resource waste. This study presents a multi-criteria decision-support framework for sustainable and resource-circular HBIM survey planning. Powered by the Predictive Scan Feasibility Estimation Model (PSFEM), the framework embeds predictive feasibility assessment directly into the planning phase. Rather than treating documentation gaps as retrospective metrics, it anticipates occlusions and coverage limitations prior to field deployment, enabling proactive strategy selection between ground-based and hybrid acquisition. The framework was validated across two Hungarian chapel case studies characterized by contrasting environmental constraints. At the vegetation-constrained Sopronhorpács Chapel, predictive assessment identified ground-based limitations in advance, supporting a targeted hybrid UAV–TLS intervention that increased geometric completeness from 54% to 96% within a single consolidated acquisition phase. At the Lucsony Szent Anna Chapel, predictive distance analysis demonstrated that optimized far-range scanning achieved 100% roof coverage, compared to 74.9% under close-range conditions. The results confirm that embedding predictive intelligence into HBIM survey workflows fosters resource circularity, minimizes environmental impact, and provides an accessible foundation for sustainable digital heritage acquisition across diverse architectural typologies

1 Introduction

Sustainability in the built environment has traditionally focused on material efficiency, operational performance, and life-cycle assessment. However, sustainable practice also requires responsible management of the digital processes that support conservation and long-term stewardship of cultural heritage [1]. As Historic Building Information Modeling (HBIM) becomes a central instrument for documentation and intervention planning [2, 3], the environmental and organizational implications of survey planning itself demand closer examination. HBIM depends on accurate geometric acquisition, and terrestrial laser scanning (TLS) is widely adopted due to its precision and density. Yet heritage environments rarely offer ideal scanning conditions. Irregular geometries, height variations, vegetation, restricted access, and constrained urban settings frequently obstruct line-of-sight visibility. When completeness is verified only after acquisition, deficiencies in elevated or occluded areas often necessitate additional field visits. These reactive loops increase transportation emissions, equipment time, processing effort, and project duration, contradicting principles of minimal intervention and resource efficiency [4].

While HBIM research has focused primarily on modeling accuracy, interoperability, and data integration [5, 6], less attention has been given to the sustainability of survey planning. Circularity principles emphasize maximizing value per resource input while minimizing redundant cycles [7]. In digital heritage documentation, this implies achieving maximal geometric completeness per mobilization event.

Addressing this challenge requires reframing completeness as a predictive planning parameter rather than a retrospective quality metric [8]. Hybrid TLS–UAV strategies are often introduced only after terrestrial limitations become evident [9]. Embedding predictive feasibility assessment prior to deployment enables proportionate, risk-aware strategy selection [10].

In response, this study introduces a sustainability-oriented decision-support framework that builds upon the Predictive Scan Feasibility Estimation Model (PSFEM) established in [11] and its uncertainty-aware formulation developed in [12], embedding these within a resource-circularity architecture that translates predictive feasibility outputs into operational efficiency indicators for more responsible digital heritage acquisition.

2 Methodology and Case

2.1 A Predictive Workflow Architecture

The proposed methodology restructures conventional HBIM survey planning into a predictive and resource-aware architecture. Instead of executing acquisition first and evaluating completeness afterward, feasibility assessment is embedded as a pre-deployment decision layer. The workflow comprises four interdependent stages (Fig. 1):

1. Preliminary Assessment: Documentation objectives required detail levels, and site constraints (vegetation, access, building height, roof inclination, setbacks) are recorded.

2. Predictive Feasibility Assessment: Planned TLS positions are evaluated using PSFEM to estimate the risk-adjusted Scan Fit Index (SFIadj).
3. Strategy Selection and Execution: Risk levels determine whether TLS-only or hybrid TLS–UAV acquisition is implemented.
4. Data Integration and Verification: Datasets are registered and evaluated, minimizing the need for iterative field returns.

This architecture transforms survey planning from a linear "acquire–verify–correct" model into a circular system in which predictive evaluation precedes resource commitment. By embedding decision logic before mobilization, environmental impact is addressed at the earliest possible stage.

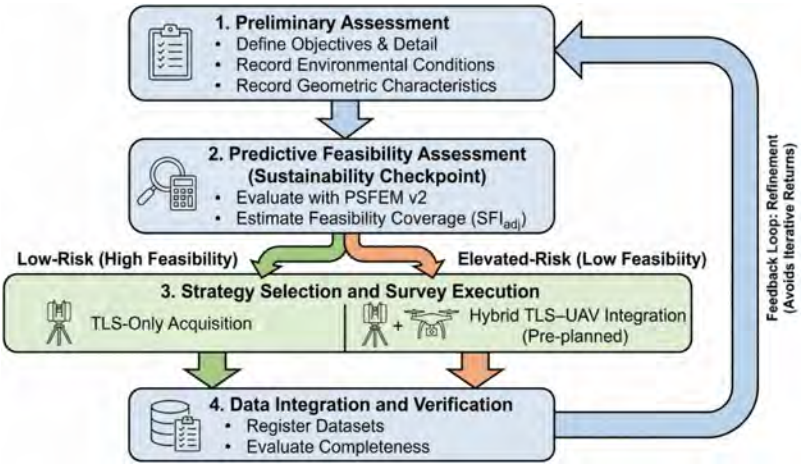

Fig. 1. Predictive Decision-Support Workflow for Sustainable and Resource-Circular HBIM.

2.2 Predictive Feasibility and Environmental Modifiers

Within the framework, PSFEM functions as a pre-deployment risk estimator, building upon the uncertainty-aware formulation developed and empirically validated in [12]. The SFIadj quantifies the expected geometric coverage achievable from a planned TLS position under prevailing site constraints. The base geometric feasibility is calculated as $SFI = \min((Rs \times \sin\theta) / Hb, 1.0)$, where Rs is the effective scanner range, θ is the vertical clearance angle, and Hb is building height. The min function caps the score at 1.0 to maintain consistency with the normalized risk-threshold scale. The environmental uncertainty modifier is then calculated as $U = 0.5(VDI) + 0.3(AF)$, where VDI is the Vegetation Density Index ($\in [0,1]$) quantifying line-of-sight obstruction from canopy cover, and AF is the Access Factor ($\in [0,1]$), where $AF = 0$ indicates unconstrained scanner placement and $AF = 1$ denotes fully restricted access. The final adjusted feasibility index is calculated as $SFIadj = SFI \times (1 - U)$. Higher VDI values reduce effective visibility, while higher AF values constrain scanner placement options. Both modifiers

are classified using a shared four-level scale (Table 1). The resulting SFIadj value is mapped to the risk thresholds in Table 2, directly informing strategy selection between TLS-only and hybrid acquisition.

Table 1. Environmental Modifier Classification Scale (applied to both VDI and AF).

Modifier Range	Interpretation
0.0–0.2	Minimal constraint
0.3–0.5	Moderate constraint
0.6–0.8	High constraint
0.9–1.0	Severe constraint

2.3 Case Evidence: Application Across Contrasting Constraint Conditions

To evaluate the practical and sustainability-related impact of the proposed framework, empirical validation was conducted across 44 TLS scan positions distributed between two Hungarian chapel case studies (Fig. 2). The selected sites represent contrasting constraint conditions: one dominated by environmental occlusion and restricted access, and the other characterized primarily by geometric sensitivity related to scanner-to-building distance.

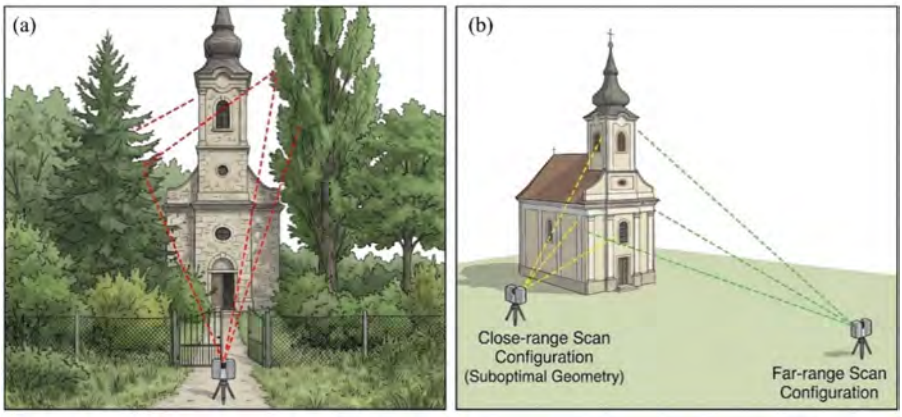

Fig. 2. Environmental and Geometric Constraints at the Case Study Sites: (a) Sopronhorpács Chapel showing vegetation obstruction and tower height and (b) Lucsony Szent Anna Chapel illustrating close- and far-range scan configurations.

This dual-case configuration enabled assessment of two distinct but complementary sustainability challenges: (1) macro-occlusion caused by environmental factors, and (2) inefficient acquisition geometry caused by suboptimal setback configuration.

Sopronhorpács Chapel: Environmental Macro-Occlusion. The Sopronhorpács Chapel features a 27 m tower partially enclosed by dense vegetation and constrained setback zones, conditions that severely restrict vertical visibility and limit effective TLS coverage. An initial TLS-only campaign comprising 28 scan positions achieved just 54% geometric completeness, leaving substantial gaps in the elevated tower and roof regions and highlighting the limitations of ground-based acquisition under environmental obstruction. Predictive feasibility assessment identified multiple positions as low-feasibility before additional mobilization occurred, thereby preventing iterative TLS-only attempts. Instead, the framework triggered a targeted hybrid TLS–UAV strategy, resulting in an integrated dataset with 96% geometric completeness, an absolute increase of 42 percentage points, achieved within a single consolidated acquisition phase. Beyond the numerical increase in coverage, the key sustainability outcome lies in the avoidance of redundant field returns and ineffective terrestrial redistribution. Environmental uncertainty was thus reframed from a reactive obstacle into a managed planning parameter embedded within the acquisition strategy.

Lucsony Szent Anna Chapel: Geometric Setback Optimization. The Lucsony Szent Anna Chapel provided a controlled setting to evaluate scanner-to-building distance as a determinant of coverage efficiency. Unlike the vegetation-constrained Sopronhorpács site, this context allowed systematic variation of setback geometry through two TLS configurations: a close-range setup comprising 10 positions at an average distance of 4.71 m, and a far-range configuration comprising 12 positions at an average distance of 14.78 m. Despite higher nominal point density at close proximity, the close-range configuration achieved only 74.9% roof coverage, as acute incidence angles restricted vertical reach and effective visibility. In contrast, far-range positions achieved complete (100%) roof coverage by improving geometric incidence conditions. Predictive feasibility assessment identified the far-range configuration as optimal prior to execution, thereby preventing inefficient close-range over-collection and eliminating the need for corrective hybrid escalation. In this case, sustainability gains were achieved not through technological substitution but through geometric optimization, demonstrating that resource efficiency can emerge from calibrated positioning rather than increased equipment deployment.

Cross-Case Synthesis: Complementary Sustainability Processes. The two cases reveal complementary sustainability pathways: at Sopronhorpács, predictive occlusion identification enabled consolidated hybrid deployment; at Lucsony, distance calibration optimized geometric incidence and avoided unnecessary data collection. In both contexts, the framework functioned as a pre-commitment filter, evaluating limitations before resource expenditure rather than correcting them afterward.

3 Results

3.1 Predictive Performance Across 44 Positions

The performance metrics reported below are based on the empirical validation dataset introduced in [12], and are re-evaluated here from the perspective of resource efficiency and sustainable survey planning. While the case studies illustrate context-specific effects,

the overall sustainability contribution of the framework is best evaluated across the complete dataset of 44 scan positions. Predictive assessment was applied prior to evaluating actual coverage outcomes, enabling direct comparison between anticipated and realized performance. Across all positions, the framework achieved an overall prediction accuracy of 88.6%, compared to 68.2% under the deterministic predecessor, an improvement of 20.4% that strengthens reliability in pre-deployment decision-making. Most critically, false-positive predictions, positions expected to achieve adequate coverage but failing in practice, were reduced from 14 to 5, corresponding to a 64.3% reduction in ineffective deployments. Each false positive represents equipment time, energy consumption, and logistical coordination expended without sufficient geometric return. Simultaneously, correctly identified infeasible positions (true negatives) increased from 9 to 15, reflecting improved anticipation of limitations and earlier identification of hybrid requirements. Together, these shifts demonstrate that sustainability gains emerge primarily from preventing waste before mobilization rather than compensating for it afterward.

3.2 Operational Decision Thresholds

The SFIadj values were translated into risk-based decision thresholds that directly informed acquisition strategy, guiding planning decisions as follows. Low-risk classifications supported TLS-only execution, moderate-risk levels enabled proportionate hybrid supplementation, and significant or high-risk conditions prevented inefficient terrestrial-only attempts. This conversion of predictive feasibility into strategy inserts sustainability within operational planning by aligning resource commitment with quantified feasibility prior to mobilization (Table 2).

Table 2. Risk-Based Operational Thresholds for Sustainable Survey Planning.

SFIadj	Risk Level	Recommended Strategy	Sustainability Effect
≥ 0.90	Low	TLS-only	Minimal equipment use
0.70–0.89	Moderate	Planned Hybrid	Controlled hybridization
0.50–0.69	Significant	Immediate Hybrid	Consolidated acquisition
< 0.50	High	UAV-dominant	Avoid ineffective TLS

3.3 Implications for Geometry-Agnostic Survey Systems

Predictive integration restructures acquisition logic beyond geometric completeness alone: it filters ineffective scan positions, consolidates acquisition phases, and prevents redundant mobilization. Because the framework operates on geometric relationships, distance, height, incidence angle, and integrates environmental uncertainty modifiers, it remains independent of specific architectural typologies, enabling transferability to towers, domes, bridges, and dense urban façades.

4 Discussion

The results indicate that sustainability gains in HBIM do not primarily stem from new hardware or increased data density, but from restructuring decision-making before deployment. By embedding predictive feasibility assessment at the planning stage, the framework shifts efficiency from post-acquisition correction to proactive design. Coverage deficiencies are no longer treated as retrospective acquisition failures but as manageable planning variables.

The sustainability contribution of this framework is evaluated through operational efficiency indicators, reduction of ineffective deployments, avoidance of repeated mobilization, and consolidation of acquisition phases, rather than through direct environmental accounting. The predictive filtering of high-risk positions reduces unnecessary equipment use, travel effort, and processing overhead, operationalizing sustainability through prevention rather than compensation [7]. Although energy use and carbon emissions were not directly quantified, the 64.3% reduction in false-positive deployments provides a measurable proxy for improved resource efficiency within HBIM acquisition workflows. At Sopronhorpács, predictive planning supported consolidated hybrid strategies to mitigate macro-occlusion; at Lucsony, distance optimization prevented inefficient over-collection [11]. These findings confirm that sustainable survey planning requires geometry-aware feasibility intelligence embedded within decision architecture [13], not technology substitution alone. Because the framework operates on spatial relationships and environmental modifiers, it remains transferable to towers, domes, bridges, and dense urban façades.

The findings demonstrate that sustainability in HBIM can be structurally embedded within workflow design, positioning predictive assessment as a governance mechanism for responsible digital resource allocation [14]. Future work should expand validation across structurally complex typologies and incorporate direct environmental performance metrics, including energy consumption and carbon emissions, to further quantify sustainability impacts.

5 Conclusions

This study demonstrates that embedding predictive intelligence within HBIM survey planning is a key enabler of sustainable and resource-circular heritage documentation, transforming reactive correction into proactive decision-making. Empirical validation across 44 scan positions confirmed improved planning reliability and reduced ineffective deployments. At Sopronhorpács, geometric completeness increased from 54% to 96% within a single consolidated phase; at Lucsony, optimized setback selection achieved 100% roof coverage without hybrid escalation. These outcomes confirm that sustainability in digital heritage documentation begins at the planning stage. By aligning acquisition strategy with quantified risk before mobilization, the framework minimizes redundant resource cycles and supports responsible digital heritage management. Future work will extend validation across additional structural typologies and incorporate direct environmental impact quantification.

Advancing Circularity in BIM: A Comprehensive Parameter Set for Deconstruction and Reuse

Arian Loli(✉), Johannes Brozovsky, and Petra Rüther

Architecture, Materials and Structures, SINTEF Community, 7034 Trondheim, Norway
arian.loli@sintef.no

Abstract. The construction industry is increasingly adopting sustainability and circularity principles to improve resource efficiency, minimise waste, and promote reuse. Despite this progress, integrating circularity attributes of existing buildings into 3D digital models remains challenging. This study, part of the EU-funded SUM4Re project, reviewed the literature on the intersection of Building Information Modelling (BIM) and circularity to identify a comprehensive set of circularity parameters for BIM integration. Analysis of key national frameworks and circularity index tools revealed a lack of harmonised criteria and methods for assessing building circularity across countries, limiting consistency and knowledge transfer. Additionally, a review of 14 scientific articles examined BIM's role in managing circularity-related data. While research provides valuable insights, findings remain fragmented and do not cover all BIM-required data. To address this, a structured taxonomy of additional sustainability and circularity parameters for BIM integration was developed through a three-layer review. The parameters were grouped into seven categories covering core attributes at the building- or product-level. Classifying these parameters as mandatory or optional could streamline data collection and BIM integration. In addition, advanced technologies such as laser scanning and computer vision could automate parameter assessment, improving both accuracy and efficiency.

Keywords: Circularity · Building Information Modelling (BIM) · Sustainable Construction · Classification System · Deconstruction · Material Reuse

1 Introduction

1.1 Background

The construction industry is a major consumer of raw materials and a significant contributor to global waste and environmental degradation [1]. Circular economy strategies, such as reuse, recycling and recovery, are increasingly promoted to reduce these impacts and extend material lifecycles [2]. However, the transition from linear to circular practices remains challenging, due to difficulties in identifying, categorising, and assessing materials for reuse, particularly at end-of-life stages [3].

L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 1457–1465, 2026.
https://doi.org/10.1007/978-3-032-34930-9_170

Building Information Modelling (BIM) is a key digital enabler for managing building data throughout the lifecycle. Traditionally, BIM has focused on the design, construction, and operation phases, with limited application in demolition and end-of-life processes [4]. To bridge this gap, the concept of BIM for deconstruction has emerged, aiming to integrate circular economy principles into digital building models [5].

1.2 Research Gap and Novelty

Despite the growing body of research on the intersection of BIM and circularity, existing approaches remain fragmented and often rely on case-specific solutions. In particular, BIM-based end-of-life applications remain underdeveloped, as current implementations depend on local waste management policies, lack interoperability across platforms, and are not supported by the available BIM tools on the market [6].

The EU-funded SUM4Re project aims to establish digital material banks for the built environment by combining urban mining techniques with advanced data-collection technologies. Achieving this goal requires effective integration with BIM; however, current BIM objects are primarily optimised for new construction and lack a globally accepted framework for demolition, recovery, and reuse. These limitations reveal a key research gap: the absence of a harmonised, BIM-compatible data structure that can integrate diverse circularity data from existing buildings. To address this gap, the present study proposes a comprehensive set of circularity parameters for BIM integration, drawing on insights from the literature, existing frameworks, and digital approaches to support material recovery and improve end-of-life decision-making.

2 Methodology

This study employed a three-part, multi-layered approach to synthesise circularity-related parameters for integration into BIM: (i) a systematic review of scientific literature; (ii) an analysis of technical reports; and (iii) a review of digital record systems.

Data extraction focused on parameters, classifications, taxonomies, and data structures related to BIM from a deconstruction and circularity perspective. A consistent extraction protocol was applied across all sources to capture diverse categorisations, requirements, metadata structures, and other technical indicators. These elements were then mapped and consolidated into a unified dataset to support the development of a circularity-oriented classification and parameter set for BIM integration.

2.1 Detailed Literature Review

A systematic literature review was conducted in Scopus to identify classification approaches for BIM integration. The search combined three thematic clusters: BIM, deconstruction/disassembly, and circularity/reuse/waste, using Boolean operators and truncation to capture lexical variants. Only peer-reviewed articles, conference papers, and reviews in English were included, with no restrictions on publication years. The search, carried out in November 2024, yielded 214 documents. A two-stage screening process (initially titles and abstracts, then full texts) yielded 14 papers that discuss classification systems. The selected papers are discussed in the results section.

2.2 Technical Reports Review

The review examined EU and sector-specific national documents on deconstruction, waste audits, and circularity assessment. Unlike scientific articles, technical literature and standards are often limited or inaccessible in search databases because of language barriers or paywalls; therefore, document selection was based on expert input and prior knowledge of disassembly and reuse practices.

The analysis drew on key EU documents, including the updated Construction and Demolition Waste (CDW) Management Protocol [7] and the Waste Audit Guidelines [8]. From these documents, the study extracted procedural requirements for waste identification and categorisation to align with wider waste-management frameworks.

Technical documents such as DIN SPEC 91484 [9], and circularity index tools such as the circularity index framework of the German Sustainable Building Council (DGNB) [10] and the disassembly potential framework of the Dutch Green Building Council (DGBC) [11] were also reviewed to obtain more detailed parameters.

2.3 Digital Platforms Review

Lastly, the study examined recent developments in digital data recording systems that support material traceability, transparency, and circularity in the built environment. The focus was on the formats of Digital Product Passports (DPP) [12] and Digital Building Logbooks (DBL) [13] to retrieve lifecycle information for circular practices.

DPP was analysed to assess how it stores detailed product-level information. The DBL repository was further assessed for building-level categories, including how the logbook structure enables connections to product- and material-level datasets.

3 Results

3.1 Outcomes of Detailed Literature Review

Across the 14 reviewed scientific articles, research on BIM-enabled circularity is rapidly expanding, emphasising the need for detailed, interoperable lifecycle parameters to support reuse, recycling, and deconstruction.

Key contributions address structural reusability and salvage estimation, using quantitative models to predict end-of-life material recovery. For example, Akanbi et al. introduced a BIM-based estimator that incorporates material and connection type [14], while Mohammed et al. developed a deconstructability scoring system for steel structures based on connection reversibility and material compatibility [15].

A second group of studies focuses on material passports and component-level classification to improve transparency and traceability. Göswein et al. proposed a Circular Material Passport (CMP) that records installation data, service life, and disassembly instructions [16], while CirBIM organises material and classification data to support circularity assessment [17]. Sanchez et al. highlighted the need for detailed disassembly parameters for BIM and reuse planning [18]. In addition, Kim and Kim developed a graph-based BIM tool to evaluate deconstructability, CO_2 emissions, and reuse value, emphasising the significance of embodied energy and joint-type data [19].

The literature also discusses Design for Disassembly (DfD) and lifecycle-oriented BIM classifications. Mattaraia et al. introduced a DfD framework categorising elements by layers and disassembly potential [20], and Sanchez et al. proposed Model View Definition (MVD), an Industry Foundation Classes (IFC)-aligned model that incorporates lifecycle stages and energy requirements for disassembly [21].

Additional studies link BIM to the management of CDW and circular economy workflows. Schamne et al. [22] and Kuzminykh et al. [23] connect BIM to waste management systems and marketplaces, while Charef [24] introduces an 8D Deconstruction Information Model that includes contamination and regulatory data. Work by Gupta et al [25]., Royano et al [26]., and Jayasinghe et al [27]. highlights deficiencies in current classification systems, inconsistencies between frameworks such as Uniclass and OmniClass, and the need to incorporate logistics, safety, and secondary-market information into digital circularity workflows.

The literature shows significant progress towards a circularity-focused BIM classification, though fragmentation persists. Recurrent parameters across studies highlight an emerging need to standardise the information that BIM must record to support circular construction workflows.

3.2 Outcomes of Technical Reports Review

The review of technical literature reveals a broad yet fragmented landscape of guidance on waste audits, disassembly potential, and circularity scores. At the EU level, the CDW guidelines and protocols outline procedures for waste identification, separation, hazard detection, logistics, and quality management, thereby fostering confidence in secondary materials. National frameworks offer more detailed operational guidance. DIN SPEC 91484, through a two-stage pre-demolition audit, requires component-level data on construction year, technical documentation, material samples, pollutants, connection types, dismantlability, and reuse potential. The DGNB circularity index tool provides a quantitative method based on weighted indicators, including material origin, pollutant load, flexibility, compatibility, and recycling potential. Additionally, the DGBC framework assesses disassembly across components and building layers, considering technical, process, and financial factors, as well as concepts such as adaptability, toxicity, value development, and environmental indicators.

These developments reflected substantial progress in formalising circularity-related procedures, yet they also revealed persistent inconsistencies in scope, terminology, and classification systems. This variability highlights the need for harmonised data models, shared definitions, and interoperable classifications across jurisdictions.

3.3 Outcomes of Digital Platforms Review

The review of digital platforms revealed that DPP and DBL offer complementary systems for organising circularity data at product and building levels. DPP provides a detailed product-level profile, including information on origin, composition, manufacturing, environmental impacts, repairability, service life, and end-of-life options, supported by digital identifiers such as Quick Response (QR) codes, Radio Frequency Identification (RFID) tags, or blockchain to ensure traceability throughout the lifecycle. DBL,

meanwhile, organises building-level information, including material inventories, energy performance, renovation history, hazards, indoor-environment indicators, and circularity attributes, enabling these data to be linked across different scales.

The digital platforms demonstrated strong potential to enhance lifecycle transparency and support circularity-focused decision-making, but non-standardised data formats and limited interoperability with BIM constrain their effectiveness. These issues reduce the consistency with which DPP and DBL support workflows for reuse, recycling and material recovery in digital construction environments.

3.4 Review Synthesis

The reviews highlight significant efforts by industry, government, and research bodies, but also emphasise the fragmented, narrow, and non-standardised nature of BIM practices for demolition-related properties. Information is inconsistently organised, and terminology varies across sources, reducing coherence and efficiency. Table 1 presents a comparative summary of the three reviews conducted in this study.

Table 1. Summary of the findings from various reviews

Aspect	Detailed Literature	Technical Reports	Digital Platforms
Scope	Academic studies on circularity and BIM	Frameworks, standards, and technical guidelines	Digital tools and platforms for circularity data
Focus	Circularity parameters for disassembly and reuse	Structured methodologies and defined indicators	Data structures and implementation approaches
Type of information	Broad, diverse circularity concepts and parameters	Formalised indicators and requirements	Operational data fields and digital attributes
Strengths	Theoretical depth and range of perspectives	Structured and standardised approaches	Practical implementation and data handling
Limitations	Fragmented and heterogeneous in scope and terminology	Variability and limited alignment across frameworks	Limited interoperability and standardisation
Overall implication	Highlights the diversity of approaches	Need for aligned and harmonised frameworks	Need for BIM-compatible data structures

3.5 Circularity-Oriented Property Set

BIM provides essential data fields for detailed digital representations of buildings; however, the reviews revealed a lack of a coherent BIM-enabled structure for demolition

and circularity. To address this gap, a set of parameters encompassing key end-of-life attributes at the building- or product-level is proposed. Table 2 summarises the comprehensive set of parameters extracted from the three-layer review.

The dataset is organised into seven main categories and respective subcategories, covering various aspects of circularity in construction. Although extensive, the list is not exhaustive and can be further refined through research and practical applications.

Table 2. Dataset for integration of circularity parameters in BIM

Main category	Subcategory	Parameter
General Building Information	Building Identification	Building name / Building Address / Building Type / Year of Construction / Unique Identifier
	Maintenance, Repair, and Renovation History	Maintenance Records / Service Life of Components / State of Use and Ownership
Building Performance Indicators	Energy Performance	Operational Energy Consumption / Energy Performance Certificates (EPC) / Renewable Energy Integration
	Indoor Environmental Quality (IEQ)	Air Quality / Thermal Comfort / Lighting Conditions / Acoustic Conditions
Product and Material Information	Product and Material Identification	Primary Material Type / Product Composition / Product Name / Product Type / Product Model / Manufacturer / Origin / Manufacturing Process
Lifecycle Impact Data	Environmental and Carbon Footprint	Embodied Carbon / Other Environmental Impacts
	Water and Energy Use	Water Usage During Production / Energy Consumption During Production
Circularity and Disassembly Data	Disassembly Planning	Modularity / Product Type / Connection Type / Product Identification / Global Disassembly Model / Dependency Hierarchy / Detachability
	Disassembly Process	Disassembly and Recovery Guidelines / Accessibility / Tools and Methods / Physical Interface
	Salvageability and Circularity Data	Condition / Reuse/Recycling Opportunities / Reusability / Recyclability / Circularity Score

(*continued*)

Table 2. (*continued*)

Main category	Subcategory	Parameter
	Disassembly Performance	Disassembly Time / Disassembly Cost / Disassembly Revenue / Disassembly Energy Consumption / Disassembly Distance
Waste and Recycling Management	Waste Management and Recycling	CDW Diagnosis and Classification / Waste Destination / Waste Output Flow / Recycling and Waste Treatment Methods
	Hazardous Waste Data	Hazardous Material / Toxicity Data / Waste Scenarios for Hazardous and Toxic Waste
Certifications and Digital Integration	Regulatory Compliance	Compliance with EU and International Standards / Environmental Product Declaration (EPD) / Third-Party Certifications
	Digital Integration and Traceability	QR Code / RFID Tracking / Blockchain Storage / Documentation and Reports

4 Discussions

A major challenge is the complexity of compiling such an extensive dataset. A complete digital model of a decommissioned building would require estimates of technical, environmental, and functional properties, as well as economic, safety, and logistical data. Collecting or assessing this information is labour-intensive, increases the time and cost of demolition projects, and often relies on human judgement, introducing subjectivity. A tiered approach that distinguishes between mandatory and optional parameters would reduce complexity while maintaining the relevance of decisions.

Inconsistent terminology and classification systems hinder interoperability and reduce the comparability of circularity data across projects and regions. Current frameworks differ in their rating systems, circularity indices, and disassembly metrics, limiting the transferability of reuse practices beyond national borders. Developing unified BIM-based data structures and evaluation systems is therefore essential for systematic implementation. Advances in laser scanning, computer vision, and automated data collection can further reduce documentation effort and improve accuracy.

5 Conclusions

This study highlights the need to extend BIM models to include dedicated end-of-life properties, such as disassembly effort, material condition, contamination risks, and reuse or recycling pathways. Furthermore, incorporating building-level information, such as maintenance history, environmental and energy performance, waste classification, and hazardous material data, is essential for lifecycle transparency. Overall, the results emphasise that BIM must evolve beyond its current scope to include circularity and demolition-related information. Implementing a harmonised set of parameters can support more reliable assessment of reuse and recycling options and contribute to more circular decision-making in the built environment.

Funding. The work was supported by the project SUM4Re (Creating materials banks from digital urban mining), funded by the Horizon Europe research and innovation programme under grant agreement No. 101129961.

A PSO-Based Decision Support Framework for Sustainable Tall Building Design

Gökçe Nihan Demirel(✉)

Middle East Technical University, Ankara 06800, Türkiye
nihant@metu.edu.tr

Abstract. The preliminary design phase of tall buildings plays a critical role in determining sustainable design, long-term material consumption, spatial efficiency, and environmental performance. However, early design decisions are often made with limited quantitative feedback due to the complexity of interdisciplinary performance evaluations. This paper presents a digital optimization framework for the preliminary design of tall buildings, employing Particle Swarm Optimization (PSO) integrated with parametric modelling and automated structural analysis to support sustainable design decision-making. The proposed framework links architectural design parameters—plan dimensions, core ratio, building height, and structural system—with structural performance metrics through API-based automation of finite element analyses. PSO is customized using a representative subset of design alternatives to efficiently explore a large solution space while minimizing computational effort. The optimization objectives are defined as maximizing leasable floor area and minimizing construction material demand, addressing both economic viability and resource efficiency. The methodology is applied to a design space of hypothetical tall building configurations. Results demonstrate that PSO can identify near-optimal design solutions by evaluating less than half of the total solution space, significantly reducing analysis time while preserving solution accuracy. The findings indicate that PSO-driven early-stage design exploration enables informed trade-off analysis between spatial and material efficiency. By integrating digital automation and optimization at the preliminary design stage, the framework provides a scalable foundation for sustainability assessments and future extensions toward embodied carbon evaluation.

Keywords: Sustainable Design · Particle Swarm Optimization · Preliminary Design · Tall Buildings

1 Introduction

Rapid urbanization and increasing land values have led to a growing demand for tall buildings in dense metropolitan areas. As cities expand vertically, the design of tall buildings has become a complex interdisciplinary challenge involving architectural design, structural engineering, environmental performance, and economic feasibility. Tall buildings are structurally sensitive systems where design decisions strongly influence structural efficiency, material consumption, and spatial performance.

In the early stages of design, architects must evaluate multiple competing objectives. Maximizing leasable floor area increases the economic value of a project, whereas minimizing structural material usage supports sustainability goals and reduces environmental impact. However, these objectives are often conflicting. Increasing floor area can lead to higher structural loads and increased material consumption, while minimizing structural material may limit usable space or structural performance. Traditional design approaches often rely on sequential trial-and-error evaluations. Such approaches are inefficient when dealing with large design spaces and complex interactions between architectural and structural parameters. Consequently, designers may overlook promising alternatives or fail to fully understand the trade-offs between competing objectives.

Recent developments in computational design and optimization techniques provide new opportunities for addressing these challenges. By integrating parametric modelling, automated structural analysis, and optimization algorithms, it becomes possible to systematically explore large design spaces and identify high-performing design alternatives. This study proposes a PSO-based decision support framework for the preliminary design of tall buildings. The framework integrates parametric design variables with automated structural analyses to evaluate both spatial and material performance. The aim is not to identify a single optimal design, but to reveal high-performing design alternatives and provide insight into the relationships between design parameters and performance outcomes. Reducing the number of required structural analyses is particularly important during the preliminary design phase, where architects must evaluate multiple evolving design alternatives within limited timeframes. Rather than focusing solely on computational efficiency, the proposed framework aims to support broader design space exploration and faster comparison of competing architectural strategies.

2 Background and Related Work

Metaheuristic optimization algorithms have been widely applied in structural engineering to address complex design problems involving multiple variables and constraints. Among these algorithms, Particle Swarm Optimization (PSO) has gained attention due to its simplicity and efficiency in exploring large design spaces. Previous studies have demonstrated the effectiveness of PSO in structural optimization problems. Fourie and Groenwold (2002) applied PSO to structural size and shape optimization and reported competitive performance compared to traditional metaheuristic approaches. Perez and Behdinan (2007) and Luh and Lin (2011) further demonstrated the robustness of PSO in optimizing truss structures, highlighting its ability to efficiently search large design spaces while satisfying structural constraints. Elegbede (2005) applied PSO for structural reliability assessment under uncertainty, while Li et al. (2007) proposed a heuristic PSO approach for pin-connected structure optimization that improved convergence behavior. Multi-objective applications have also been explored, such as the VEPSO method introduced by Omkar et al. (2008), which balances competing performance objectives in composite structure design. Gholizadeh and Fattahi (2014) proposed a modified PSO algorithm for steel tall building design that improves convergence through adaptive penalty functions. More recently, PSO has been integrated with advanced analysis methods such as isogeometric analysis to optimize structural forms in building engineering applications (Tsiptsis et al., 2019).

Despite these advances, most existing studies focus primarily on optimizing structural member sizes or predefined structural configurations. Architectural parameters such as plan layout, core arrangement, and building height are often treated as fixed inputs rather than dynamic variables within the optimization process. This limitation reduces the relevance of such studies for architectural design workflows, particularly during the early design stage where decisions regarding building form and spatial organization are still evolving. To support architects during conceptual design, optimization frameworks must integrate architectural design variables and provide insights into how these variables influence structural and spatial performance. The present study addresses this gap by integrating architectural design parameters with structural analysis and PSO-based optimization within a unified computational workflow.

3 Optimization Framework

Design parameters, their variables and two objective functions are defined. The whole solution space, 810 models, is named as the target group and a subset of them, 126 models, is named as sample group. Sample group is modelled parametrically and analyses for structural performance. The results are used to customize the PSO algorithm. Then the algorithm is applied to the target group and results are compared. Figure 1 shows the overall workflow.

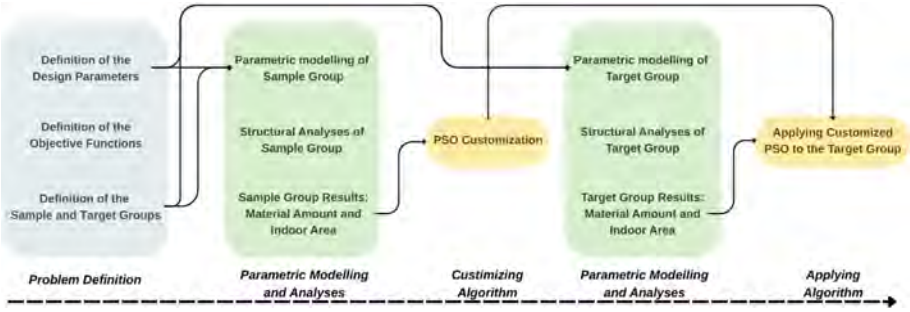

Fig. 1. The workflow of the automated optimization process

3.1 Design Parameters and Objectives

The proposed framework explores a design space defined by several architectural parameters that significantly influence spatial and structural performance: plan dimensions, core ratio, building height, and structural system. Plan dimensions vary between 30 to 50 m with 2.5-m intervals. Three different core ratios are modelled which are 18, 21 and 24%. Height of the models are 240, 300 or 360 m. Two structural systems are analysed which are outriggered frame (OF) and frame tube (FT). These inputs are defined parametrically so that multiple design alternatives can be generated automatically. Each design configuration is evaluated through structural analysis to determine its material

demand and structural feasibility. Figure 2 shows all of the parameters and corresponding variables.

Two primary objectives are defined for the optimization problem are: maximizing leasable floor area, representing spatial and economic performance and minimizing structural material consumption, representing resource efficiency and sustainability. Together, these objectives encourage solutions that provide efficient spatial use while reducing environmental impact.

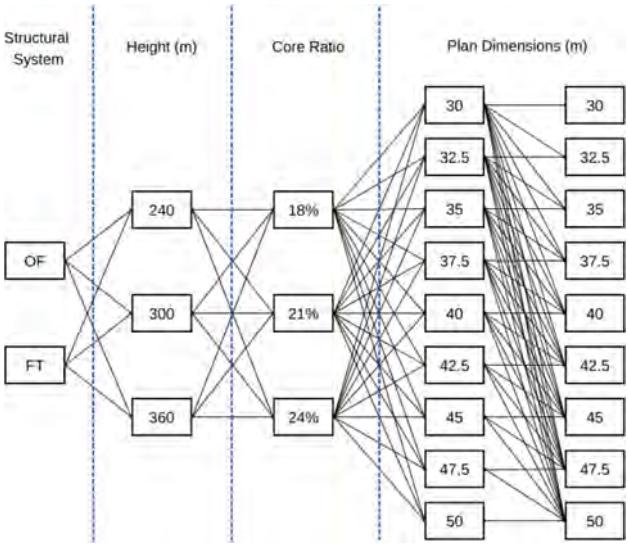

Fig. 2. Design parameters and mapping of all models

3.2 Particle Swarm Optimization Strategy

PSO is used to explore the defined design space efficiently. In the PSO framework, each particle represents a potential design solution defined by a specific combination of architectural parameters. The algorithm begins with an initial population of particles distributed across the design space. Each particle is evaluated according to the defined objective functions. During each iteration, particles update their positions based on two factors: their individual best solution encountered so far and the best solution identified by the entire swarm. This iterative process guides the swarm toward regions of the design space with better performance. The optimization process continues until convergence is achieved or no further improvement is observed. The workflow of the PSO-based optimization process is illustrated in Fig. 3.

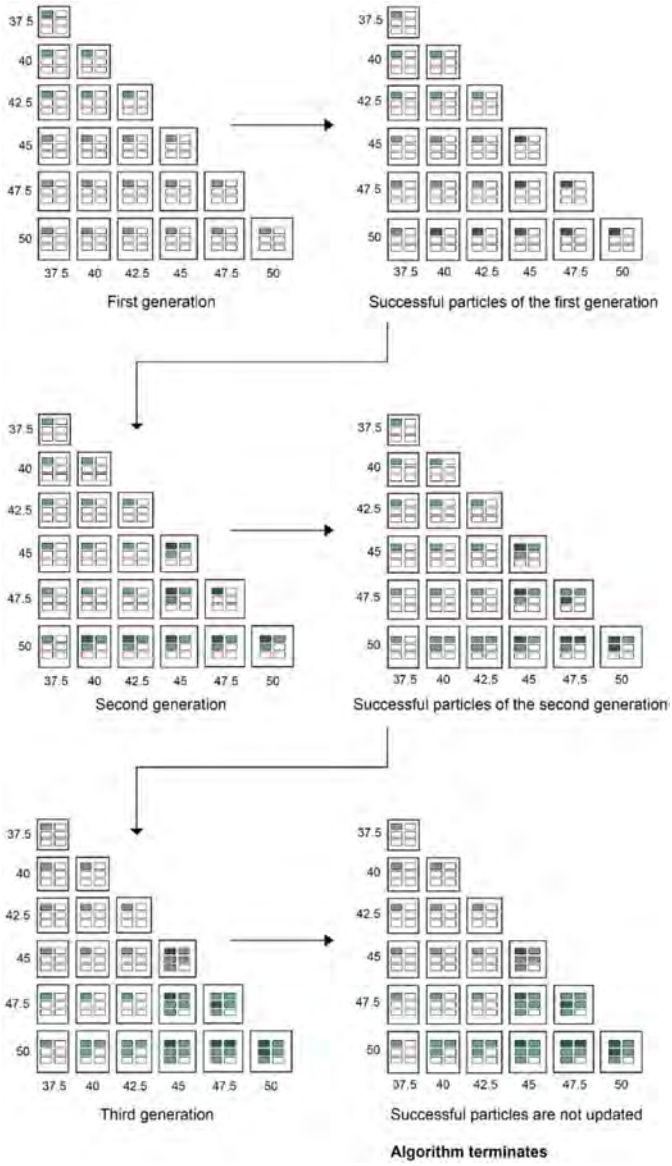

Fig. 3. The workflow of the PSO-based optimization process

4 Results

Several PSO configurations are tested by varying the number of successful particles used for generating new iterations and the number of neighbouring solutions explored. These configurations influence the exploration behaviour of the algorithm and the number of structural analyses required.

The results show that PSO can effectively identify high-performing design solutions while significantly reducing the number of required analyses. In configuration 10, the algorithm terminated before detecting the optimum solutions; therefore, this configuration was excluded from further evaluation. In the best-performing configurations, 8 and 11, the algorithm successfully detects optimal solutions by evaluating 33% of the sample group and 30% of the target group. Results of the sample and target groups are given in Table 1 and 2, respectively. The total required analyses are approximately 44% of the total solution space**.** Results also show that the performance of PSO is consistent between the sample group and the target group. Figure 4 shows the comparison of the results.

Table 1. PSO results of the sample group

Configuration	1	2	3	4	5	6	7	8	9	10	11

5 Discussion

The results indicate that PSO can significantly reduce the computational effort required to identify high-performing design solutions. By exploring less than half of the solution space, the algorithm is able to locate optimal or near-optimal configurations while avoiding the need for exhaustive evaluation of all possible alternatives.

An important advantage of the proposed methodology is its integration of architectural design parameters into the optimization process. Unlike traditional structural optimization studies that focus solely on member sizing, this approach allows architects to explore how decisions regarding building form, plan layout, and core size influence structural performance and spatial efficiency. The framework also supports the exploratory nature of architectural design. Instead of identifying a single optimal configuration, the methodology detects a set of high-performing solutions that represent approximately the top 10% of the solution space. This approach provides architects with multiple viable design options and allows them to make informed design decisions based on broader performance insights. Another key advantage of the proposed framework is its scalability. Because the design parameters and optimization algorithms are defined parametrically, the framework can be extended to larger design spaces or additional performance criteria, such as embodied carbon or environmental performance metrics.

The present study has several limitations. The framework evaluates hypothetical design configurations and focuses primarily on structural material demand and spatial efficiency during the preliminary design stage. Structural analyses are based on linear elastic modelling and do not include detailed nonlinear behaviour, construction constraints, or lifecycle assessment.

6 Conclusions

This study presents a PSO-based optimization framework for supporting sustainable tall building design during the preliminary design phase. By integrating parametric modelling, automated structural analysis, and PSO, the framework enables systematic exploration of complex design spaces.

The results demonstrate that PSO can identify near-optimal solutions while evaluating less than half of the total solution space. This reduction in computational effort significantly improves the feasibility of applying performance-based design exploration during early design stages. Unlike many previous studies that focus solely on structural optimization, the proposed framework integrates architectural parameters and emphasizes the relationship between spatial efficiency and material consumption. The methodology therefore provides a practical decision-support tool for architects seeking to balance economic and environmental considerations.

Future research may extend the framework by incorporating additional sustainability indicators, such as embodied carbon and life-cycle environmental performance, as well as integrating aerodynamic performance metrics for more comprehensive tall building optimization.

Additive Manufacturing with Earthen Materials: A Comparative Analysis of On-Site and Off-Site Fabrication Challenges

Hendrik Benz(✉) and Katharina Klemt-Albert

Institute for Construction Management, Digital Engineering and Robotics in Construction, RWTH Aachen University, Aachen, Germany
benz@icom.rwth-aachen.de

Abstract. Additive manufacturing with earthen materials is increasingly explored as a low-carbon construction approach, but remains strongly shaped by moisture sensitivity, drying behaviour, shrinkage, and environmental exposure. These characteristics make the distinction between on-site and off-site workflows especially relevant. This paper compares both fabrication settings through a focused review of literature and selected full-scale prototype references. It examines how challenge profiles change when earthen additive manufacturing shifts from direct in-situ printing toward off-site and prefabrication-oriented production. Protected off-site fabrication can reduce exposure-related instability during printing and curing, but introduces new requirements for segmentation, handling, transport, assembly, and interface coordination. By distinguishing material-related and process-related challenges, the paper clarifies that fabrication location affects not only production conditions, but also design, handling, and integration strategies. This shift is synthesized through a graphical comparison of selected material-related and process-related challenges. Off-site production therefore does not remove complexity, but redistributes it across the construction process, with implications for repairability, reuse, and circular design.

Keywords: earthen construction · additive manufacturing · on-site printing · off-site prefabrication · design for assembly

1 Introduction

Additive manufacturing with earthen materials is increasingly explored as a low- carbon and resource-conscious construction approach. Existing research has shown its potential for digital fabrication, but also its dependence on moisture sensitivity, drying behaviour, shrinkage, and changing environmental conditions. These characteristics make earthen additive manufacturing materially and operationally different from more established concrete-based construction printing.

A central question is the location of fabrication. On-site production enables direct printing in the construction setting and reduces the need to transport finished components. At the same time, fabrication remains tied to local site conditions, including machine

L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 1475–1483, 2026.
https://doi.org/10.1007/978-3-032-34930-9_172

setup, calibration, environmental exposure, and long-duration printing sequences. For earthen materials, this dependence can intensify uneven drying, shrinkage, cracking, and the need for temporary protection during fabrication. Off-site production offers a more controlled environment for printing and curing, but changes the construction logic once printed elements must be segmented, handled, transported, assembled, and integrated into a larger building system.

Although on-site and off-site construction printing have already been compared in the broader literature, these discussions remain shaped mainly by concrete-based systems. For earthen additive manufacturing, the comparison requires a different emphasis. Relocating fabrication does not simply improve production conditions; it redistributes challenges across the construction process. Controlled off-site production may reduce fabrication-stage vulnerabilities, but it can also introduce new dependencies related to segmentation, lifting, transport, assembly, tolerances, and long-term integration. These implications remain only partly structured for earthen systems.

This paper presents a preliminary discussion of how challenges shift between on-site and off-site workflows in earthen additive manufacturing. Based on a focused review of literature and selected full-scale prototype references, it compares both fabrication pathways through material-related and process-related dimensions. Graphical synthesis is used to highlight selected recurring challenge patterns and to show how the move toward off-site production shifts the problem field from exposure-driven fabrication constraints toward segmentation, handling, transport, assembly, and system integration.

2 Review Approach and Analytical Framing

The comparison follows a focused narrative review approach. It draws on literature from earthen additive manufacturing and from broader research on on-site and off-site construction printing to examine how fabrication location changes the challenge profile across the construction process. Sources were selected for their relevance to material behaviour, fabrication setting, and workflow-related challenges, including drying, shrinkage, cracking, environmental exposure, segmentation, transport, assembly, and interfaces.

The analytical framing distinguishes between material-related and process-related challenges. Existing earthen AM research mainly addresses material composition, printability, drying behaviour, and fabrication-stage conditions, while questions of prefabrication, movement, transport, reassembly, and interface design remain less developed, especially for earthen elements.

Selected full-scale prototypes are used as case references to ground this comparison in concrete workflow conditions. They function as contrasting examples of on-site and off-site fabrication and support the graphical discussion in Sect. 4. Table 1 links the selected challenge themes represented in Figs. 4 and 5 to the literature and case references that informed the graphical comparison.

Table 1. Selected challenge themes underlying the graphical comparison in Figs. 4 and 5, distinguishing between literature-backed themes and case-informed observations.

Challenge Theme	Dimension	Workflow	Support Type	Indicative Sources
Environmental exposure during fabrication	Material-related	On-site	Literature	[1–8]
Drying, shrinkage, and cracking risk	Material-related	On-site	Literature	[1–5, 9, 8]
Protected fabrication and curing	Material-related	Off-site	Literature	[10–13]
Segmentation for transportability	Process-related	Off-site	Literature	[10–13]
Handling, transport, and assembly interfaces	Process-related	Off-site	Literature	[2, 10–13]
Site-dependent printer setup and calibration	Process-related	On-site	Case-informed	TOVA
Temporary protection measures during fabrication	Process-related	On-site	Case-informed	TOVA
Differential drying from asymmetric exposure	Material-related	On-site	Case-informed	TOVA
Fragility during movement	Material-related	Off-site	Case-informed	ClayX / Living Prototypes

3 Case References

The presented prototypes are used as illustrative case references to ground the comparison between on-site and off-site earthen additive manufacturing. Their role is not to provide equivalent comparative datasets, but to make different workflow conditions visible through built or prototypical applications.

TOVA by the Institute for Advanced Architecture of Catalonia (IAAC) is used as the on-site reference. The project demonstrates direct printing with local earth in an in-situ construction context and shows the main logic of on-site fabrication: material remains close to its final position, transport is largely avoided, and fabrication is closely tied to site conditions and printer dimensions. At the same time, the case exposes the dependence of earthen printing on environmental exposure, site organization, machine setup, calibration, and process continuity over an extended fabrication duration (Fig. 1).

The off-site side of the comparison is represented by the contribution of IAAC to the *Living Prototypes* exhibition in Berlin and in addition early demonstrators of the *ClayX* research project [14, 15]. Both cases show earthen elements fabricated in controlled settings rather than directly in their final construction position. Their analytical

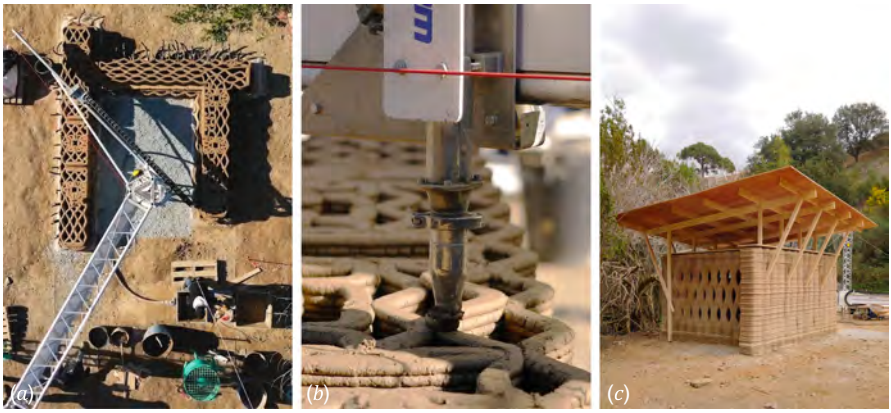

Fig. 1. TOVA by IAAC as an on-site earthen additive manufacturing case, (a) showing direct printing in context, (b) process detail, and (c) the completed prototype.

value lies in exposing the consequences of prefabrication once printed elements must be subdivided, handled, lifted, transported, assembled, and secured. Compared with the on-site case, they point less to exposure-related instability during fabrication and more to the requirements of movement, interface design, and system integration. At the same time, they indicate that prefabricated earthen additive manufacturing remains largely experimental, especially where handling, connection design, and long-term integration are concerned.

Taken together, these references provide the basis for the graphical comparison in Sect. 4, which synthesizes how material-related and process-related challenges shift between on-site and off-site earthen additive manufacturing workflows (Figs. 2 and 3).

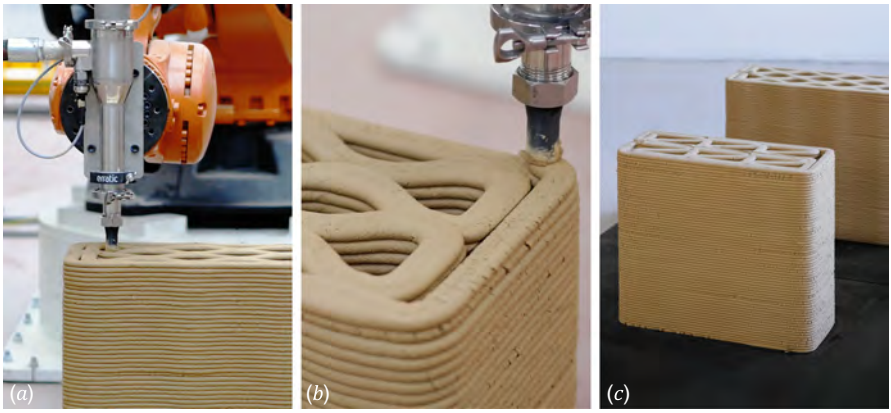

Fig. 3. ClayX as an off-site prefabrication-oriented research case, (a) showing robotic fabrication, (b) deposition detail, (c) and printed hollow test elements.

4 Comparative Discussion of Shifting Challenges

Shifting earthen additive manufacturing from on-site production to off-site prefab- rication changes the challenge profile rather than simply relocating fabrication. In on-site workflows, dominant constraints arise from environmental exposure, drying behaviour, long-duration printing, and the dependence of fabrication on local site conditions. In off-site workflows, controlled production can reduce part of this exposure-related instability, but introduces new requirements once printed elements must be segmented, moved, transported, assembled, and integrated into a larger building system. For earthen materials, this shift is especially relevant because moisture sensitivity, shrinkage, cracking risk, and early-age fragility remain active across multiple stages of the construction process. Figs. 4 and 5 synthesize this redistribution through selected material-related and process-related challenges.

4.1 On-Site Workflow: Material and Process Constraints

In the on-site workflow, the challenge field is shaped by the direct interaction between material sensitivity and site-dependent fabrication conditions. As shown in Fig. 4, material-related constraints include solar and weather exposure, differential drying, and the resulting risks of shrinkage and cracking. These effects are amplified by the fact that printing, curing, and early material stabilization take place directly in the construction environment rather than under protected production conditions. Temporary protection measures may reduce some of these effects, but they also reveal the extent to which fabrication remains dependent on changing weather and site organization.

The process dimension of on-site fabrication is equally site-bound. The printing system must be assembled locally, calibrated to the specific job site, and operated through an extended in-situ fabrication sequence. Production quality therefore depends not only on material behaviour, but on setup conditions, process continuity, and planning at the construction site itself.

Fig. 4. Graphical synthesis of selected material-related and process-related challenges in on-site earthen additive manufacturing. The illustration highlights the dependence of in-situ fabrication on environmental exposure, drying behaviour, site-specific setup, and temporary protection measures.

4.2 Off-Site Workflow: Controlled Production and Shifted Challenges

In the off-site workflow, the challenge profile changes. Protected production settings can reduce exposure-related variability during printing and curing, making it easier to stabilize drying conditions and improve process control. Compared with the on-site case, this shifts part of the problem away from environmental uncertainty during fabrication itself. Figure 5 reflects this change through protected fabrication conditions and controlled curing. At the same time, off-site fabrication introduces a broader process-related burden. Once printed elements are no longer produced in final position, they must be segmented into transportable units, handled and lifted without damage, transported to site, and assembled with sufficient dimensional control. These steps introduce new dependencies on element sizing, movement, tolerance management, interfaces, and construction sequencing. For earthen components, these issues are intensified by fragility during movement and by the need to maintain material integrity beyond the protected production environment. The main challenge therefore shifts from stabilizing the print process under exposed site conditions toward designing printed elements as movable and assemblable components.

4.3 Shift in the Challenge Profile

Off-site earthen additive manufacturing should not be understood simply as a more controlled version of on-site printing. It shifts constraints from exposed fabrication conditions toward movement, assembly, and integration, and changes the design problem from stabilizing a continuous in-situ process to designing discrete, movable, and assemblable earthen components. This is materially significant because moisture sensitivity, dimensional instability, and early-age fragility continue beyond printing and affect handling, transport, repairability, and reuse.

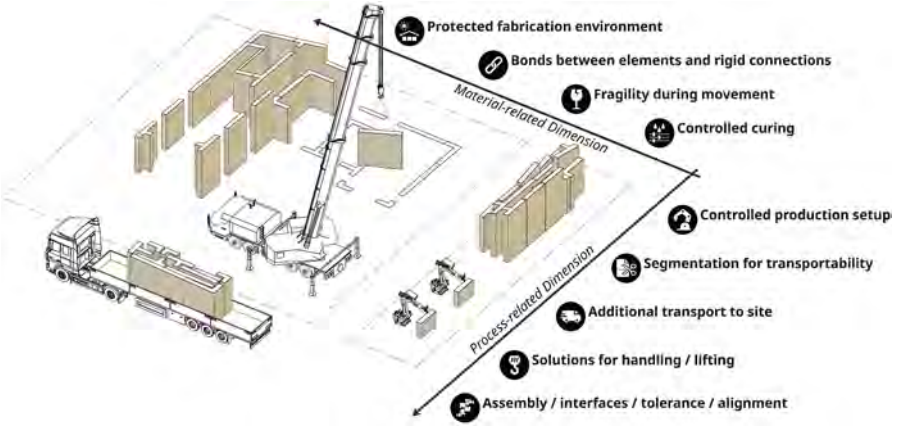

Fig. 5. Graphical synthesis of selected material-related and process-related challenges in off-site earthen additive manufacturing. Protected production conditions may reduce exposure- related instability during fabrication, but new requirements arise in segmentation, handling, transport, assembly, and interface coordination.

5 Conclusion and Future Work

The comparison between on-site and off-site earthen additive manufacturing shows that fabrication location changes the challenge profile in fundamental ways. On-site workflows are constrained primarily by environmental exposure, differential drying, shrinkage risk, site-specific setup, and long-duration in-situ production. Off-site workflows can reduce some of these fabrication-stage vulnerabilities through protected production and controlled curing, but introduce new demands related to segmentation, handling, transport, assembly, and interface coordination. Off-site earthen additive manufacturing should therefore not be understood as a simple improvement over on-site production. The main effect is a shift in where complexity occurs: from exposure-driven print-process constraints toward the movement and integration of prefabricated elements. For earthen materials, this shift is especially important because material sensitivity remains relevant beyond fabrication itself. Future work should examine segmentation, transport, reversible interfaces, repairability, and the circular potential of prefabricated earthen components.

Acknowledgments. The authors gratefully acknowledge the funding support underlying the prototype references discussed in this paper. *TOVA* was realised within IAAC's 3DPA programme, which participated in the *Living Prototypes* project supported by Zukunft Bau. *ClayX* at RWTH Aachen University was funded by the Federal Ministry for Economic Affairs and Energy (BMWE) through the Central Innovation Programme for SMEs (ZIM). The first author also thanks Alexandre Dubor, Edouard Cabay, Oriol Carrasco, Kunaljit Chadha, Eduardo Chamorro Martin, Ashkan Foroughi, and the IAAC faculty for their formative mentorship in earthen additive manufacturing.

From Design Intent to Low-Carbon Outcome: AI as a Tool for Embodied-Carbon Reduction

Anna Thompson[1], Ola Heum Muri[1], Reyn O'Born[2], and Rolf André Bohne[1](✉)

rolf.bohne@ntnu.no

[2] Department of Engineering Sciences, University of Agder, Grimstad, Norway

Abstract. The construction sector is responsible for approximately 37% of global energy-related CO_2 emissions, with up to 80% of a building's environmental impact being determined during the concept and schematic design phases. The present study investigates how artificial intelligence (AI) may be operationalised as a decision-making aid for embodied-carbon reduction in early-stage building design, through a mixed-methods approach comprising a systematic literature review, 18 semi-structured interviews with architects, engineers, and real-estate stakeholders, and a comparative analysis of five commercial AI platforms applied to a real case building. Interview findings indicate that the early integration of sustainability yields performance gains, whilst AI tools are constrained by data-quality, transparency, and workflow compatibility issues. Tool analysis produced emission estimates in the range 239–509 kg CO_2e/m^2 against a professional reference of 214 kg CO_2e/m^2, with timber structures consistently yielding the lowest embodied carbon. Rule-based tools demonstrated lower deviation from the reference than data-driven platforms. In order to accelerate AI adoption, transparent data sources, BIM-compatible integration, and revised business models are recommended.

Keywords: Artificial Intelligence (AI) · Embodied Carbon · Early-Stage Building Design · Decision-Support Systems · Building Information Modeling (BIM)

1 Introduction

The construction sector is responsible for 37% of global energy-related CO_2 emissions [1]. Up to 80% of a building's embodied-carbon impact is determined during the concept and schematic design phase [2]. This is when the decisions on structural system, cladding, and geometry decisions are still open. As electricity grids decarbonise, embodied carbon is projected to become the dominant driver of greenhouse-gas-emission from buildings [3]. Traditional LCA requires detailed material quantities unavailable at this stage [4], creating a demand for rapid AI-assisted estimation tools. However, the accuracy, sensitivity behaviour, and practical usability of such tools remain insufficiently documented. The present paper addresses: How can AI be operationalised as a decision-making aid for reducing embodied carbon in early-stage building design?

2 Background

2.1 Embodied Carbon and Early-Stage LCA

LCA, as standardised in ISO 14040/14044 and EN 15978, provides the framework for quantifying building environmental impacts across lifecycle modules A1–C4. Embodied carbon (primarily A1–A3) is governed by structural and envelope design decisions. Early-stage LCA faces a fundamental data paradox in that the phase with the highest decision leverage has the least available data. Parametric methods address this by predicting emissions from building-level descriptors, such as gross floor area, structural typology, and location, calibrated on post-design datasets [5]. Tool comparison studies have consistently revealed large inter-tool variation [6], raising questions about benchmark reliability.

2.2 AI in Sustainable Building Design and as a Decision-Support Tool

AI encompasses machine learning, neural networks, and large language models, with growing applications in the built environment [7, 8]. In carbon estimation, two model types are prevalent: rule-based tools, which generate parametric material takeoffs and apply EPD emission factors, and data-driven tools, which apply regression or ML models trained on post-design LCA datasets. From a decision-support perspective, AI carbon tools are of value when they produce outputs rapidly enough to influence a design iteration, communicate uncertainty sufficiently, and integrate with established BIM workflows [9, 10, 11]. Despite this potential, our 2024 survey of Norwegian AEC professionals identified lack of competence (80–87% of respondents), data quality, and cost as the dominant barriers to adoption.

3 Methodology

3.1 Systematic Literature Review

Searches were conducted in Web of Science, Scopus, and NTNU library collections using Boolean combinations of four concept clusters: “embodied carbon” OR “embodied GHG”; “artificial intelligence” OR “machine learning”; “early-stage design” OR “concept design”; “LCA” OR “life cycle assessment”. Inclusion criteria following PRISMA guidelines (peer-reviewed, 2015–2025, English, buildings focus) yielded 47 sources.

3.2 Interview Study

Purposive sampling was applied across three stakeholder groups: architects and design engineers (n = 9), real-estate developers (n = 5), and AI/software specialists (n = 4). Data saturation was reached at 18 interviews (45–60 min each, conducted digitally, audio-recorded with consent). Transcripts were analysed through inductive thematic coding comprising open coding, sub-theme grouping, abstraction to main themes, and cross-case validation. Participants are identified as RES 1–RES 18 to preserve anonymity.

3.3 Comparative Tool Analysis

Five commercially available platforms were selected on the basis of market presence, support for early-stage inputs, and relevance to the Norwegian AEC context: Autodesk Forma, Carbon Designer 3D (One Click LCA), C.Scale (Thornton Tomasetti), Preoptima CONCEPT, and Reduzer Automodell. Each tool was applied to the case building (Sect. 4) by the same operator using standardised inputs. Sensitivity analyses varied one parameter at a time: structural system (cast concrete, steel, mass timber, low-carbon concrete), cladding (brick, timber, glass fibre, steel panels), window-to-wall ratio (WWR: 20–40%), and floor count (6–10). Usability was assessed with the System Usability Scale (SUS; 0–100) immediately after each modelling session. An aggregate performance score (1–5 per criterion, max 15) was calculated from emission accuracy, SUS score, and modelling time.

4 Case Building

Campus Hotel Grimstad is a proposed eight-storey hotel and conference facility (7,680 m^2 GFA; developer: J.B. Ugland; architect: ENO Arkitekter) located in Grimstad, Norway. A detailed professional LCA by Sweco (NS 3720/TEK17, modules A1–A5) established a reference value of 214 kg CO_2e/m^2, which served as the benchmark for all tool comparisons. The baseline configuration comprised a cast-in-place concrete frame, brick/masonry cladding, 30% WWR, and no basement (Fig. 1).

Fig. 1. Campus Hotel Grimstad: aerial view (left) and architectural rendering (right).

5 Results

5.1 Interview Findings

Four themes emerged from thematic analysis. (i) Sustainability integration: respondents emphasised that sustainability must be incorporated from project inception, with a growing trend towards embodied carbon, material reuse, and developed. (ii) Current AI use:

tools are primarily applied to volume studies, daylighting simulation, and rapid visualization; some firms have developed in house language models to democratize access to sustainability knowledge. (iii) Challenges and barriers: low trust in automated estimates, poor workflow integration, outdated IT infrastructure, and opaque data sources were most frequently cited. As stated by RES 5: "Architectural processes cannot be replaced, but they can be optimised with respect to the environment." (iv) Future outlook: AI was expected to grow in importance for repetitive tasks, whilst the desire for a single integrated LCA-cost-BIM tool was frequently expressed but acknowledged as still distant.

5.2 Estimated Emission Levels

All five tools overestimated the reference value of 214 kg CO_2e/m^2 (Table 1; Fig. 2). Deviation ranged from +12% (Carbon Designer 3D) to +138% (Preoptima CONCEPT). It was observed that rule-based tools (Carbon Designer 3D, Reduzer Automodell) showed systematically lower deviations than data-driven platforms (Autodesk Forma, C.Scale, Preoptima CONCEPT).

Table 1. Estimated embodied carbon per tool and deviation from the 214 kg CO_2e/m^2 reference.

Tool	Model type	Estimate (kg CO_2e/m^2)	Deviation (%)
Autodesk Forma	Data-driven	347	+62
Carbon Designer 3D	Rule-based	239	+12
C.Scale	Data-driven	327	+53
Preoptima CONCEPT	Data-driven	509	+138
Reduzer Automodell	Rule-based	277	+29

5.3 Sensitivity Analysis

Tables 2a and 2b present the sensitivity of estimated emissions to changes in structural system and cladding. WWR and floor-count results are described in the text.

Mass timber was the most carbon-efficient structural option across all five tools; steel produced the highest values in four of five. Structural system had the greatest influence on emissions, with the spread widest in Preoptima CONCEPT (342–600 kg CO_2e/m^2) and narrowest in Carbon Designer 3D (182–293 kg CO_2e/m^2). Cladding type had a smaller effect; WWR showed minimal tool responsiveness. Floor count produced diverging trends across tools. Figure 3 presents the combined sensitivity results.

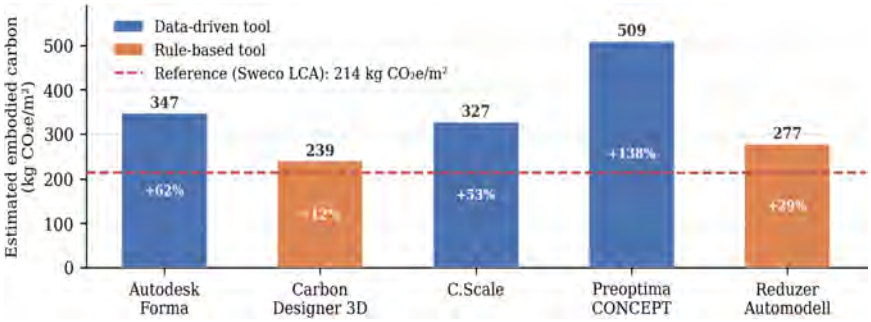

Fig. 2. Estimated embodied carbon (kg CO_2e/m^2) from five AI tools vs. reference value

Table 2a. Structural system sensitivity (kg CO_2e/m^2).

Tool	Concrete	Steel	Mass timber	Low-C concrete
Autodesk Forma	347	472	226	283
Carbon Designer 3D	239	293	182	n/a
C.Scale	327	284	219	n/a
Preoptima CONCEPT	509	600	342	349
Reduzer Automodell	277	314	241	294

Table 2b. Cladding sensitivity (kg CO_2e/m^2).

Tool	Brick/masonry	Timber	Glass fibre	Steel panel
Autodesk Forma	365	347	389	330
Carbon Designer 3D	313	239	287	304
C.Scale	251	382	241	242
Preoptima CONCEPT	482	509	496	492
Reduzer Automodell	246	277	n/a	304

Table 3 presents the lowest-emission configuration identified by each tool. All tools concur on mass timber as the optimal structural system, whilst optimal cladding, WWR, and floor count diverge substantially.

5.4 Usability and Overall Performance

SUS scores ranged from 52.5 (Reduzer Automodell) to 95.0 (Autodesk Forma and

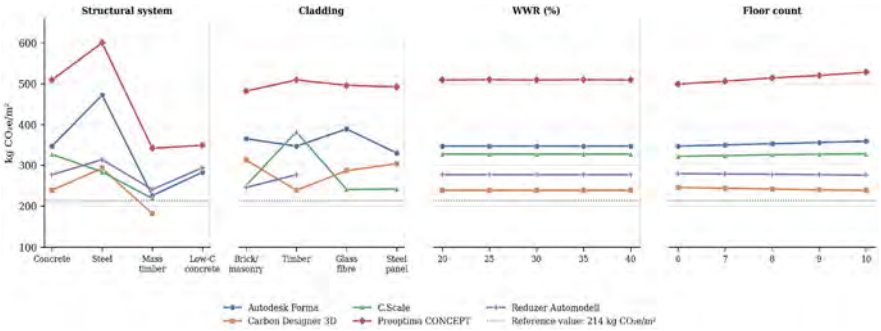

Fig. 3. Combined sensitivity line chart: CO_2e/m^2 per tool across all parameter variations (structural system, cladding, WWR, floors)

Table 3. Lowest-emission design configuration per tool.

Tool	Structure	Cladding	WWR	Floors	kg CO_2e/m^2
Autodesk Forma	Mass timber	Timber	25%	6	231
Carbon Designer 3D	Mass timber	Timber	30%	10	218
C.Scale	Low-C concrete	Low-C panel	35%	6–8	322
Preoptima CONCEPT	Mass timber	Masonry	40%	6	323
Reduzer Automodell	Mass timber	Timber	30%	8	160

Carbon Designer 3D). Modelling time ranged from 60 min (Autodesk Forma) to 210 min (Reduzer Automodell). On the aggregate performance scorecard (Table 4; Fig. 4), Autodesk Forma and Carbon Designer 3D tied at 12/15. Reduzer Automodell scored lowest (6/15), despite producing the second-smallest emission deviation, owing to poor usability and long modelling time.

Table 4. Aggregate performance scores (1 = worst, 5 = best per criterion; max = 15).

Criterion	A. Forma	C. Designer 3D	C. Scale	Preoptima	Reduzer
Emission accuracy	2	5	3	1	4
SUS score	5	5	2	3	1
Modelling time	5	2	3	4	1
Total	12	12	8	8	6

6 Discussion

6.1 Tool Accuracy and the Rule-Based vs. Data-Driven Divide

The 2.4-fold spread between the lowest (239 kg CO_2e/m^2) and highest (509 kg CO_2e/m^2) estimates raises concerns regarding single-tool reliance. In practice, outputs should be treated as relative indicators; deviations within ±30% can guide design, whilst larger divergences call for multi-tool triangulation.

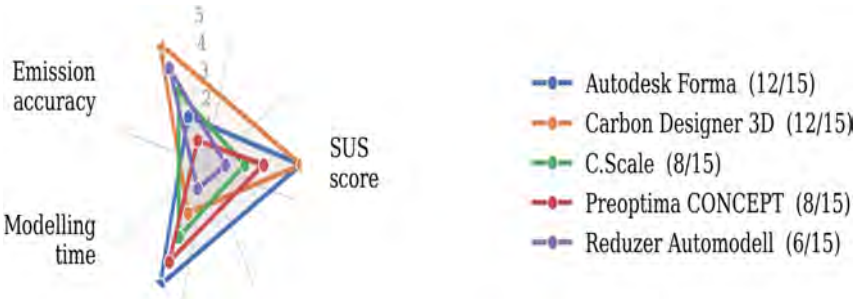

Fig. 4. Radar chart: aggregate performance scores for the five AI tools.

Systematic overestimation by all platforms may reflect broader system boundaries or conservative default assumptions. The superior accuracy of rule-based tools is consistent with comparable studies [6]: explicit parametric models render assumptions auditable, whereas data-driven tools embed assumptions within training data. The inconsistency of sensitivity responses across tools—most notably opposing floor-count trends—aligns with the low trust reported by interview participants.

6.2 Barriers, Recommendations, and Limitations

AI-based embodied-carbon tools remain at an early stage of maturity; the principal barriers are structural rather than user-related. Three clusters of recommendations are identified. For the industry: invest in capacity building, data sharing, and pilot projects linking AI outputs to actual design decisions. For tool developers: prioritise transparency of EPD sources and calculation pathways, BIM interoperability, and user control over parameters. For policy and business models: adopt project-based licensing and position AI as a decision-support layer rather than a replacement for professional judgement. Moreover, AI tools can support circular design strategies at concept stage, including low-impact material selection and design for adaptability. The study has several limitations: the tool analysis was based on a single building typology and location; the reference value covers A1–A5 under NS 3720/TEK17, whilst some tools may include additional modules, which may partly explain the systematic overestimation; and interview findings reflect the Norwegian AEC context. The reported deviations should therefore be treated as context-specific rather than universal benchmarks. Future work should replicate across typologies, normalise system boundaries, and assess inter-user variability.

7 Conclusions

Five conclusions emerge: (1) All five tools overestimated the 214 kg CO_2e/m^2 reference by $+12\% - +138\%$; rule-based platforms were more accurate than data-driven ones. (2) Mass timber was the most carbon-efficient structural system; cladding, WWR, and floor count diverged substantially. (3) AI tools add value in early-stage design, yet trust remains low due to transparency deficits and workflow incompatibility. (4) Autodesk Forma and Carbon Designer 3D performed best on the combined performance scorecard. (5) Systemic change is required: industry capacity building, transparent and interoperable tool development, and new business models that lower entry barriers. (6) Practitioners should triangulate across tools; deviations within $\pm 30\%$ can guide design, whilst larger divergences warrant professional verification.

Greening the Built Environment: Traditional and AI Design Tools to Promote Circularity, Nature, and Enhance Energy Efficiency in the Refurbishment of Sassari's Municipal Swimming Pools

Antonello Monsù Scolaro(✉), Laura Ara, Roberto Mura, Alessandro Rozzo, and Silvia Pulina

Department of Architecture, Design and Urban Planning, University of Sassari, Sardinia 07100, Italy
amscolaro@uniss.it

Abstract. The adaptive reuse of the built environment presents an opportunity to reduce the exploitation of primary resources and to improve the energy efficiency of the building stock constructed over the past thirty years worldwide, in line with the European framework. This paper focuses on the refurbishment of Sassari's municipal swimming pool, beginning with a comprehensive analysis of the existing building in terms of structural, physical, and technological requirements, followed by a participatory identification of new requirements and needs. An integrated methodological approach was applied to enhance the building's environmental, social, and economic efficiency by valorizing existing materials, reducing waste, and improving technological performance; the refurbishment intervention relies entirely on dry construction solutions. The design process also incorporates principles of biophilic design to strengthen the interaction between users and nature, promoting psychological and physiological wellbeing. This approach is implemented through strategies that enhance natural daylight, visual connections with outdoor elements, and the integration of natural environmental features within the built space. In addition, thanks to the AI-powered design tools, it is shown how big data can be managed to inform design decisions that are effective from both environmental and technological performance perspectives, with particular attention to indoor air quality and user wellbeing.

Through detailed drawings, the findings present a comparative scheme of design alternatives, enabling the designer to make informed choices regarding the associated environmental impacts.

1 Circularity, Nature, and Energy Efficiency in the Refurbishment of the Built Environment

Since at least 40% of buildings in developed economies were constructed before 1980, retrofitting is challenging. In 2020, buildings represented 42% of the European Union's final energy consumption and were responsible for approximately 35% of its energy-related greenhouse gas emissions. These resulted from the direct burning of fossil fuels and energy consumption in the form of electricity, heating and cooling [1]. The EU has set a target to reduce greenhouse gas emissions by 20% by 2020 compared to 1990 levels and by more than 55% by 2030. In 2020, the European Commission launched the Renovation Wave strategy as part of the European Green Deal to promote energy-efficient renovations in the EU. Renovating existing buildings to achieve zero carbon emissions by 2030 and 2050 is crucial for meeting decarbonization goals. To achieve zero-carbon readiness in 20% of these buildings by 2030, an annual deep renovation rate exceeding 2% is required [2]. Meanwhile, the New European Bauhaus has proposed an integrated vision of sustainability, beauty, and community, requiring that every new construction or renovation project consider people's needs. A substantial body of medical and environmental research has shown that contact with natural environments provides significant physiological benefits for humans, and this need became particularly evident during the COVID-19 lockdowns [3]. Consequently, restoring meaningful connections between people and nature has become an important challenge for contemporary urban architecture [4]. In this context, by integrating natural elements and processes into the built environment, biophilic design can contribute to more sustainable architectural practices and improved resource management [5], generating multiple co-benefits, including enhanced human health and well-being, and support for climate change mitigation and adaptation. Hence, the refurbishment of existing buildings combined with biophilic design is an opportunity to create built environments that promote positive physical and psychological responses by reintroducing meaningful experiences of nature into everyday urban life.

2 The Lu Fangazzu Municipal Swimming Pool in Sassari

The swimming pools in Sassari are key landmarks in Sardinia's aquatic sports history. Designed in the mid-1970s, they feature indoor training and diving pools, alongside an outdoor Olympic-sized pool for summer competitions. The pools were inaugurated on 7 January 1981. The swimming center addressed local demand for sports infrastructure and a regional need for structured aquatic education for youth. In the 1990s and early 2000s, the complex expanded and adapted to meet the growing user demand and diverse program requirements. Rehabilitation pools, fitness area, and wellness facilities were added to the original design, enhancing community services. However, the lack of a comprehensive redesign led to spatial fragmentation and functional inefficiency over time (see Fig. 1).

The complex was built using outdated construction methods that today are no longer effective in structural terms and technological performances. The structure features a load-bearing steel frame on a reinforced concrete foundation. The exterior consists of

Fig. 1. The actual plan with the evident fragmented spaces (source: Ara L., Mura R., 2025).

concrete blocks rising to 1.5 m, topped with brick that includes an inner rock wool insulation layer and an internal brick finish. Roofs are categorized into two types: 1) the common space roof, made of galvanized corrugated steel sheets on steel beams with concrete, waterproofing, and gravel layers; 2) the swimming pool roofs, built with metal trusses, secondary beams, sheet metal insulation panels, and polyurethane foam. Current transmittance values: perimeter walls 0.45 W/m^{2}K, ground slab 2.61 W/m^{2}K, ceiling 0.44–0.48 W/m^{2}K, and windows 1.65 W/m^{2}K.

Over the years, the incremental additions made for immediate operational needs have led to a fragmented floor plan, characterized by a disorganized arrangement of spaces and poor wayfinding. The outdoor area, featuring a seasonal open-air swimming pool, lacks a defined year-round function (see Fig. 2). The design strategy addresses the needs of managers and users while promoting energy efficiency, material circularity, and environmental integration.

Fig. 2. The external area and the west façade (source: Ara L., Mura R., 2025).

3 An Integrated Methodological Approach to Greening and Refurbishing the Built Environment

The design approach adopted is substantially rooted in the threefold integrated vision of the New European Bauhaus (NEB): sustainable, beautiful and together. The goal is to promote sustainable development in environmental, economic, and social aspects. The refurbishment strategy is based on three key principles: circularity, biophilia, and energy efficiency. Circularity focuses on design choices that enhance the performance of structural and material components to minimize waste, reduce raw material consumption, and maximize the reuse of building materials [6]. Biophilic design reshapes the interaction between indoor users and the outdoors [3]. Energy efficiency improves the building's envelope, leverages bioclimatic benefits, and utilises technological solutions for heating and cooling, also harnessing latent thermal energy when possible [7].

The operative approach informed decision-making at all intervention scales, from spatial reconfiguration and programmatic redistribution to envelope optimization and landscape design. The refurbishment involved a systematic analysis of the physical deterioration and functional weaknesses of the existing building systems and materials, to enhance their residual performance in terms of environmental sustainability. The design was framed through a biophilic lens, prioritizing the wellbeing of workers, users, and visitors [8]. Operatively, among the 14 recognized biophilic design patterns indicated by [9], the following were implemented in the project: 1) Nature in the space (visual connection with nature, dynamic and diffuse light, connection with natural systems); 2) Natural analogues (biomorphic forms and patterns, complexity and order).

The alternatives were evaluated using AI software to improve energy efficiency, incorporate biophilic design elements like natural light and comfort, and minimize environmental impact by preserving existing materials.

3.1 Spatial Reconfiguration

The refurbishment design intervention was developed in full compliance with the Technical Standards issued by the Italian National Olympic Committee in 2005. These standards impose specific dimensional, functional, and safety requirements that directly influence spatial organization and technical design solutions.

The design process began by fixing "spatial anchors", namely the three pools (indoor rehabilitation and 25-m training, outdoor Olympic), within whose framework all other interventions were structured. The external perimeter of the complex remained unchanged, focusing modifications solely on the interior layout. Key interventions improved spatial permeability, with two main circulation axes: an east–west axis from the main entrance to the former diving pool and a north–south axis through the rehabilitation pool entrance. The plan was simplified by removing non-load-bearing partitions, resulting in a clearer spatial arrangement while preserving the original structural grid and load-bearing system (Fig. 3).

3.2 The Envelope and the Biophilic Design Contribution

To optimize the building envelope for aesthetics and performance while maximizing passive solar gain, the existing structural framework will be largely retained. A façade

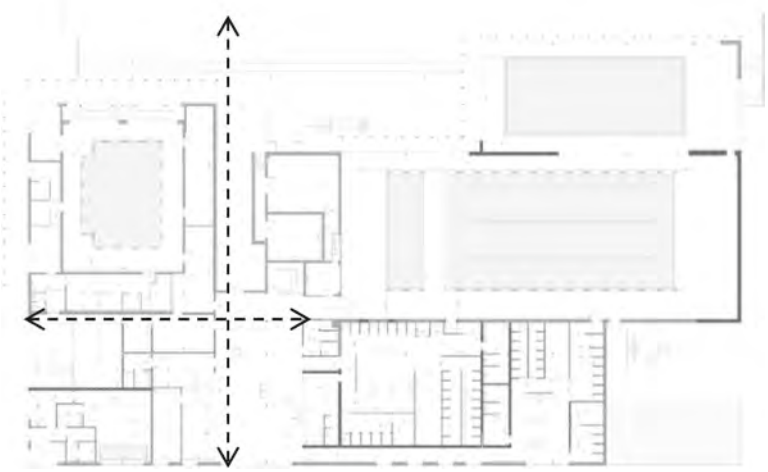

Fig. 3. The new plan with the two axes emerged (source: Ara L., Mura R., 2025).

shading system made from thin sheet metal was designed with the aim of not compromise visual connection with the surrounding landscape and based on solar radiation analysis specific to the complex's location. This established the summer and winter zenith and relative azimuth angles (see Fig. 4). The external screening geometry was verified, and the sheet metal grid was separated from the glass façade to reduce direct solar radiation in summer while allowing it in winter, optimizing natural light and occupant comfort. The building envelope features a ventilated façade with a 5 cm air gap, clad in sandwich panels made of steel sheets and polyurethane foam. The panels provide thermal transmittance values of $U = 0.536$ W/m^{2}K and $U = 0.55$ W/m^{2}K. A steel support frame, anchored to the existing wall, holds both the insulation panels and a glass façade that lets light into the swimming pools. This façade connects to the roof frame, stabilizing the entire steel structure. The envelope is completed with a new double-glazed system featuring low-emissivity glass. This system has a thermal transmittance value of $Ug = 1.1$ W/m^{2}K, representing a significant improvement on the $Ug = 5.7$ W/m^{2}K value typically achieved with single glazing (see Fig. 4).

The shading system employs a dual biomimetic design [10] with an overall wave form to evoke water and the primary function of the site, and with a pattern inspired by the structure of water molecule. The atomic mass proportions of oxygen and hydrogen are represented by two circles, with the oxygen circle being fifteen times larger and arranged according to the 104.45° bond angle. This creates an inverted 'V' shape motif that is perforated into the metal cladding, generating various openings to achieve the desired solar shading.

The vegetation strategy enabled the establishment of a multi-layered green frontage composed of arboreal, shrub, and herbaceous strata. Species were selected to ensure ecological coherence with the local context. The arboreal component consisted of both evergreen and deciduous trees to enhance users' perception of nature within the space throughout seasonal variations in foliage color and leaf fall. Tree species were specifically employed to re-establish a natural barrier along the southern boundary to protect from

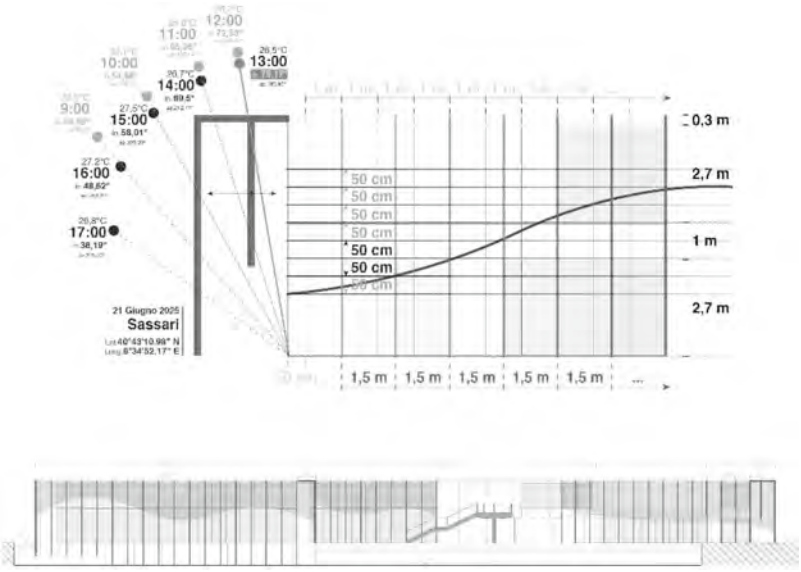

Fig. 4. Solar radiation and biomimetic western façade screening (source: Ara L., Mura R., 2025).

prevailing winds and summer solar exposure for both the outdoor pool and the west-facing façade.

3.3 The AI Design Support Decision

Afterwards, the design choices were optimized using a series of analytical tools from the American open digital platform, Cove.Tool. The EnergyPlus Weather (EPW) file enabled climate analysis of the intervention area, offering data on temperature, humidity, solar radiation, and wind. Using the psychrometric graph from the Givoni method, optimal bioclimatic strategies for the local climate were identified.

The architectural elements were assessed regarding building layers and materials, exploring alternative solutions for energy performance (thermal transmittance, U value), carbon emissions ($kgCO_2/m^2$), and renovation costs per square meter. The current situation was compared with two design scenarios: one based on traditional post-design choices aligned with regulatory limits, and another optimized for better energy performance and reduced environmental impact. Further simulations analyzed factors such as solar radiation, shading, indoor visual quality, ventilation efficiency, and air quality. Parameters were calculated based on occupancy, hours, and seasonal changes, helping to create a more realistic scenario for building energy consumption.

The building's energy consumption stands at 317.18 kWh/m^2 annually, which can be reduced to 234.34 kWh/m^2 with improvements. Current CO_2 emissions are 185.6 tCO_2e per year, with a 2030 target of 73.7 tCO_2e. A 100-year lifecycle reuse strategy could lower embodied emissions to 270.7 tCO_2e, down from 1,678 tCO_2e, while operational emissions would decrease to 18,372.7 tCO_2e from 169,562.5 tCO_2e.

Given that a significant portion of energy and emission reductions relies on renewable energy sources, two scenarios were analysed: the first one considers the use of photovoltaic panels, while the latter incorporates solar thermal systems.

Proposal A - Installation of 80 photovoltaic panels with Energy consumption 193.33 kWh/m^2/year and an annual emission of 147.1 tCO_2e. In this proposal, electricity costs €32,651.92/year, gas costs €87,831.48, and total emissions are 13,756.7 tCO_2e, representing a 26.2% reduction from the current scenario.

Proposal B - Installation of 34 photovoltaic panels and 80 solar thermal panels with an energy consumption of 125.89 kWh/m^2/year, slightly below the target value, and an annual emission of 104 tCO_2e. In this proposal, electricity costs 39,179.34/year, gas costs €46,144.95/year. The total emissions are 10,074.3 tCO_2e, representing a 45.95% reduction compared with the post-design phase.

The difference between the two scenarios is also evident in the GHGI indicator: 3.646 $kgCO_2e/m^2$ for Proposal A and 2.670 $kgCO_2e/m^2$ for Proposal B, representing a further reduction of 26.77%.

From an economic perspective, the analyses estimate a total building cost of approximately €1,830,644 for the non-optimized project, €2,033,830 for Optimization Proposal A, and €2,171,820 for Proposal B. The differences are mainly related to the renewable energy systems adopted. A precise cost comparison with the existing building is not possible, since material and labor costs at the time of construction differed significantly from current values.

4 Conclusions and Future Perspectives

This design experiment started with a classical approach then focusing on environmental, urban, spatial, structural, technological, and economic factors. Artificial intelligence (AI) played a key role in material selection, by comparing reused project materials against alternative options based on key characteristics such as cost, thermal transmittance (U-value), and embodied carbon emissions (tCO_2), also comparing total GHG emission factor ($kgCO_2eq/m^2$). This data-driven approach helped identify the most suitable materials. AI was also applied to energy optimization, evaluating the existing HVAC systems against more efficient alternatives to select solutions with better performance, lower emissions, and reduced operational costs. Artificial intelligence is now widely recognized as an enabling technology capable of orientating design alternatives against performance objectives, while managing a wide variety of data and reducing the margin of error.

On the other hand, biophilic design helped optimise design solutions by strengthening the relationship between users and natural environment. However, although its potential benefits are supported by a strong theoretical framework, empirical evidence remains limited, and relatively few projects have been assessed using rigorous experimental approaches [11].

This research evaluated how refurbishment interventions that apply an integrated methodological approach based on key principles of circularity, biophilia, and energy efficiency can improve users' well-being, conserve resources, minimize waste and climate impacts in line with international policies. Further studies are needed to explore

the connection between greening buildings and biophilic design for integrated and measurable design solutions [12].

Abstract. The rapidly increasing global demand for housing, rising construction costs, shortages of skilled labor, and high environmental and economic impacts of conventional construction have highlighted the urgent need for extensive re-search in the field of sustainable construction. In this context, alongside the development of green materials, the adaptation of novel production techniques to the construction sector has gained significant momentum, with the primary objectives of reducing emissions, energy consumption, environmental burden, and overall costs. Considering the need to reshape the built environment in a circular and sustainable manner, this study investigates the development of environmentally friendly, cost-effective, and sustainable mix designs suitable for 3D concrete printing (3DCP) through the use of waste materials (recycled concrete aggregate). Research examines the production of modular structural elements, their rapid on-site assembly, and the required technical infrastructure to enable such applications. Through this approach, circularity within the construction sector can be achieved by reintroducing waste materials into the production cycle as secondary raw materials. The adoption of 3DCP enables the construction of fast, flexible, and eco-friendly structures, while the modular nature of the elements allows construction activities to be carried out largely independent of site conditions. The findings demonstrate that this approach can lead to substantial material savings and significantly reduced construction times, with the structural shell of a 75 m^2 building printed in less than 30 working hours. Overall, the study demonstrates that sustainable production model can be integrated into construction industry through effective use of circular economy–based materials.

Keywords: 3D Concrete Printing · Sustainable Built Environment · Modular Construction · Circular Economy · Waste Utilization

1 Introduction

The rapid growth of the global population, increasing demand for housing and infrastructure, and the renovation or demolition of aging buildings generate billions of tons of construction and demolition waste (CDW) annually worldwide [1, 2]. This waste

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 1502–1510, 2026.
https://doi.org/10.1007/978-3-032-34930-9_175

stream accounts for approximately one-third of the total global solid waste generation [3]. The valorization of such a massive material flow through its reintegration into the construction sector as secondary raw materials within a circular economy framework has therefore become increasingly critical. Otherwise, the continued disposal of CDW will lead to further occupation of fertile agricultural lands and intensify soil, water, and air pollution problems [4–6]. The construction sector, already responsible for a significant share of global greenhouse gas emissions and characterized by high energy consumption and environmental impact, faces mounting pressure to adopt transformative solutions [7]. Efficient use of natural resources, reduction of landfill disposal, and the development of environmentally friendly green materials are no longer optional but inevitable pathways toward sustainable development. In addition, the rising cost of construction materials provides strong economic motivation for the high-value utilization of CDW. While earlier applications predominantly relied on low-tech or down-cycling approaches—such as the use of CDW as road subbase or non-structural fill materials—recent research highlights its potential both as recycled aggregate and as supplementary cementitious material (SCM) [8, 9]. Particularly, the introduction of TS EN 197–6 has officially enabled the use of recycled materials as mineral constituents in cement production, accelerating the transition toward value-added recycling strategies. Through such applications, CDW contributes to the development of environmentally friendly, low embodied carbon, cost-effective, and sustainable materials.

Alongside green material development, increasing productivity, minimizing production-related waste, reducing dependency on skilled labor—which is becoming increasingly scarce worldwide—and integrating advanced technologies have driven the digital transformation of the construction industry [10]. Within this context, additive manufacturing, commonly referred to as 3D concrete printing (3DCP), has emerged as a promising alternative production model. This technology fabricates structural elements layer by layer by extruding fresh concrete filaments through a nozzle, following a pre-defined digital toolpath derived from a 3D model. By eliminating conventional formwork, 3DCP enables the realization of geometrically complex and architecturally flexible designs [11]. Since formwork operations constitute a substantial portion of construction time and cost, the reduction or elimination of formwork provides considerable economic and operational advantages [12]. Compared to traditional construction methods, 3DCP offers significant benefits, including improved cost efficiency, faster construction speed, reduced labor requirements and labor-related errors, enhanced occupational safety, and lower material waste generation during execution [13–16]. Consequently, real scale buildings are increasingly being constructed worldwide, while the integration of standards and guideline documents into national regulatory frameworks is still in its early stages.

For 3DCP applications, two primary production strategies exist: on-site printing and off-site prefabricated (modular) manufacturing. The selection between these approaches depends on several factors, including equipment capability, site conditions, environmental exposure, architectural requirements, and logistical constraints. Although on-site applications are currently more widespread, off-site prefabricated and modular production has gained increasing attention. This approach allows uninterrupted production in controlled indoor environments, independent of adverse weather conditions

such as wind, precipitation, extreme temperatures, and humidity fluctuations [17, 18]. It also eliminates frequent printer transportation—particularly critical for gantry-type systems—thereby reducing mechanical wear and operational risks. A stable supply chain, improved quality control, and minimized environmental exposure further enhance technical reliability. However, modular 3DCP introduces new research challenges, particularly regarding joint detailing and structural performance [19]. Comprehensive investigations are required to ensure that modular systems can achieve mechanical performance comparable to monolithic on-site printed walls. Additionally, careful consideration must be given to transportation and assembly processes, as cracking or damage during handling may adversely affect structural integrity [20, 21]. If these concerns are systematically addressed through design optimization and performance validation, prefabricated modular 3DCP could enable fast, flexible, and environmentally responsible construction for a sustainable built environment. Furthermore, such systems inherently support the "design for deconstruction" principle emphasized in international circular economy policies by facilitating disassembly, reuse, and material recovery at the end of service life.

Although the development of green materials tailored for 3DCP systems is widely studied in the literature, research on prefabricated and modular 3DCP applications remains limited. This gap constitutes the primary motivation of the present study. Additionally, the urgent global demand for rapid yet sustainable housing solutions further underscores the importance of this research. Within the scope of the study, a 75 m^2 building was designed and modularized for 3DCP production. Recycled CDW was utilized as a replacement for natural aggregate in the printable concrete mixture, and critical considerations regarding production, transportation, and assembly were systematically evaluated. By integrating circular material utilization with modular additive manufacturing, this study contributes to the current state of the art by (i) providing design and production guidelines for modular segmentation of small-scale housing units, (ii) identifying transportation- and assembly-related risks, (iii) advancing the integration of circular economy principles with digital construction technologies. Through this integrated approach, the research aims to support the transition toward low-carbon, resource-efficient, and digitally enabled sustainable construction.

2 Methodology

In this study, a cement-based mixture incorporating CDW-derived aggregates tailored for 3DCP was developed, with detailed mixture proportions provided in Table 1. The primary binder was CEM I 42.5 R cement, while aggregates included recycled concrete aggregate (RCA) below 2 mm—produced by crushing and sieving demolished concrete—and natural aggregates. A superplasticizer (SP) and a viscosity-modifying agent (VM) were incorporated to achieve the desired rheology and reduce segregation. The mixture was designed to ensure adequate extrudability (as demonstrated in the printing trials shown in the subsequent figures) and exhibited a compressive strength of approximately 40 MPa, indicating sufficient mechanical performance for structural applications. Within the framework of developing a fast, flexible, and eco-friendly modular construction model, a 75 m^2 social facility was digitally designed (see Fig. 1) and configured

as a modular structural system. The wall elements were segmented in accordance with prefabricated 3DCP production principles, considering printability, dimensional constraints, handling, transport, and rapid on-site assembly requirements. Both gantry-type and robotic-arm printing systems were evaluated as capable of producing the designed elements (with particular consideration of the geometric constraints and limited build envelope of robotic-arm systems). The scenario focused on key aspects of modular construction—including element design, segmentation, handling, transport considerations, and assembly strategies—highlighting how prefabricated 3DCP components could support fast, flexible, and eco-friendly construction for a sustainable built environment. Selected wall segments were illustrated to demonstrate the mixture's printability and to support the analysis of modular workflows. This approach provides a comprehensive framework for evaluating modular 3DCP construction, combining mixture performance with practical considerations for prefabrication, logistics, and assembly, without implying full-scale realization of the entire facility.

Table 1. Mixture proportion details (kg/m^3).

Mixture	Cement	Sand	RCA	Water	SP	VM	Fiber
	600	600	600	400	6	3	2

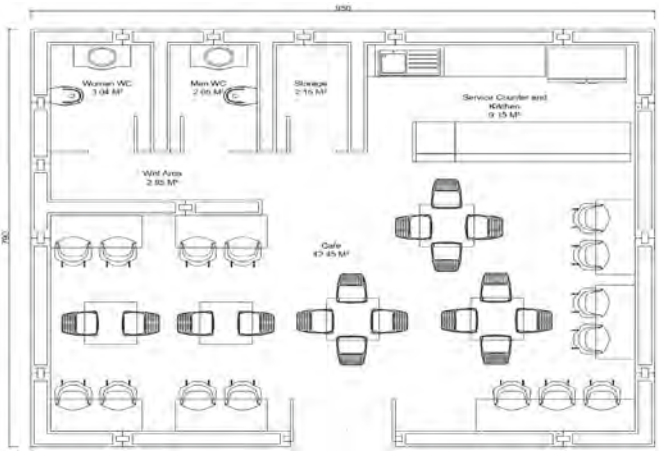

Fig. 1. 75 m^2 modular building plan.

3 Integrated Modular 3DCP Construction Approach

The 75 m^2 social facility was designed to be produced through a modular construction strategy following detailed configuration studies. The primary objective during the modularization process was to minimize the number of modules in order to simplify production, reduce on-site assembly time, and limit the number of connection details and associated labor. At the same time, modules were dimensioned as large as practically feasible while remaining suitable for transportation. Larger modules reduce the number of joints, connection interfaces, potential weak zones, and assembly-related workmanship requirements. In addition to production efficiency, several architectural and technical considerations were considered. These included interior spatial configuration, structural continuity, transportation constraints, and integration of building services. In particular, routing of electrical installations was considered during the design phase; where services were intended to pass through internal wall cavities rather than surface-mounted conduits, module geometry and segmentation were adapted accordingly. To further reduce the number of modules, window openings were planned to be cut after on-site assembly, rather than being printed as separate framed elements during production. This strategy enabled a more compact modular configuration. However, this approach may generate additional material waste during post-processing, which should be considered in terms of sustainability and waste management. Considering these criteria, the 75 m^2 structure was successfully configured using four primary modules, as illustrated in Fig. 2. First, a corner module (Module 1) was designed to define the primary orthogonal geometry. Second, a T-shaped module (Module 2) was developed to provide internal partition connectivity. Third, a long straight wall module (Module 3) was designed to connect corner and T-shaped modules and form the main exterior envelope. Finally, a shorter linear module (Module 4) was introduced to provide architectural flexibility and close remaining wall segments where required. Through this modular logic, the building envelope could be assembled progressively in a rational and repeatable manner.

Based on preliminary production observations and depending on mixture characteristics, it is recommended that printed modules remain undisturbed for at least 2–3 days prior to lifting, and that transportation be conducted after approximately seven days of curing to ensure sufficient early-age strength development. Particular care is required during lifting and loading operations, as printed wall elements—containing lower reinforcement ratios compared to conventional precast reinforced concrete elements—may exhibit relatively brittle behavior. The primary objective during handling is to ensure uniform load distribution along the wall to prevent stress concentrations. Figure 3 presents the 3DCP modular construction workflow, including printing, lifting, placement, service installations, and opening configurations.

During transportation, impact-absorbing materials should be placed beneath the elements, and adequate fastening systems should be employed to minimize movement and vibration. Similar caution is necessary during unloading and positioning on site. Due to their comparatively lower ductility, impact-induced cracking may occur more easily than in heavily reinforced precast systems; therefore, controlled and carefully monitored placement procedures are essential. The step-by-step on-site assembly strategy of the four modules is schematically illustrated in Fig. 4. Excluding transportation time and assuming a prepared foundation, the production and installation of the wall

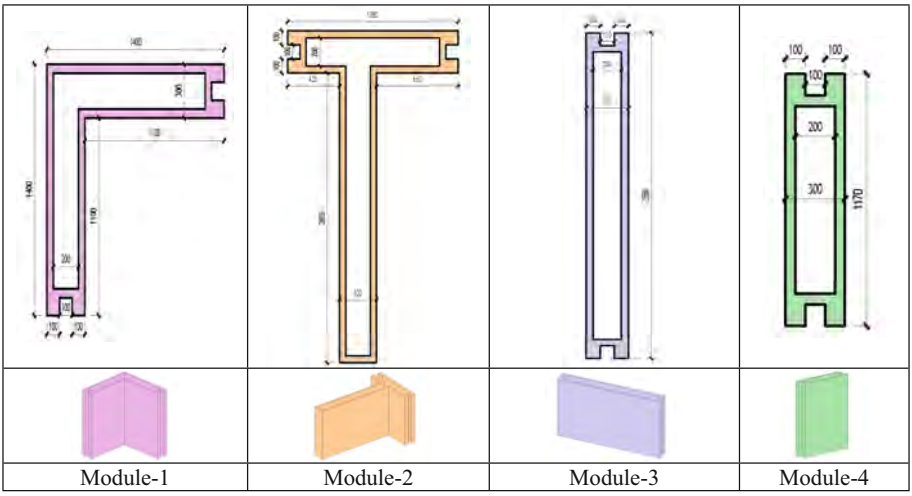

Fig. 2. Building Modules

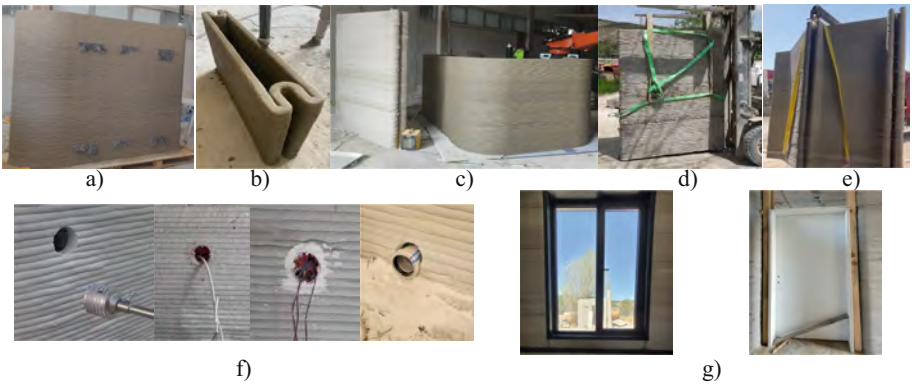

Fig. 3. Representative images of printing (a, b, c), lifting (d), on-site placement operations (e), service installations (f), opening configurations (g)

modules are projected to be completed within approximately 30 h of active operation. Roofing, window installation, and finishing works were not included in this estimation. This time estimation was derived from typical operational parameters of extrusion-based 3D concrete printing systems, including average printing speeds, toolpath lengths, and layer deposition rates. In addition, short intermittent pauses (e.g., approximately 30-min cleaning, maintenance and material conditioning intervals after every 4–5 h of continuous printing) were considered. The overall workflow was further calibrated based on prior on-site experimental printing experiences and reported field implementations of similar robotic and gantry-based systems.

Following installation, a wet joint connection detail (Fig. 5) was adopted to ensure composite action between adjacent wall modules. Based on previous findings [19],

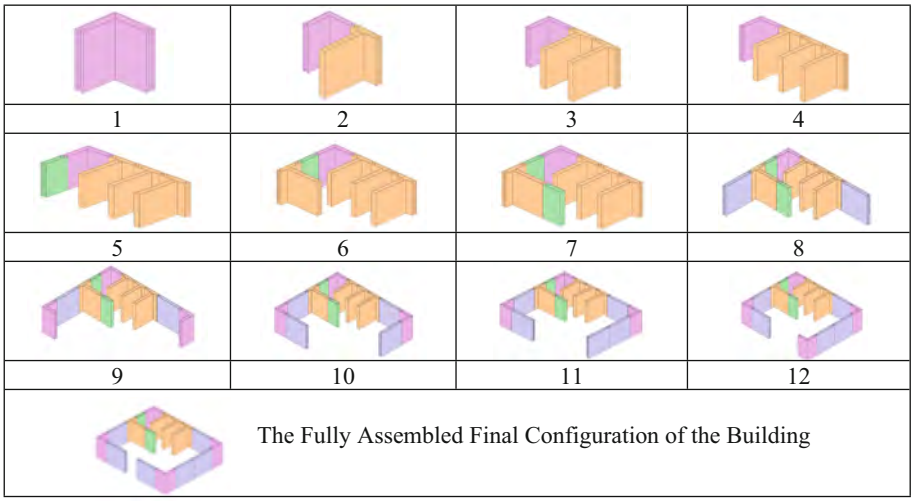

Fig. 4. On-site assembly strategy of 75 m^2 modular building

similar wet joint applications have demonstrated structural performance comparable to monolithic casting, supporting the structural integrity of the modular configuration.

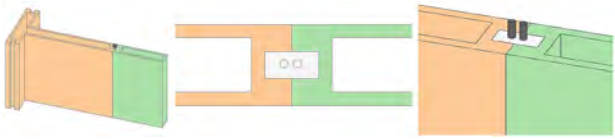

Fig. 5. Schematic connection details of the modular walls

4 Conclusion

In conclusion, this study highlights the potential of a fast, flexible, and eco-friendly modular construction approach as a transformative pathway for a more sustainable built environment. By integrating 3DCP with modular structural design, the proposed system enables rapid production, simplified on-site assembly, and a significant reduction in construction time. The demonstrated ability to complete the structural shell of a 75 m^2 building in very short working hours confirms the efficiency and practical feasibility of this method, particularly in contexts where speed and adaptability are critical. Beyond construction speed, the flexibility of modular design—combined with environmentally conscious material selection—supports a more resource-efficient and resilient building paradigm. The system minimizes material waste, reduces labor dependency, and allows construction processes to be carried out largely independent of site constraints.

Economic Impact of Digitalization on Prefabricated Façade Modules: A Life Cycle Cost Assessment

Marzieh Zarei(✉) and Riccardo Pinotti

Institute for Renewable Energy/Eurac Research, Bolzano 39100, Italy
marzieh.zarei@eurac.it

Abstract. This study evaluates the impact of digitalization on Life Cycle Costs (LCC) associated with the prefabrication and installation phases of prefabricated façade modules for building retrofit applications. A comparative analysis was conducted between a semi-automated prefabrication workflow, characterized by significant manual operations, and a fully automated workflow implementing advanced automation throughout the evaluated phases, from design and manufacturing to on-site installation. The research focused on a standard opaque façade module with dimensions of 9.6 × 3.4 m as a case study. An LCC assessment methodology was developed to systematically identify and evaluate relevant cost parameters from pre-design measurement to installation of the module. Quantitative data regarding digitalization impacts were collected through structured interviews with prefabricated module manufacturers and suppliers of automated construction machinery, supplemented by literature review, market-based datasets, and technical documentation. The research methodology encompassed three main phases: structuring the analytical framework and selecting comparison parameters, estimating LCC parameters through industry consultation and literature analysis, and performing comparative calculations. Results indicate that comprehensive digitalization of the prefabrication process yields significant economic benefits, resulting in approximately 21% lower total cost for the stages under evaluation and about 53% reduction in execution time per module. The findings indicate the potential economic advantages of digitalized prefabrication technologies for façade retrofit applications under the investigated assumptions and industrial-scale production conditions, while supporting the broader adoption of automated manufacturing processes in the construction industry and contributing to more sustainable building renovation practices.

Keywords: Life Cycle Cost · Prefabricated Façade · Digitalization · Building Retrofit · Automated Construction · Manufacturing Process

1 Introduction

The building sector plays a key role in European decarbonization strategies, making the renovation of existing buildings essential for achieving climate neutrality. In this context, the Renovation Wave strategy aims to at least double renovation rates by 2030

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 1511–1519, 2026.
https://doi.org/10.1007/978-3-032-34930-9_176

while promoting more efficient and scalable renovation approaches, which require both significant investment and a faster renovation process [1]. Prefabricated façade retrofit systems have been proposed as a promising solution to accelerate renovation processes while improving construction quality and reducing on-site disruption [2]. At the same time, the growing adoption of digital technologies, robotics, and automated production processes reflects the broader transition toward Industry 4.0 in the construction sector, where digitalization has the potential to enhance productivity and process efficiency [3]. Despite these developments, the economic implications of digitalized construction processes remain poorly quantified. Existing Life Cycle Cost (LCC) tools generally focus on conventional cost categories such as materials and labor and are not designed to capture additional cost drivers associated with digitalization, including digital infrastructure, automated production systems, and advanced surveying methods. As a result, the potential economic benefits of fully automated prefabrication workflows across the façade retrofit supply chain are still not well understood. This study aims to address this gap by assessing the economic impact of digitalization in prefabricated façade retrofit modules through a comparative LCC analysis. The analysis compares a Semi-Automated prefabrication workflow with a fully automated workflow and supports the development of an LCC framework that can capture cost drivers associated with digitalized construction processes.

2 Literature Review

Off-site prefabricated façade retrofit systems have been widely studied as an effective approach for accelerating building envelope renovation by improving productivity, quality control, and safety in construction while reducing renovation time and on-site disruption compared with conventional renovation processes [2, 4]. Recent studies highlight the growing role of digital technologies in supporting prefabricated renovation processes. Digital surveying techniques such as point-cloud acquisition allow accurate capture and processing of existing building geometry, which is important for designing prefabricated façade modules that fit existing structures [2]. These techniques support digital workflows while reducing both process time and costs [5]. In addition, Building Information Modelling (BIM) supports the integration of design, manufacturing, and construction processes by enabling digital information exchange, production planning, and coordination across project stages [6]. Scan-to-BIM workflows allow the automatic generation of digital building models from point-cloud data, improving modelling efficiency and reducing errors compared with traditional manual modelling processes [7]. In prefabricated construction, production lines typically include automated stations such as cutting, framing, insulation installation, and assembly. Automation technologies such as CNC machines and robotic systems can improve accuracy, productivity, and consistency [4, 8]. Robotic façade installation systems can significantly improve installation productivity, reduce labor demand and installation time compared with conventional crane-based installation methods [9]. Although previous studies have mainly focused on technological developments and productivity improvements in digitalized prefabrication processes, limited research has evaluated their economic implications across the full prefabricated façade supply chain. In particular, the life-cycle economic impacts

of transitioning from conventional semi-automated workflows to fully digitalized and automated prefabrication processes remain poorly quantified.

3 Methodology

This study explores the economic impact of digitalization on prefabricated façade modules used in building retrofit projects. The analysis combines a comparative LCC assessment with a process time evaluation. Two supply chain configurations are compared. The first is a Semi-Automated prefabrication Workflow (SAW), which relies heavily on manual operations. The second is a Fully Automated Workflow (FAW) that applies a higher degree of automation across surveying, design, manufacturing, and on-site installation stages. Figure 1 shows the methodological framework adopted in this study.

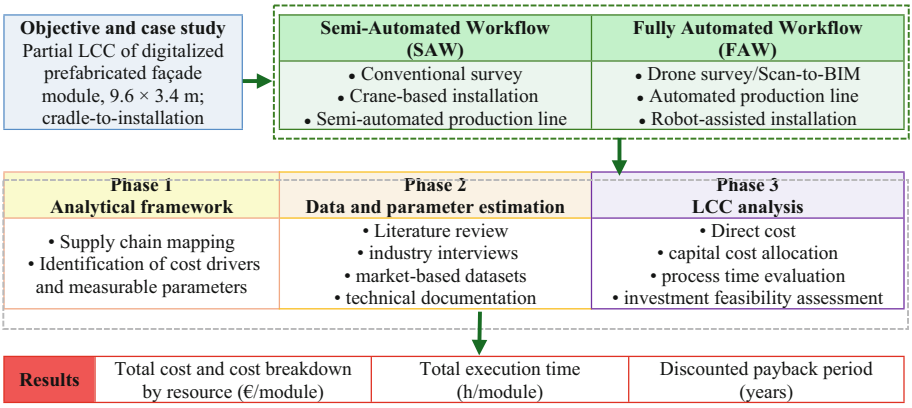

Fig. 1. Methodological framework for comparative LCC assessment of SAW and FAW

3.1 Research Design and Analytical Framework

The main digitalization-related cost drivers were converted into measurable parameters, including labor, waste, machinery investment, energy consumption, and execution time. The case study considers a prefabricated opaque timber façade module for building retrofit applications with dimensions of 9.6 m × 3.4 m, based on a façade element developed within the INFINITE retrofit project [10]. The economic assessment uses a cradle-to-installation system boundary. This includes façade surveying of the existing building, layout generation and 3D modelling, material acquisition, manufacturing of the façade module, and on-site installation. All costs were based on this Functional Unit (FU) for consistent comparison between the two supply chains. Although the assessment does not include operational or end-of-life stages, the study adopts a partial LCC assessment in accordance with ISO 15686-5 to evaluate the economic implications of digitalization across the defined system boundary. The selected cradle-to-installation

scope was considered appropriate because the investigated digital technologies primarily affect surveying, design, manufacturing, and installation processes rather than the operational performance of the façade system. The comparison focuses on evaluating the influence of digitalization within the defined prefabrication process.

3.2 Data Collection and Parameter Estimation

Input data for the economic assessment were obtained from multiple sources to support the robustness and reliability of the cost model. Most parameters were derived from scientific literature, market-based construction cost databases, technical documentation, and national statistical sources, providing information on labor costs, waste generation ratios, installation productivity, economic indicators, and energy prices. In addition, structured interviews with key industrial stakeholders, including façade system designers and automated production technology suppliers, were conducted to gather data on investment costs, operational characteristics of automated production lines, and modelling time requirements. Because publicly available industrial data for automated façade systems remain limited, interview-based estimates were primarily used for automation-related parameters and cross-checked against literature sources and technical documentation to improve robustness. Although the number of interviewees was limited, they represented key actors directly involved in automated façade production and technology supply. The collected information supported the quantification of process times, labor requirements, energy consumption, and investment costs for both workflows, forming the basis for the calculation of resource-related costs.

Table 1 summarizes the key parameters used in the cost model together with their corresponding data sources.

Table 1. Input data and assumptions for LCC calculation

Parameters	SAW	FAW	Source
Geographical context	Italy		Assumption
Real discount rate (%)	0.4	0.4	[11, 12]
Data acquisition (h/m^2)	0.15	0.038	[13]
Data processing (h/m^2)	0.47	0.073	[13]
3D modeling (h/m^2)	0.07	0.35	Industry, [13]
Survey tool / life (years)	Total station, 12	UAV system, 6	[14, 15]
Material costs	Common material cost for both		[16]
Waste generation ratio (%)	6%	3%	[17]
Production line investment (€)	6,500,000	11,000,000	Industry
Production line maintenance (%)	10%	10%	Industry
Production workers (Number)	25	7	Industry
Energy use (MWh/year)	350	441	Industry
Equipment life (years)	25	25	Industry

(*continued*)

Installation maintenance (%)	Not owned	10%	[9]
Installation workers (Number)	6	4	[9]
Installation time (h/m^2)	0.5	0.22	[9]

3.3 Life Cycle Cost Calculation Approach

The economic assessment was carried out using the LCC approach in accordance with ISO 15686-5. Costs were classified into two main categories: direct and allocated costs. Direct costs, such as material and labor costs, can be calculated directly for the defined FU. Allocated costs correspond to capital-intensive resources shared across multiple production cycles, such as production machinery, robotic systems, and digital surveying equipment. The allocation of capital costs was calculated assuming an annual production capacity of 3215 façade modules for both SAW and FAW configurations. This assumption was derived from industry interviews and manufacturing line productivity data. The assumed production capacity reflects a large-scale industrial retrofit scenario with continuous operation of the automated production line. Since capital-intensive automated systems strongly depend on production volume, the economic performance of the defined configurations may vary under different production scales. As capital assets are used across multiple years and production cycles, investment costs were annualized using the Capital Recovery Factor (CRF) [18] and distributed across the annual production capacity. In addition to the cost calculation per FU, an investment feasibility analysis was conducted to evaluate the economic viability of investing in an automated production line. The analysis compares the additional capital investment required for the fully automated production line with the operational cost differences between the automated and semi-automated production lines. The additional investment associated with the automated production system was considered as an initial cash outflow in year zero. Annual cash flows were calculated by considering operational cost differences, including labor cost savings as well as additional maintenance and energy costs. These annual cash flows were discounted using the real discount rate assumed in the study and accumulated over the analysis period. The discounted payback period was defined as the year in which the cumulative discounted cash flow becomes positive. The analysis was carried out over a 25-year period corresponding to the assumed service life of the production equipment. To conduct the LCC analysis, an existing tool [19] was used and adapted to reflect the characteristics of digitalized prefabrication processes. The framework was expanded to include resources associated with digital technologies and automated manufacturing, such as robotic production equipment, digital surveying tools, and related energy consumption, in addition to conventional resources like materials, labor, and transportation. This adaptation allows a more comprehensive representation of digitalized prefabrication supply chains and their economic implications across life

cycle stages. The cost modelling follows an activity-based approach, where the prefabricated façade supply chain is divided into individual activities. For each activity, the required resources are identified and quantified, and costs are calculated based on their consumption. This structured classification enables a consistent evaluation of cost drivers in both SAW and FAW.

4 Results

The analysis compared two supply chain configurations defined in the methodology: a SAW and a FAW. Results are expressed per FU of one prefabricated façade module. The FAW results in a lower overall cost per module compared with the SAW. The total cost decreases from €8651 per module in the SAW to €6833 per module in FAW, corresponding to an overall cost reduction of approximately 21%. Figure 2 highlights the main cost drivers across the analyzed stages. Material acquisition represents the largest share of total costs in both scenarios, accounting for approximately 67.8% in FAW and 53.7% in SAW. In the manufacturing stage, equipment and robotic systems represent a larger share of costs in the FAW, while in the SAW labor costs dominate the manufacturing stage. A similar pattern is observed in the installation stage, where labor represents a significantly higher share of costs in SAW, whereas FAW shows a reduced labor contribution due to the use of automated installation technologies. SAW requires more manual surveying effort, whereas FAW requires more detailed 3D modelling for automated production.

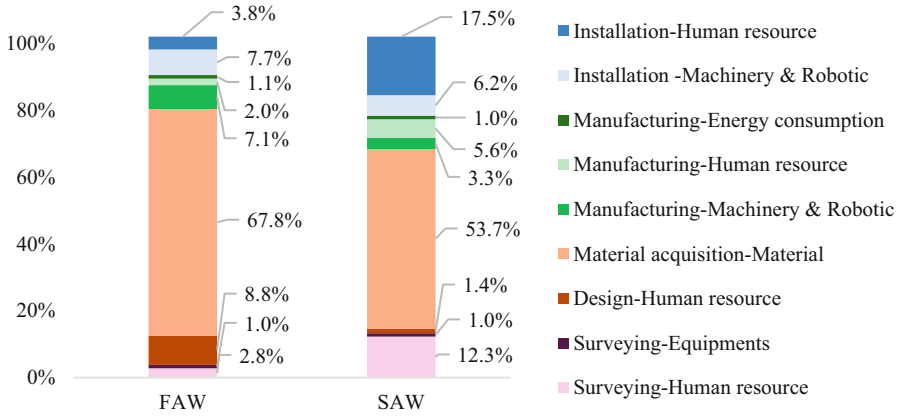

Fig. 2. Cost breakdown for FAW and SAW (percentage)

The total execution time was evaluated, and the results show a decrease from 17.5 h in SAW to 8.2 h in FAW, mainly due to automation in the installation stage. Investment feasibility analysis was conducted, and the results indicate that the additional capital investment required for the automated production line can be recovered within approximately 7.5 years, assuming a 25-year service life of the production equipment.

5 Discussion and Conclusions

The results suggest that automation can significantly improve both the economic performance and process efficiency of prefabricated façade production. The lower costs observed in the FAW mainly result from changes in the supply chain cost structure. In the SAW, labor-intensive activities account for a large share of total costs, particularly during manufacturing and installation. In contrast, the FAW shifts costs toward machinery and automated systems while reducing labor requirements and improving process efficiency. Automated installation technologies reduce the number of workers required and shorten installation time, contributing to the significant time and cost reductions observed in the FAW scenario. The results also highlight the importance of production scale for the economic viability of automation. Since automated systems require high capital investment, their economic advantage increases when production volumes are sufficient to distribute investment costs across multiple façade modules. Lower production volumes would weaken this advantage. Therefore, digitalized prefabrication appears economically promising, particularly for large-scale retrofit projects under the assumptions considered in this study. Beyond economic efficiency, digitalized prefabrication may also support broader sustainability objectives in building retrofit practice. Improved production accuracy and reduced material waste can contribute to more resource-efficient construction processes, while faster and more industrialized renovation workflows may facilitate the large-scale implementation of energy retrofit strategies aligned with circular and low-carbon construction goals. Among the investigated parameters, labor costs, annual production volume, investment costs of automated systems, and maintenance costs have the strongest influence on the economic outcomes. In particular, the reported cost reduction and discounted payback period are sensitive to assumptions regarding industrial-scale production capacity and labor intensity. Since labor is one of the most cost-intensive resources, economic outcomes may vary across different geographical contexts and wage levels. The findings should be interpreted within the context of the selected case study and assumptions adopted in the analysis. The assessment focused on the production and installation stages of the prefabricated façade supply chain rather than a complete building life cycle evaluation, since the study specifically investigates the economic implications of digitalization within surveying, design, manufacturing, and installation processes. In addition, several parameters related to automated production systems were estimated through structured interviews with industry stakeholders due to the limited availability of publicly accessible industrial data. Consequently, the reported cost reduction and payback period may vary under different façade typologies, labor markets, and production scales. Future research should investigate multiple case studies, regional conditions, and sensitivity analyses to further evaluate the robustness and generalizability of the results.

Abstract. Over the past decade, the scientific community has increasingly recognized reuse as one of the most promising strategies for transforming the building sector in line with circularity and sustainability principles. Reclaimed structural steel has emerged as a valuable solution with the potential to transform the decarbonization pathway of the construction industry. Despite the limited maturity of current research on automated design tools under conditions of limited material availability, major logistical challenges remain the primary obstacle. These include supply-chain constraints and the complex coordination among multiple stakeholders, which collectively reduce the attractiveness of transitioning from steel recycling to steel reuse. This study focuses on interdisciplinary logistics–technical dimensions in structural steel reuse, to accelerate adoption and overcome persistent systemic inertia in a contested landscape. This approach underscores the necessity of establishing a new supply-chain model in which additional actors are introduced to address critical questions: What is the quantity of steel that can realistically be recovered from deconstructed buildings? How can the appropriate quantity of steel be made available upon request while coordinating diverse—and at times conflicting—interests, such as client and designer demands (technical) versus the supply capacities of demolition and stockholding contractors (logistical)?

Keywords: Reusing Steel · Supply Chain · Embodied Carbon · Artificial Intelligence

1 Introduction

The construction sector is the largest consumer of raw materials. It accounts for 50% of the total material use in Europe [1] alone and 25%–40% of the total CO2 emissions globally [2]. The building construction drives current energy consumption and greenhouse gas (GHG) emissions, representing 36% of total energy use and 37% of the global

https://doi.org/10.1007/978-3-032-34930-9_177

GHG emissions, respectively [3]. Approximately, 10% of these emissions are carbon emissions caused by the production of materials in buildings [4]: The average embodied carbon emissions associated with new buildings are approximately 600 $kgCO_2eq/m^2$, with nearly 70% occurring upfront during the building production and construction stages. Besides, construction activities produce the highest amount of waste among all other sectors [4]. As a result, the construction industry is under more scrutiny than ever to reduce resource consumption, construction, and demolition-related waste while encouraging reusing practices unquestionably represent an efficient path to promote Circular Economy [5]. At the heart of a circular economy lies the fundamental principles of reducing waste generation and maximising the service-life of products and materials [6]. Thus, there is a unique incentive to use existing materials in the construction industry by reusing structurally functional parts (re-using) or the use of raw materials as components to produce new structural elements (recycling). Based on the waste hierarchies, reuse is vastly superior to recycling. Specifically, the environmental benefits of reusing structural steelwork reside in the low carbon intensity of 50 $kgCO_2$ eq./t compared with a sector average of 1740 $kgCO_2$ eq./t for new steelwork [7]. As a consequence, adopting reclaimed steel leads to a significant reduction in virgin material providing huge benefits in terms of sustainability aspect. Despite this, most construction and demolition waste recovery occurs through recycling rather than reuse. Steel is a circular material, with about 85% recycled globally at the end of its first life. In the EU, approximately 90% of scrap steel is recycled but only 5% reused, highlighting a significant gap. For example, in the UK, a leader in decarbonisation, steel reuse remains limited, representing only 8–11% of steel recovered from demolition [8].

This study aims to systematically identify, classify, and assess barriers to steel reuse to determine critical system bottlenecks. It also proposes a prioritization framework to distinguish barriers that significantly constrain market upscaling from those addressable in later phases. This classification supports the development of an enhanced supply chain configuration that mitigates key bottlenecks through the introduction of a dedicated Service Centre coordinating entity to facilitate complex information exchange among stakeholders.

2 Distinguishing the Technical and Logistical Dimensions of Steel Reusing

Based on the literature, researchers and steel associations consistently identify six major barriers to reuse [9]: (1–2) social and psychological factors related to limited reuse markets and perceived risks in specifying reused materials; (3–4) timing and cost issues associated with deconstruction and transportation logistics; (5) certification procedures (e.g., Material Passports); and (6) technical challenges during design and construction. Recent stakeholder surveys highlight supply chain dynamics and reused steel availability as the most critical barriers [10, 11]. Accordingly, a clear prioritization strategy is required, beginning with grouping these barriers into two main classes: (1) technical and (2) logistical dimensions of the steel reuse challenge.

2.1 The Technical Dimension

The technical dimension mainly accounts for all the activities occurring during the design and construction phases as well as all the certification procedures. The technical dimension of the steel reusing challenge can be summarized in the following key points.

Limited stock availability requires resolving complex allocation mathematical problems within stock-constrained design frameworks. In recent years, researchers have developed computational tools integrating cutting-stock and assignment algorithms into early-stage design optimization to manage this complexity. These methods have been applied to various structural typologies, including trussed frames, gridshells, and diagrid systems, often relying on optimization, form-finding, or AI-based frameworks using assumed or randomly generated stock inventories. However, real-world implementation remains limited, particularly in balancing computational efficiency with structural analysis accuracy. Furthermore, limited research has integrated cradle-to-cradle life-cycle assessment (LCA) methods accounting for global warming potential (GWP) from raw steel production across building life-cycle stages A1–D. Many tools also show strong performance for specific typologies but limited generalizability across structural systems. Design flexibility depends on available salvage components, while higher reuse rates may require trade-offs in structural efficiency, increasing weight and architectural constraints. Table 1 summarizes recent stock-constrained optimization tools.

Deconstruction processes, constructability considerations, and erection feasibility associated with the reuse of structural components remain among the most significant technical challenges in steel reuse practices. Time constraints frequently render deconstruction less economically attractive than conventional demolition methods. Furthermore, the majority of existing steel buildings are characterized by joints that are either inaccessible or irreversible, thereby complicating design-for-deconstruction strategies. Evidence from successful case studies highlights the critical role of systematic numbering and labeling of reusable components in ensuring project efficiency and overall success. These challenges prompt critical reflection on the importance of promoting design-for-deconstruction practices in the development of future building designs.

Material/product passport and **reusing marketplace digitalization** are well-known as fundamental requirements for steel reusing. As highlighted by Costa in [12], Materials Passports give every material an identity. Each passport is a digital record that consolidates essential information about the material in a centralized, accessible location. By tracking a material's chain of custody, materials passports reduce waste, support better design, and improve reuse rate. They also promote data transparency and traceability, document circularity metrics, measure carbon expenditure and inform decision-making processes. This comprehensive database has been integrated with information on the damage levels of reusable components.

Certification protocols for reusable steel components require time-intensive testing to verify their structural integrity. Factors such as corrosion and accumulated mechanical stress may significantly alter material properties, complicating reliable structural assessment. Current research is increasingly integrating advanced digital technologies and image-based detection methods to automate portions of pre-demolition audits and reuse assessment procedures, thereby reducing costs and improving reliability. AI-based

Table 1. State of the Art of the Stock-Constrained Design Optimisation Tools

Reference	Year	Design Variables	Algorithm	AI	LCA	Case Study	Carbon Savings	Assign. Problem	CS Problem
[13]	2019	Geometry Topology	MILP/NLP	no	yes	Truss	56–63%	yes	no
[14]	2020	Size	MILP/NLP	no	yes	2D frame	35%	yes	yes
[15]	2024	Size	GA	no	yes	Truss	36–63%	no	yes

reusability prediction models can be trained on structural images to support rapid preliminary condition assessments, significantly reducing the time required for conventional non-destructive testing**.**

There are currently **no standardized design rules** specifically applicable to the reuse of reclaimed steel components on a global scale. Although certification and execution protocols, as well as guidelines for the assessment of existing structures, have been developed, these typically vary from country to country, thereby limiting the scalability of the reuse market.

2.2 The Logistic Dimension

The logistic dimension of the steel reusing challenge mainly refers to the complex interaction of activities between the different actors of the supply chain. Below, we summarize the main issues which refer to logistic aspects.

Optimizing the alignment between demand and supply timing within reuse supply chain operations is essential for ensuring efficient material recovery and deployment. Unlike newly produced steel, the availability of reusable steel is highly dependent on the careful, damage-free demolition and dismantling of existing structures, with the majority of reusable steel currently originating from demolition activities. Consequently, timely access to reliable information regarding available steel stock—whether from single or multiple sources, depending on project requirements—is critical for supporting design decision-making within client-commissioned projects. In particular, design teams must be able to assess the feasibility of integrating reused steel components during the early stages of project development. This process becomes significantly more complex when the required stock is not readily available in storage but instead depends on the disassembly of donor buildings, thereby introducing additional uncertainties related to scheduling, logistics, and material availability.

Availability of comprehensive market data plays a crucial role in improving supply chain efficiency. A systematic mapping of the quantity of reusable steel available on the market—at regional, national, or continental scales—would support more informed sourcing decisions. Such mapping could contribute to reducing transportation costs and optimizing efficiency across the supply chain, including sourcing, fabrication, and refinement processes associated with reused components. Activities of this nature should be undertaken by governmental bodies or accredited third-party entities operating at local or national levels, with the objective of collecting and disseminating reliable information regarding reusable steel stock that is ready for deployment. An example of such an initiative is provided by the Efestos Hub, which represents one of the first organizations to develop a detailed mapping (called e-maps) of potential reusable steel stock and donor buildings within the United Kingdom. Based on preliminary estimates, 1,073 buildings have been mapped, corresponding to a potential reusable steel stock of approximately 1.9 Mt. and an estimated CO_2 savings of 2 Mkg.

Institutional coordination mechanisms are necessary to facilitate collaboration among the various stakeholders involved. Certified entities capable of acting as coordinating bodies could support communication and alignment among all actors in the process. In particular, these entities should effectively harmonize the requirements of clients (e.g., designers and construction companies) with those of stockists and fabricators. This entity should support the stockholder or the client in the early review of the range of reusable steel components available, and suggest fabricators/steel erectors potentially interested. By facilitating this alignment, it becomes possible to identify the most suitable stock for specific design and construction needs, while simultaneously reducing delays and improving overall project delivery timelines.

3 A New Supply Chain: A Service Centre-Like Coordination Entity

Following the identification of barriers to steel reuse, it is essential to prioritize those requiring immediate intervention. Beyond the technical challenges outlined in Sect. 2.1, the main limitation to reuse market development lies in uncertainties affecting the current supply chain. While advances in design optimization tools, certification, and product traceability represent important enabling measures, they remain insufficient to address the complex logistical challenges associated with effective stakeholder communication and coordination. For clarity, reference is made to consolidated reuse supply chain models reported in Fig. 1. Among the available configurations, the model adopted here assumes that ownership of reclaimed steel is retained by the stockholder, who purchases materials from demolition contractors and subsequently sells them on the open market.

Within this supply chain configuration, the stockholder is responsible for receiving reclaimed steel from demolition contractors, supplying materials to steel contractors and, when required, directly to erectors, while coordinating with the main contractor. The main contractor manages on-site erection and procures stock to meet designer and client requirements. The accumulation of these responsibilities often leads to operational overload, where delays in communication or coordination can result in significant additional costs. In other words, structural steel reuse depends not solely on improved design

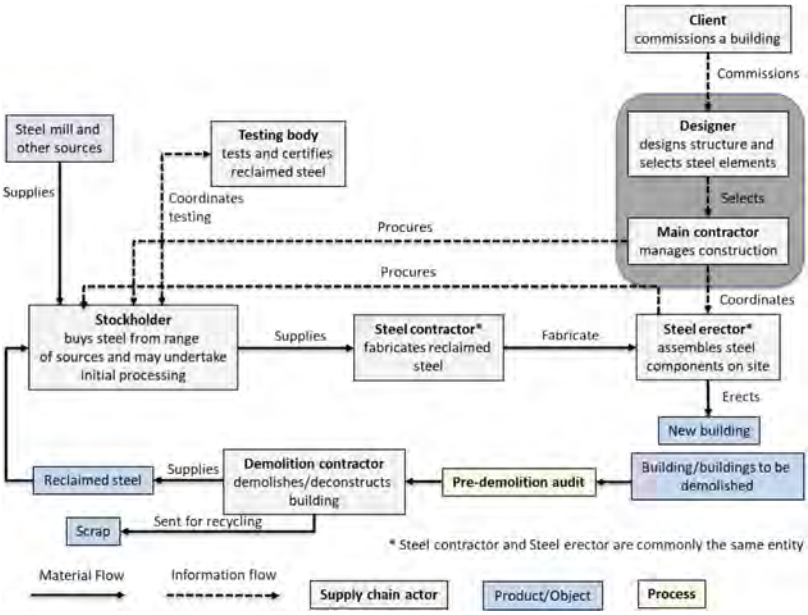

Fig. 1. Current Stockholders-driven supply chain of reusing steel.

tools or advanced rapid damage-detection technologies, but critically on a coordinated, information-driven supply chain centred on a dedicated logistics intermediary.

Figure 2 presents a Service centre–driven supply chain model that centralises coordination and enables iterative, data-driven matching of supply and demand, addressing the key logistical constraints limiting structural steel reuse.

In the proposed model, the introduction of an additional actor—referred to as the Autonomous Agentic Service Centre—plays a central role in coordinating reuse supply chain operations. This entity functions as a hub operating at regional, national, or continental scales, with the objective of mapping, in near real time, the availability of reusable steel and organizing marketplace information within a dynamic database.

An agentic AI platform would process real-time data from steel contractors and stockholders, assigning targeted marketplace search tasks to virtual AI agents to identify the most suitable stock for a given project. The Agentic Service Center platform would also generate a Digital Material Passport containing information on stock provenance and the economic and sustainability costs associated with certification, transportation, and fabrication. Each AI agent would be trained to optimize technical, sustainability, and economic objectives according to client-defined preferences and priorities. The database is continuously updated with data provided by stockholders and steel contractors, who remain responsible for the storage, certification, and fabrication of reclaimed components. The Call Centre can be activated by designers or main contractors during early design stages to identify suitable stock that meets project requirements and client expectations. This activation process is inherently iterative (see Fig. 2), enabling continuous

evaluation of alternative stock options to accommodate design revisions, architectural modifications, and site-specific constraints until an acceptable solution is achieved.

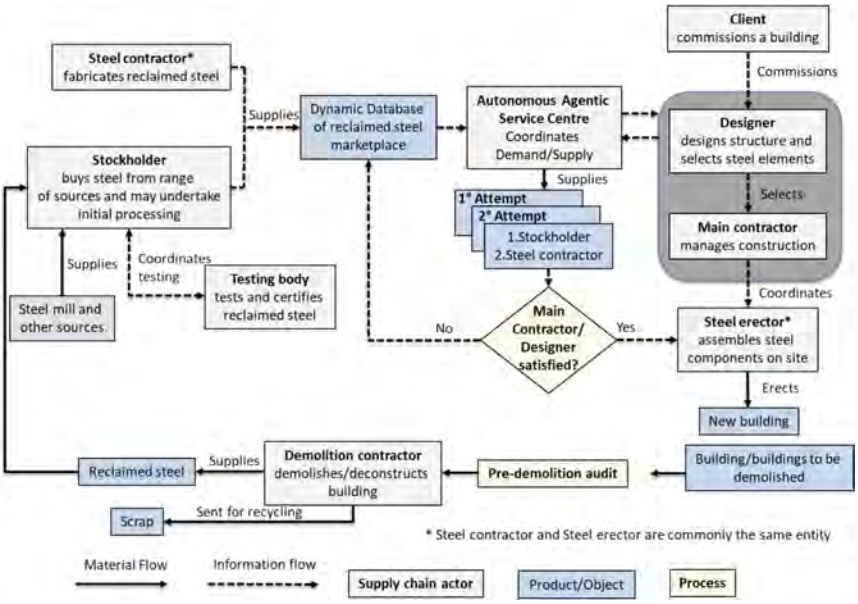

Fig. 2. Agentic Service Centre–driven model of the reusing steel supply chain

4 Conclusions

In this study, the authors provide a comprehensive analysis of the current barriers to steel reuse, with the objective of improving the understanding of the most critical challenges hindering large-scale implementation. Among the identified barriers, the logistical dimension emerges as one of the principal bottlenecks within the reuse process, highlighting the need for an intermediary entity capable of coordinating the complex flow of information among the various stakeholders involved. To address this limitation, the authors propose a novel supply chain model as an alternative to conventional, well-established frameworks. The proposed model introduces a new actor—referred to as Autonomous Agentic Service Centre Coordination Entity—responsible for collecting and analyzing information from the reuse marketplace, facilitating interactions among stakeholders, and accelerating the responsiveness of supply availability to meet design and construction requirements.

Abstract. The construction industry is among the largest sectors that generate one-third of the global greenhouse gas emissions. Therefore, it is essential to integrate a circular economy approach to drive transformation in the construction sector. The introduction of Digital Product Passports (DPPs) can accelerate this transformation by offering a digital framework that integrates material intelligence, demountable design, and systematically embedding environmental performance assessments of building materials from procurement, through construction and asset management to facilitate future re-use. A DPP is an electronic platform that registers, processes, and shares data for products at material, component, product, system, and building levels to enhance product traceability and supply chain transparency. The implementation of DPPs in the construction industry will improve resource circularity, reduce emissions, and strengthen supply chain governance. It forms a key regulatory element of the EU's Circular Economy Action Plan, mandating the electrical, textile, packaging, and construction industries to provide implementation milestones by 2026. This study aims to identify the barriers and potential drivers to implementing DPPs by conducting a focus group and semi-structured interviews with participants from different functions within a large Social Housing organisation which is at the early stages of their exploration of circular construction and the adoption of DPPs. The initial findings suggest that there are significant challenges, especially political and economic barriers. However, significant tangible benefits emerged in terms of procurement and financial leverage for funding. The findings from this paper could offer fresh perspectives for organisations ready to embark on a path towards Circular Construction.

1 Introduction

1.1 DPP in Circular Construction

The construction industry plays a significant role in global resource use and carbon emissions. It accounts for about 40% of energy use and generates nearly one-third of greenhouse gas emissions [1]. Improving resource efficiency and reducing environmental impacts throughout the building lifecycle are critical for the sector's transition to a circular economy. In this context, Digital Product Passports (DPPs) have emerged as key digital tools supporting circular construction supply chains. By recording and integrating product lifecycle information, DPPs enable the traceability of building materials from production to end-of-life. Existing research recognises that DPPs are more than information tool ets; they serve as digital infrastructure supporting the circular economy. They link product lifecycle information, supply chain participants, and circular reuse practices [2]. By integrating material properties, environmental data, and usage information, DPPs enhance transparency and stakeholder collaboration and provide data-driven support for decision-making in the design, construction, and demolition phases.

1.2 Drivers of DPP

Existing research indicates that the adoption of DPP within the construction supply chain is driven by multiple factors, which can be broadly categorised into three dimensions: policy drivers, technological advancements, and socioeconomic incentives. Firstly, policy frameworks serve as a crucial catalyst for DPP development. In recent years, the European Union has introduced policies such as the European Green Deal and the Circular Economy Action Plan (CEAP) to encourage enterprises to enhance the transparency of product environmental information and disclose lifecycle data [3, 4]. These policies aim to reduce greenwashing and strengthen environmental accountability in supply chains by establishing mechanisms for product information disclosure and traceability [5, 6]. Furthermore, policy financial instruments—such as subsidies and sustainability-linked loans—can facilitate DPP system implementation by mitigating enterprises' investment risks in digital infrastructure [7]. Secondly, the digitalisation of the construction industry and advancements in material technology create essential conditions for implementing DPP. With the widespread adoption of Building Information Modeling (BIM), the Internet of Things (IoT), and data management systems in construction, the collection and sharing of building lifecycle data have become increasingly feasible [8, 9]. These digital capabilities enable enterprises to more effectively record and manage product information, thereby providing the technological foundation for DPP applications. In addition, the enhanced performance of recycled materials has significantly broadened their scope of application in construction, improving thermal insulation, soundproofing, environmental sustainability, and cost-effectiveness [10]. Comparative analyses between new and traditional materials, along with feasibility studies, have driven demand for DPP. Finally, socioeconomic factors also drive corporate adoption of DPP systems. Research indicates that sustainable construction typically reduces operational energy consumption and lowers waste disposal costs [11]. Concurrently, growing demands from investors, customers, and regulators for transparency in environmental performance are driving

companies to adopt digital management systems that enhance supply chain visibility [12].

1.3 Barriers to DPP

Despite the significant potential of DPPs to drive circular transformation in the construction sector, their implementation faces multifaceted barriers encompassing policy, technological, and market or societal challenges. Firstly, at the policy level, fragmented regulatory frameworks may increase the complexity of implementing DPP for businesses. Existing environmental regulations, building codes, and safety standards often lack coordination, resulting in higher costs for businesses that must comply with multiple regulatory requirements [13, 14]. At the same time, without sufficient policy funding, small and medium-sized enterprises (SMEs) may struggle to bear the investment required for digital system development [15]. Secondly, technological and data challenges present significant barriers. Many construction projects lack comprehensive lifecycle data, particularly during the material reuse and end-of-life management phases [16]. The absence of unified data standards across different digital platforms further complicates system integration [17]. Furthermore, existing digital tools often prioritise environmental metrics while offering limited capacity to assess economic performance, making it difficult for businesses to comprehensively evaluate the financial viability of circular strategies [18]. Finally, market and societal factors also constrain the adoption of DPP. Implementing DPP systems typically requires significant upfront investment, including certification, testing, and the development of digital infrastructure [12]. At the same time, public awareness of circular building concepts remains limited, and consumer interest in sustainable housing does not necessarily translate into actual market demand, with conflicting perceptions among different consumer segments [19]. Furthermore, the highly fragmented supply chain structure within the construction industry complicates information sharing and collaborative management among diverse stakeholders [20].

1.4 An Exploratory Study of Social Housing in Scotland

The net-zero agenda is widely recognised. However, it is imperative to adopt circular economy principles, wherein buildings are conceived to be assembled, utilised, disassembled, and repurposed as necessary. This approach not only aligns with the net-zero agenda but also prioritises waste reduction in building design. This research study goes 'beyond' net zero by addressing carbon reduction through a circular economy approach, which will not only impact the built environment but will also relate to biodiversity, human and ecosystem health to ensure and maintain a just society and flourishing ecological systems across Scotland. The construction sector has been identified as one of eight sectors with the highest circularity potential. The role of social housing providers in Scotland is vital to a just transition that ensures everyone can afford the energy they need to live comfortably, which requires a systems view that incorporates a circular approach. In order for this to be realised, the development of a circular supply chain at the city level will need to be examined. Moreover, digitalisation and data management can support better tracking and management of materials, thereby improving decision-making. Through the examination of solutions such as the DPP, techniques such as cost-benefit

analysis could be used to establish evidence that will enable positive change. The aim of this research study is to contribute towards a DPP-enabled circular supply chain for social housing by identifying the drivers and barriers to circularity and providing recommendations for transitioning towards DPP-enabled circular supply chains. While existing research increasingly explores the potential of DPP within circular supply chains, empirical application studies within the construction sector remain limited, particularly in the social housing domain. Compared with commercial buildings, social housing projects typically require balancing sustainability objectives with housing affordability while navigating multiple factors, including long-term asset management, public policy regulations, and technology implementation costs. Therefore, understanding the implementation conditions and potential impacts of DPP within social housing supply chains is crucial for advancing circular economy practices in the construction industry.

2 Methods and Methodology

This study employed a mixed-methods approach to explore the potential and identify what needs to be done to build a digital product passport (DPP)-enabled circular supply chain, focusing on social housing in Scotland. A systematic review was conducted to map the current state of research, identify key drivers, and categorise the types of barriers to implementing DPP-type circular approaches in the construction sector. The literature review was conducted using Scopus and Web of Science using keywords such as DPP, circular supply chain, built environment, and drivers and barriers. A total of 176 articles were screened based on titles, abstracts, and keywords, resulting in 92 articles included in the review. The literature review provided a foundation for identifying and categorising the drivers and barriers to DPP implementation. This research study primarily focused on qualitative methods. Qualitative and semi-quantitative methods were employed to obtain in-depth insights and structured perceptions from stakeholders. This methodology was chosen to understand the potential and barriers to DPP implementation across organisational roles. The participants were purposively selected from different roles and departments to ensure the representation of key functional areas within the organisation. This research study included one focus group and semi-structured personal interviews from procurement, new build, and finance departments to understand both role-specific and general perceptions of the key drivers and barriers of DPP.

3 Data Collection

3.1 Focus Group

A focus group was conducted with 8 stakeholders who are currently involved in delivering their Sustainability Strategy and who could share their expertise to explore the potential of DPP to enable a circular supply chain. The stakeholders involved in the focus group came from a variety of roles, including Procurement Manager, Contract Management System Coordinator, Finance Manager, Sustainability Officer, Business Improvement Coordinator, Development Manager, Demolition Officer, and Group Investment Lead, among others. The focus group was held in person and lasted around 2 h. The session

was audio-recorded to ensure data collection and subsequent analysis. The focus group began with a short introductory presentation outlining the concept of DPP and its potential role in enabling circular supply chains in the built environment, drawing on past case studies. Each barrier was sub-categorised into 14 sub-barriers (B1-B14), as shown in Table 1, identified from the systematic review, and discussed to capture the group's perceptions of the importance and impact of each to implementation.

Table 1. Barriers and sub-barriers to DPP implementation, used in the focus group.

Barrier Category	Sub-Barriers
Policy and Incentive Barriers	B1: Absence of an Integrated Regulatory Framework for Circular Building Design and Product Governance
	B2: Regulatory Inconsistency and Conflicting Standards
	B3: Insufficient Economic Stimulus Measures
Data and Technology Barriers	B4: Incomplete Life Cycle Data and Traceability Gaps
	B5: Data Lacks Standardisation and Format Consistency
	B6: Data Inaccuracy
	B7: BIM/LCA Tools Do Not Fully Work Together
	B8: Limited Decision-Support and Integration of Economic Factors in the Related Tools
Market and Society Barriers	B9: Inadequate Corporate Financial Evaluation Frameworks
	B10: Long Payback Periods and Uncertain Added Value of Digital Information Platforms
	B11: High Costs of Green Transformation and Certification
	B12: Poor Knowledge Sharing and Ad-hoc Project Basis
	B13: Lack of Cross-Entity Collaboration Mechanisms
	B14: Conflict between Data Sharing and Privacy

3.2 Semi-Structured Personal Interviews

Semi-structured personal interviews were conducted with 3 key stakeholders from the procurement, new-build development, and finance departments. These roles were selected to capture department-specific perspectives on the benefits, feasibility, potential challenges, and operational implications of implementing DPP. These interviews were aimed at evaluating in-depth insights into participant's perspectives based on their roles in the organisation. The interviews were conducted while maintaining consistency across key discussion themes by using 8 common and 2 role-specific multiple-choice questions on the following. The interviews were conducted individually to allow participants to provide detailed responses and lasted approximately 30 min, with each interview audio-recorded with consent to ensure accurate data capture. The collected audio from interviews was later transcribed for further analysis.

4 Key Findings

The focus group discussion explored potential drivers and barriers to implementing DPP within the social housing supply chain. The key areas of discussion were the perceived benefits of DPP, policy and incentive barriers, data and technological barriers, and market and societal barriers. All participants agreed on the perceived benefits of implementing DPP in the construction industry and social housing, mainly increased availability and traceability of lifecycle information across different stages of construction and building development. They emphasised the direct benefits of DPP, including improved decision-making regarding material use, replacement of building parts, and maintenance efficiency. Furthermore, they placed importance on customer service, which is central to their organisation, and emphasised the direct, tangible benefits to tenants from DPP. One of the participants noted that "*Having clear information about the materials used in the building would improve future maintenance, and material traceability would help in making replacement decisions much easier and faster*".

Overall, participants emphasised that DPP has the potential to support circular economy practices, such as enabling the tracking and reuse of materials in refurbishment, further supporting sustainable construction practices.

Policy and regulatory barriers were identified as key influences for stakeholders regarding the implementation of DPP in the Scottish Social Housing sector. The participants shared a collective view on the need for a stronger, clearer policy direction for DPP adoption in the construction sector. The participants showed a concern regarding uncertainty in current legislation to support DPP implementation through statements like "*There is a requirement of stronger policy guidance before construction and social housing organisations are required to expand their investments in DPP-type initiatives*". Therefore, a strong policy backbone at the national level is required as a key driver of DPP implementation; otherwise, it is a significant barrier to its implementation. Data & technological barriers, such as incomplete lifecycle data, traceability gaps, and data standardisation gaps, were considered by the participants to be of considerable importance to DPP implementation. Whereas data inaccuracies, limited integration of BIM/LCA tools, and limited integration of economic factors in tools were considered to have medium to low impacts on DPP implementation. One of the participants highlighted the complexity of managing large volumes of material data by stating that "*The actual challenge is not just the collection of material data but ensuring that it is standardised for usage in wider systems and tools*". Market and society barriers were given the least importance among all barrier categories. However, one of the most important sub-barriers, given high importance, was supply chain fragmentation, which could significantly influence DPP implementation. The participants highlighted that contractors and suppliers may not have the capacity to meet the data needs of DPP. A participant stated that "*The supply chain needs to adapt significantly, and smaller suppliers may be unable to provide sufficient or good quality material data*".

The personal interviews with the stakeholder from the Procurement team emphasised policy and regulatory support as the backbone of the DPP implementation, stating that "*the approach feels very abstract because there needs to be legislation and policy-driven enforcement is likely necessary*". Further, they emphasised that there are inconsistent approaches among suppliers, which might create a significant barrier to meeting

DPP data requirements. The second interview with the stakeholder from the New Build team emphasised the need to integrate DPP into current digital construction systems for effective implementation, stating that "*DPP would need to integrate with the current systems; otherwise, it would just become another layer of data management*". The third interview with the stakeholder from the Finance team emphasised that the organisation would need robust business cases and evidence of investment returns from approaches such as DPP before committing to wider implementation.

5 Conclusions and Implications for DPP Implementation

This research study investigated the potential drivers and barriers to implementing DPP in social housing. The focus group and personal interview findings indicate that policy and regulation barriers will be the most significant challenges for DPP adoption in Scotland. At the same time, the results highlight significant benefits from DPP, including increased material traceability, supply chain transparency, and better asset management in social housing. Overall, the results indicate that the successful implementation of DPP requires strong legislation, data standardisation, and supply chain collaboration. The study warrants future research into practical implementation frameworks and data requirements for DPP adoption for social housing in Scotland.

Using AI Models in Life Cycle Inventory Analysis to Support Product Ecodesign Practices

Andréa Franco Pereira(✉), Arthur Filipe Neves Silva, and Leonardo Oliveira

Universidade Federal de Minas Gerais, Belo Horizonte, Brazil
andreafranco@ufmg.br

Abstract. Project support systems are constantly incorporating advances in information technology, and currently, Artificial Intelligence (AI) is part of the evolution of these systems. Concerning product design, the main applicable AI categories are machine learning, neural networks, computer-aided visualization systems, and natural language processing systems (such as Large Language Model - LLM). The objective of this study has been to understand how to use AI to assist the practice of ecodesign through Life Cycle Assessment (LCA), especially the Inventory Analysis phase. Studies are very recent on the application of AI into the LCA method. In this work, the proposed methodology has had an exploratory approach, seeking (1) to analyze the literature on studies incorporating AI into the LCA method; (2) to understand the AI categories applicable to Life Cycle Inventory Analysis (LCIA); (3) to identify AI models to propose their application; and (4) to conduct application testing. In attempts to integrate AI into LCA, it has been observed that the most frequently used categories have been machine learning and neural networks, especially for predicting environmental impacts, based on previous LCA studies. In addition to these, LLMs have proved to be interesting in assisting the arduous task of LCI. Thus, the aim of this study is the application of an LLM to a light shelf project, in which the LCA had already been performed by the team, in order to compare the performance of applying such LLM, with a view to analyzing its potential use in other projects. The application has proved promising, assisting designers in the practice of LCIA phase and for decision-making.

Keywords: Artificial Intelligence · AI · Life Cycle Assessment · LCA · Life Cycle Inventory Analysis · LCIA · Ecodesign · light shelf

1 Introduction

Research on design-aid systems and artificial intelligence (AI) is not new; some of it dates back over 60 years. All the technological advances arising from these areas have significantly impacted the way we develop projects. The personal computer, CAD (Computer Aided Design), NURBS (Non-Uniform Rational Basis Spline) surfaces, and BIM (Building Information Modeling) are some examples. However, the use of AI-supported systems has currently gained prominence.

L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 1538–1546, 2026.
https://doi.org/10.1007/978-3-032-34930-9_179

Design-aid systems have historically incorporated advances in information technology and algorithms focused on, for example, 3D modeling, dimensional databases, or CNC (Computer Numeric Control). Today, embedded AI modules are a definitive part of the evolution of these applications, which is dedicated to performing a single task in an extremely efficient and valid manner (Mielke, 2021).

Scott and Shaw (2023) define AI as a broad category of technologies whose goal is to automate tasks by mimicking human behavior. These adjacent technologies are experiencing rapid growth in applicability. The main categories, or drivers of AI development, include: a) machine learning, b) neural networks, c) computerized visualization systems, and d) natural language processing systems. Table 1 briefly describes these development categories.

Table 1. Artificial intelligence research typology (Gomes, Pereira, 2023).

Name	Description
Machine Learning (ML)	Training and algorithms to learn from data and make predictions or decisions without being programmed. Examples: recommendation algorithms, fraud detection, and image recognition.
Neural Networks	AI models inspired by the structure and function of the human brain, used in image recognition and natural language tasks.
Generative Adversarial Networks (GANs)	A subset of Neural Networks, where two networks compete against each other. Examples: generating images, creating deepfakes, and generative systems for AECD.
Deep Learning (DL)	A subset of Machine Learning, to process and analyze complex data. Examples: autonomous vehicles, language translation, among others.
Natural Language Processing (NLP)	AI model focused on understanding and generating human language. Examples: customer service chatbots, generative chatbots from text, virtual assistants Siri or Alexa, and language translation tools.
Speech Recognition	AI that converts spoken language into written text. Examples: voice assistants, voice controls, and speech-to-text transcription.
Computer Vision	AI model that understands and interprets visual information from images or videos. Examples: Facial recognition, object detection, and autonomous vehicle perception systems
Expert Systems	AI models that mimic human expertise in a specific domain, using knowledge and rules to make recommendations or decisions. Examples: Medical diagnostic systems, financial planning systems, AECD creation aids, and customer support chatbots.
Robotics AI	AI models used in robotics, enabling environmental recognition, decision-making, and the execution of physical tasks. Examples: Autonomous robots, drones, and industrial robotic assistants.

(*continued*)

Table 1. (*continued*)

Name	Description
Generative AI	AI models capable of generating text, images, or other media in response to requests in plain language.
Reinforcement Learning	AI models that train an agent to make decisions in an environment, with feedback in the form of rewards or penalties. Examples: Games, autonomous robots, and optimization algorithms.

Concerning product design, the main applicable AI categories are machine learning, neural networks, computer-aided visualization systems, and natural language processing systems (such as Large Language Modeling - LLM).

As part of product design, this study focuses on ecodesign, with the objective of understanding how to use AI to assist the practice of ecodesign through Life Cycle Assessment (LCA), especially the Inventory Analysis phase. The aim is the application of an AI model, such as LLM, to a light shelf project, in which the LCA had already been performed by the team, in order to compare the performance of applying such LLM, with a view to analyzing its potential use in other projects.

2 Literature Review

2.1 Studies Incorporating AI into the LCA Method

LCA is a method defined by the ISO 14040 series of standards (ISO, 2006), which evaluates the environmental impacts of a given product's life cycle, from the extraction of its raw materials to its disposal or reuse through recycling or energy conversion processes. It consists of four phases: 1. Objective and Scope: defining the purpose of the study and the limits of the system to be modeled; 2. Inventory Analysis: identifying the processes involved in the system and collecting quantitative input and output data; 3. Impact Analysis: categorizing and evaluating potential environmental impacts based on the results of the inventory analysis; 4. Interpretation: understanding the modeling and analyzing the results for decision-making. Although recognized as a useful method for quantitative analysis of various categories of impact, LCA continues to be considered a costly method in terms of knowledge and time, especially in the Life Cycle Inventory (LCI) Analysis phase, which is estimated to account for 70% to 80% of the time and costs of an LCA study (Popowicz et al., 2025).

In light of this, over the past five years, several studies have been conducted with the aim of integrating AI into LCA practice. Some articles present literature reviews, showing the increase in research seeking this integration, such as Cerchione et al., 2025; Popowicz et al., 2025; Gachkar et al., 2024; Martinez-Ramon et al., 2024.

It is possible to observe a search for the combination of mathematical models, statistical methods, and AI models to predict potential environmental impacts. Koyamparambath et al. (2022) have tried to use data from environmental product declarations (EPDs) of construction products to predict the environmental performance of a product. Jesus, Oliveira-Esquerre, Medeiros (2022) have studied AI models to predict impacts on

industrial water treatment. Martinez-Ramon et al. (2024) have proposed frameworks for the application of machine learning enabling predictions of LCIs or LCA performance indicators. Ibn-Mohammed et al. (2023) have explored machine learning frameworks for improved predictions of impacts of functional materials and devices. They suggest that "deep learning (DL) approaches like convolutional neural networks (CNN) can be used to automatically develop a bill of quantity of materials from images, diagrams, or maps to serve as input data for LCA". Mohammadi-Kashka et al. (2023) compared AI models for predicting energy use, employing neural networks and ANFIS (Adaptive Neuro-Fuzzy Inference System) – a hybrid system that combines fuzzy logic and artificial neural networks.

Such research is still in its early stages and seeks to predict the environmental impacts caused by products using methods that require extensive specialized knowledge in computer science. However, currently, in the practice of LCA application, the impact analysis phase is not a major problem, since it is done using LCI databases, software and methods that are recognized and accepted. For this reason, this study seeks to explore the use of AI to facilitate the costliest phase, which, as mentioned, concerns the LCI Analysis.

In this sense, Natural Language Processing (NLP), such as Large Language Modeling (LLM), appears to be a more effective alternative. According to Ibn-Mohammed et al. (2023), these "techniques can be used to automatically extract relevant data from text-based websites sources, such as scientific literature, reports, or NLP web scraping algorithms can be utilized to perform tasks such as text mining, entity recognition, and sentiment analysis to extract data related to the inventory of a product or process, including raw material inputs, energy consumption generation emissions estimates, and waste". MacMaster and Sinistore (2024) have investigated the ability of LLMs to automate Data Quality Assessment, and the model demonstrated a high ability to mimic human reasoning. Tu et al. (2024) draw attention to the multimodal capabilities of LLMs. They possess reasoning capable of performing semantic searches and inferring processes through multidisciplinary knowledge acquired during training.

The integration of customized LLMs into LCA allows researchers, even without in-depth training, to find qualitative solutions and technical guidance (Chen et al. 2024).

2.2 AI Categories Applicable to Life Cycle Inventory Analysis

Preuss, Alshehri and You (2024) indicate that LLMs hold significant promise for developing a LCI and summarizing and communicating LCA results. Although, "challenges arise from the inclusion of hallucinations in the content generated by the LLM, which can be mitigated if the LCA practitioner uses prompt engineering techniques". Furthermore, according to the authors, when integrated with multi-modal LLMs, vision-based tasks (images and video) can be performed, which can aid in the dissemination of LCA results.

A study has been done using three state-of-the-art LLMs, including Google Gemini, Gemini Advanced, and GPT-4 (Preuss, Alshehri, You, 2024). They have considered a LCA scenario where focuses on potential choices for land use change with tradeoffs between food and energy production. It has been asked to respond to: Prompt 1: "The following is an example scenario for a life cycle assessment. What is an appropriate goal and scope definition for this scenario? Please justify your choices"; Prompt 2: "what

would be an appropriate functional unit for the LCA in this scenario?"; and Prompt 3: "Should I use ReCiPe 2016 or CML as a life cycle assessment methodology?".

For the present study, only the first of these three prompts will be relevant. Therefore, Table 2 shows some conclusions reached by the authors.

Table 2. Responses' discussion. (Preuss, Alshehri, You, 2024).

LLMs	Prompt 1
Gemini	Gemini is able to understand some of the contents of a goal and scope definition, but also included extraneous. It's ability to identify a goal, LCA type, functional unit, and system boundaries are adequate, but could significantly benefit from further refinement. The system boundaries are vague, but a geographic boundary was given with an appropriate justification.
Gemini Advanced	Gemini Advanced provides a specific goal, system boundary, and functional unit. Provides an adequate system boundary. The functional unit provides is suitable, but needs verification from an LCA practitioner before being used as the basis of an LCA.
GPT-4	GPT-4 provides a detailed discussion for the goal and scope definition of the scenario. A specific goal and functional unit are specified and justified, while the system boundary does not mention which stages of the product life cycle the LCA covers. While the LLM recognizes that the functional unit should enable a fair comparison between the systems, it chooses different functional units for different pathways.

3 Method

LLMs have proved to be interesting in assisting the arduous task of LCIA. In this work, its application has been based on the study of Preuss, Alshehri, and You (2024). Therefore, its application to a light shelf project, designed by the team, has been proposed, in which the LCA had already been accomplished previously. The aim is to compare the performance of LLMs results with the LCI analysis already carried out.

Two LLMs have been used for this study: (i) Gemini 3, a multimodal generative AI chatbot and virtual assistant developed by Google, and (ii) DeepSeek, an AI chatbot developed by a Chinese AI research lab. The data and the AI architecture for Gemini are based on Deep Multimodal Reasoning, an Agent-oriented approach, and Native Multimodal model, and for DeepSeek, they are based on a Mixture of Experts, a Hybrid Attention architecture, and Manifold-constrained Hyper-connections.

3.1 Object of Study: LCIA of a Light Shelf

The concept of the light shelf present in this study (Pereira, 2019) can summarize as: to reduce the consumption of electric light controlling lighting and diffusion of natural light

in a built space; target audience: architects who seek to meet the needs of environmental comfort in buildings; search for commercial products; commercial standardization, modularity, ease of installation, use and maintenance; modularity for internal and external use; static use, providing easy cleaning; curve for better reflection of light; simple fittings; use of recycled aluminum in foundry process and profiles available in the market; finishing for better light reflection on top; valorization of recycled aluminum. The product presents four modules of different dimensions for better adaptation to the façade orientations.

The LCI (see Fig. 1) has been modeled in GaBi 6.0 LCA software using its process database. It is defined as: the light shelf is composed of two sinuous side pieces, similar to a French hand for attachment to the wall. In these parts, longitudinal round rebars are fixed in which flat plate sheets accompany this longitudinal line. It is expected that the manufacture of this light shelf will be done at Belo Horizonte, Minas Gerais, Brazil and will use of recycled aluminum cast in the side parts, round rebar and aluminum plates available on the market for the other components. The function of the product concerns the reflection of natural light in opening windows corresponding to a length of 1500 mm. The functional unit is therefore established by the reflection surface of 1.3m^2, defined by the dimensions of 865 x 1500 mm of the module considered standard in the design. The quantitative data has been defined as follows: 6 parts of 19 mm rebar = 6.976 kg, 5 parts of 1.5 mm sheet = 9.518 kg and 2 side parts by casted aluminum = 6.005 kg.

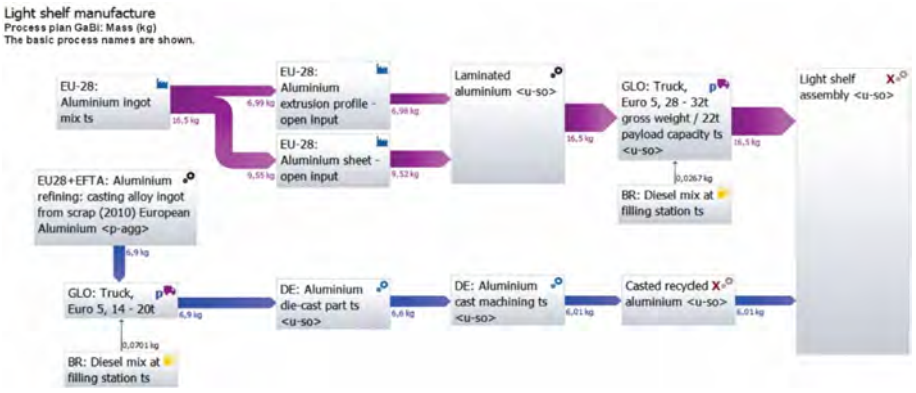

Fig. 1. LCI of the Light shelf - aluminum and side parts from recycled aluminum (Pereira, 2019).

3.2 Testing LLMs to LCI Analysis of the Light Shelf

For the LCI Analysis, four questions have been defined for LLMs application:

Prompt 1: "The following is an example scenario for a life cycle assessment. What is an appropriate goal and scope definition for this scenario? Justify your choices."
Prompt 2: "What industrial processes are involved in this scenario?"
Prompt 3: "How far from Belo Horizonte, Brazil, will I find the processed materials needed to assemble the light shelve at Belo Horizonte?"

Prompt 4: “What is the best visual representation of the production system in this scenario? Do not forget the distances involved in the process.”

In Gemini 3, all questions have been asked using the “reasoning” tool and in DeepSeek, it has been asked using the “deep thinking” tool. Furthermore, the questions have been asked in both English and Portuguese. In general, DeepSeek provided more detailed and in-depth answers compared to Gemini 3. Apparently, Gemini 3’s answers have been based on the reference article published by the team (Pereira, 2019). Despite this, the answers to Prompts 1 and 2 have been correct and relatively similar in both LLMs.

For Prompt 3, the DeepSeek responses have been much more accurate and detailed, including specific supplier names. However, the question in Portuguese generated more accuracy regarding the raw material production locations than the question asked in English. For Prompt 4, the diagram produced by Gemini 3 proved to be more illustrative and communicative (see Fig. 2), while the DeepSeek diagram has been more technical, corresponding better to the usual LCA diagrams.

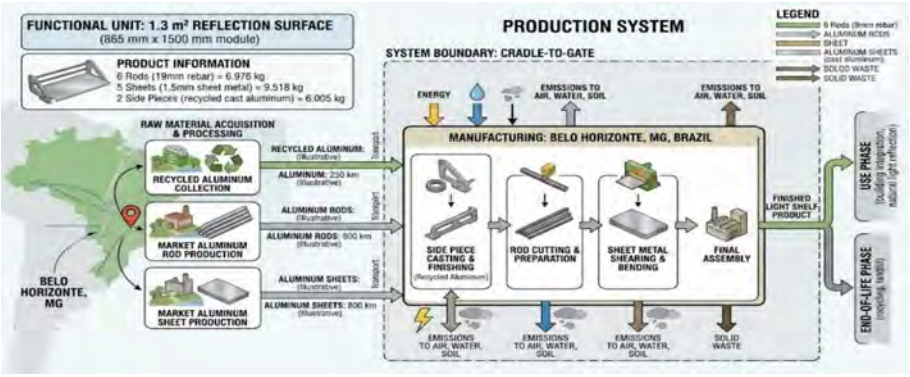

Fig. 2. Diagram produced by Gemini 3 - more illustrative and communicative

4 Conclusion

This study has sought to understand how to use AI to assist the practice of ecodesign through LCA, especially the LCI Analysis phase. For this, it has been proposed the application of two LLMs, Gemini 3 and DeepSeek, to a light shelf project, in which the LCA had already been performed by the team, in order to compare the performance of applying such LLMs. The results showed that the application of LLMs is promising for facilitating the task of inventorying the processes involved and visualizing the product system under analysis. To this, the question in Prompt 3 appears to be the most important, and should be well-developed as precise as possible based on the design specifications. The answer generated in this question will be fundamental for a better representation of the diagram. Prompt 1 and 2 have proved to be preparatory and perhaps unnecessary. In this initial exploratory study, a simple product involving few processes has taken as the

object of analysis. The continuation of the research foresees the application of LLMs to a more complex product.
