Lecture Notes in Civil Engineering (LNCE) publishes the latest developments in Civil Engineering—quickly, informally and in top quality. Though original research reported in proceedings and post-proceedings represents the core of LNCE, edited volumes of exceptionally high quality and interest may also be considered for publication. Volumes published in LNCE embrace all aspects and subfields of, as well as new challenges in, Civil Engineering. Topics in the series include:

- Construction and Structural Mechanics
- Building Materials
- Concrete, Steel and Timber Structures
- Geotechnical Engineering
- Earthquake Engineering
- Coastal Engineering
- Ocean and Offshore Engineering; Ships and Floating Structures
- Hydraulics, Hydrology and Water Resources Engineering
- Environmental Engineering and Sustainability
- Structural Health and Monitoring
- Surveying and Geographical Information Systems
- Indoor Environments
- Transportation and Traffic
- Risk Analysis
- Safety and Security

To submit a proposal or request further information, please contact the appropriate Springer Editor:

Preface

As Organisers of ReSBE 2026, we are honoured to present the Proceedings of the International Conference *ReShaping the Built Environment through Sustainability and Circularity*, held in Thessaloniki, Greece, from the 20th to the 23rd of October 2026.

Published in Open Access by Springer, these Proceedings reflect our commitment to making research and practical innovation at the intersection of sustainability, circularity, and the built environment widely available. By ensuring that the contributions can be consulted, cited and applied without restrictions, we hope to support informed decisions and accelerate positive change in the built environment and in society as a whole.

Society and governments require a more efficient, resilient, and regenerative built environment. Buildings and infrastructure shape patterns of resource use, energy demand, carbon emissions, social well-being, and economic development. In this context, the Circular Economy offers a vital framework for decoupling value creation from the consumption of finite resources by extending the service life of products and materials, enabling reuse and recovery, and promoting the valorisation of by-products and waste. Construction and the built environment have therefore become priority areas for policy, research, and professional practice, including within the European Commission's Circular Economy Action Plan. In parallel, the implementation of sustainability principles into the various scales of the built environment remains a primary goal of numerous policies and scientific efforts worldwide. ReSBE 2026 responds to this complex agenda by moving beyond incremental improvement and by advancing transformative approaches that drive systemic change across the design, construction, operation, and renewal of the built environment.

The conference was organised by the Laboratory of Building Construction and Building Physics of the School of Civil Engineering, Aristotle University of Thessaloniki, and the Department of Civil Engineering of the University of Minho, in collaboration with the COST Action CA21103 "Implementation of Circular Economy in the Built Environment – CircularB", with the support of the International Initiative for a Sustainable Built Environment (iiSBE).

ReSBE 2026 also marked an important moment in the journey of COST Action CircularB. Alongside presenting cutting-edge research, the conference provided an opportunity to showcase the Action's achievements, disseminate its results, and celebrate the collective efforts of its international network in advancing circularity in the built environment. More importantly, it created a platform for engaging the wider scientific, professional, and policy communities, fostering new collaborations and extending the impact of CircularB beyond the lifetime of the Action.

Within the ReSBE 2026 programme, the 1SBE event "Sustainability in the Built Environment Supported by Circular Strategies: Theory Meets Practice" further strengthened the conference's international scope. As part of the SBE Conference Series, this event created a forum for dialogue among policymakers, industry representatives, social

partners, and academics, thereby linking scientific knowledge with implementation challenges and opportunities.

ReSBE 2026 was devoted to presenting recent scientific advances, showcasing practical applications that bridge academia and industry, and discussing key issues concerning the contribution of sustainability and circularity to the modern and future built environment, its construction, and its infrastructure. A principal goal of the conference was to foster the exchange of ideas, methods, and evidence in ways that inspired innovative research paths and advanced new collaborative endeavours across disciplines, geographies, and sectors.

The conference received 541 abstracts from 1368 authors across 71 countries. Following a rigorous peer-review process, 335 full scientific papers were accepted for publication and organised into twelve thematic sections:

1. *Circular Design and Construction:* design for adaptability, reuse, and disassembly; material passports; modularity and standardisation.
2. *Sustainable Buildings, Infrastructures and Cities:* sustainability assessment frameworks, sustainable design, construction, operation and management; synergies across scales.
3. *Lifecycle Assessment, Metrics and Monitoring:* whole-life carbon, embodied energy, circularity indicators, benchmarking frameworks, multi-criteria decision-support methods, and AI/IoT-enabled lifecycle monitoring.
4. *Digitalisation and Automation:* BIM-based approaches, digital twins, digital passports, AI-powered tools, and decision-support systems.
5. *Climate Adaptation and Resilience:* climate-responsive design, resilient infrastructure, and nature-based solutions.
6. *Energy and Performance:* net-zero energy, carbon-neutral buildings, renewable energy integration, and smart grids.
7. *Materials and Innovation:* bio-based and regenerative materials, advanced composites, and secondary raw materials through industrial symbiosis.
8. *Urban and Regional Perspectives:* circular cities, heritage regeneration, and urban mining.
9. *Financing and Market Transformation:* circular business models, green financing, and innovative procurement strategies.
10. *Policy and Governance:* regulatory frameworks, certification systems, and leadership for circularity.
11. *Stakeholders and Collaboration Models:* roles, interactions, and governance mechanisms for systemic change.
12. *Societal and Educational Dimensions:* awareness, equity, skills, and capacity-building for sustainable transitions.

The contributions in these proceedings offer readers a broad and timely overview of the concepts, tools, technologies, policies, and case studies that are shaping the transition towards a sustainable and circular built environment. They address questions of direct relevance to researchers, designers, engineers, architects, policymakers, educators, and industry stakeholders, from whole-life performance and digitalisation to financing models, governance frameworks, stakeholder collaboration, and capacity-building.

Taken together, these contributions demonstrate that innovation, circularity, and sustainability are deeply interconnected. They also show that progress depends not only on technical solutions, but also on new forms of cooperation, new metrics for value and performance, and a shared willingness to rethink established practices. In light of this, the present Open Access publication aims to be a collection of high-quality research and serve as a catalyst for further inquiry, dialogue, collaboration and action.

We extend our deepest gratitude to all authors, the members of the Scientific Committee, the reviewers whose careful work upheld the excellence of the selected articles, and our publishing partners for their invaluable support. May these Proceedings inspire and facilitate the ongoing effort to engineer a sustainable, circular, and regenerative built environment for all.

The Organising Committee,

Luís Bragança
Katerina Tsikaloudaki
Christina Giarma
Ricardo Mateus
Karolos Kontoleon
Rand Askar
Adriana Salles
Camila Cervantes

Acknowledgments

This publication is based upon work from COST Action CA21103 CircularB (Implementation of Circular Economy in the Built Environment, https://circularb.eu/), supported by COST (European Cooperation in Science and Technology).

COST (European Cooperation in Science and Technology) is a funding agency for research and innovation networks. Our actions help connect research initiatives across Europe and enable scientists to grow their ideas by sharing them with their peers. This boosts their research, career and innovation. www.cost.eu.

Revitalizing Cultural Heritage Through Passive Design Strategies: The Case of Vernacular Houses in Sredačka Župa

Mirjana Miletić(✉) and Nebojša Gadžić

Architecture, Faculty of Technical Sciences, University of Priština in Kosovska Mitrovica, 38220 Kosovska Mitrovica, Serbia
mirjana.miletic@pr.ac.rs

Abstract. Cultural heritage buildings embody centuries of climate-responsive knowledge and provide valuable insights for addressing contemporary sustainability and circularity challenges. This paper investigates the vernacular residential architecture of a settlement in Kosovo, characterized by compact dwelling forms and masonry construction, in order to examine how traditional passive design strategies can inform regenerative and circular renovation approaches. The study combines field-based morphological analysis with digital environmental simulations conducted in DesignBuilder. The typical Sredačka Župa house, defined by thick stone walls, timber upper floors, deep eaves, internal courtyards, and small, strategically oriented openings, reveals a coherent system of passive climate control. These features contribute to high thermal mass, effective seasonal shading, favorable surface-to-volume ratios, and microclimatic regulation through semi-open transitional spaces. A representative dwelling was modeled to assess environmental performance under current climatic conditions. The results indicate that the pronounced thermal inertia of the traditional construction system plays a significant role in stabilizing indoor thermal behaviour. Furthermore, minimal and reversible interventions, including selective interior insulation, improved airtightness, and optimized shading strategies, demonstrate measurable reductions in heating energy demand of up to 22% without compromising architectural authenticity. The findings highlight vernacular architecture as an inherently circular system and emphasize its potential to support energy-efficient adaptive reuse and regenerative renovation strategies.

Keywords: Vernacular Architecture · Passive Design Strategies · Design Builder Simulations · Circular and Regenerative Design

1 Introduction

Climate change has intensified the need for more sustainable and resource-efficient approaches in the building sector, which remains one of the largest consumers of energy and materials worldwide. Contemporary architectural discourse increasingly acknowledges that technological solutions alone cannot adequately address environmental challenges without integrating accumulated spatial and climatic knowledge. In this context,

https://doi.org/10.1007/978-3-032-34930-9_1

cultural heritage buildings represent a valuable repository of climate-responsive intelligence developed through centuries of empirical adaptation. Vernacular architecture, in particular, embodies construction principles that inherently integrate environmental, material, and functional efficiency. These traditional systems frequently demonstrate sophisticated passive strategies capable of minimizing energy demand while ensuring adequate indoor comfort [1–3].

The houses of Sredačka Župa represent a compelling example of such architecture, characterized by compact volumetric forms, massive stone walls, timber structural systems, and carefully articulated semi-open transitional spaces. These architectural features indicate the presence of a coherent system of passive environmental control embedded within traditional design logic [4, 5]. The environmental implications of these systems require systematic validation through contemporary analytical tools. Therefore, this study investigates the vernacular residential architecture of Sredačka Župa through an integrated morphological and simulation-based approach.

The research is guided by the following central question:

RQ: *How do traditional passive design strategies and construction systems influence the environmental performance of vernacular houses, and to what extent can minimal, reversible interventions improve their energy efficiency?*

2 Theoretical Background

Vernacular architecture represents a cumulative body of knowledge shaped through long-term adaptation to local climatic, material, and socio-cultural conditions. Traditional dwellings typically rely on passive environmental strategies embedded within their spatial organization, materialization, and construction systems [6]. These strategies commonly include high thermal mass, compact building forms, controlled openings, and semi-open transitional spaces, all contributing to thermal regulation and indoor comfort. Previous research indicates that such principles can significantly enhance environmental responsiveness while reducing energy demand [7].

Vernacular structures often exhibit inherently circular characteristics, including the use of local materials, low-energy construction techniques and long service life [8].

However, the environmental performance of vernacular houses requires systematic validation through quantitative approaches. Building performance simulation provides a reliable framework for assessing thermal behavior, energy demand, and the effects of minimal, reversible renovation strategies. This study builds upon these theoretical perspectives by examining vernacular residential architecture through the integrated lens of passive design, sustainability, and circular renovation [9, 10].

3 Case Study

The research investigates the vernacular residential architecture of **Sredačka Župa**, Kosovo, a rural mountainous region distinguished by its compact settlement morphology and long-standing continuity of traditional construction practices (see Fig. 1). The built environment of this area reflects a close relationship between architecture, climate, and locally available resources, resulting in highly adapted dwelling typologies.

Fig. 1. Geographic position of the analyzed vernacular house in Sredačka Župa (source: Google Maps).

Traditional house in Sredačka Župa is characterized by **compact volumetric forms,** which minimize heat loss and optimize the surface-to-volume ratio. The structural system is primarily defined by **massive stone perimeter walls**, typically ranging from **60 to 80 cm in thickness**, providing both structural stability and significant thermal mass. Stone masonry, commonly bonded with mud mortar, represents a dominant construction technique rooted in local material availability and craftsmanship traditions (see Fig. 2).

Fig. 2. Floor plan and vertical section of the representative vernacular house (left) and exterior view of the dwelling (right) (source: author).

The internal organization of these houses frequently incorporates transitional spatial elements such as the **čardak** and **pretkuća,** which function as semi-open buffer zones. These spaces play a crucial environmental role by moderating thermal exchanges, enhancing natural ventilation, and providing seasonal adaptability. The building envelope is further defined by **small, strategically positioned openings**, deep roof eaves, and a hipped roof configuration, all contributing to solar control and protection from climatic exposure.

In addition to masonry elements, the construction system integrates **timber structural components**, particularly in inter-floor assemblies and internal partition walls. This hybrid system combines the thermal advantages of stone with the flexibility, reparability, and reduced material intensity of timber. Such architectural features indicate the presence of a coherent system of **passive environmental control**, making these dwellings particularly suitable for evaluating climatic responsiveness and circular renovation potential. Based on typological representativeness and preservation of original architectural characteristics, a typical Sredačka Župa house was selected for detailed analysis and simulation modeling [5].

4 Methodology

The study employs an integrated methodological framework combining **morphological analysis** and **building performance simulation**. The initial phase involved field-based architectural investigation of traditional houses in Sredačka Župa, focusing on spatial organization, construction systems, materialization, and passive environmental strategies. Key parameters influencing environmental performance, including wall composition, envelope characteristics, and opening configurations, were systematically documented to define a representative dwelling model [11].

Based on typological representativeness, a typical house was digitally reconstructed using **DesignBuilder**, version 5.03.007. The baseline model reflected the original construction properties and regional climatic conditions. To evaluate renovation potential within conservation-sensitive costraints, several **minimal and reversible intervention scenarios** were tested, including selective interior insulation, improved airtightness, and shading optimization. Environmental performance was assessed through comparative analysis of heating energy demand and thermal behavior across baseline and intervention models [12]. Standard residential occupancy profiles, internal gains, infiltration rates and regional weather data were applied in DesignBuilder. Model validation was performed through comparison with documented thermal characteristics of vernacular buildings in the Balkan region.

5 Simulation Analysis

5.1 Baseline Model

A representative vernacular house was reconstructed in DesignBuilder using the EnergyPlus simulation engine (see Fig. in Table 1.). The baseline model reflects the original construction characteristics typical of traditional Sredačka Župa houses, including massive stone walls, timber structural elements, compact volumetric form, and small window openings. External walls were modelled as thick stone masonry assemblies (approximately 0.70 m), capturing the high thermal mass that dominates the envelope's thermal behaviour. The roof and floor structures were defined according to documented vernacular construction systems. Simulations were conducted using climatic data representative of regional continental conditions with standardized occupancy assumptions. Results indicate that the baseline model exhibits stable thermal behaviour despite the absence of modern insulation. The substantial thermal inertia of stone walls moderates heat transfer and reduces temperature fluctuations. Although heating demand remains relatively high, the envelope demonstrates inherent passive performance advantages (Table 1).

Table 1. Thermal Properties and Envelope Characteristics of the Baseline Model

Element	Description	Thermal Properties	
External Walls	Stone Thickness: **0.70 m**	Conductivity: **1.7–2.2 W/mK** Density: **2200–2400 kg/m^3** Specific heat: **800–900 J/kgK**	 1
Roof	Timber structure with metal sheet covering	U-value **~2.5–3.0 W/m^{2}K**	
Floor	Rammed earth / stone assembly	U-value: **~1.5–2.0 W/m^{2}K**	
Windows	Small openings, single glazing	U-value: **~5.0–5.8 W/m^{2}K**	

[1] *DesignBuilder model of the house*

5.2 Intervention Scenarios

To evaluate energy improvement potential within conservation-sensitive constraints, minimal and reversible interventions were examined. The first scenario introduced selective interior insulation (rock wool of 5 cm thickness), significantly reducing conductive heat losses while preserving the external architectural character.

Comparative simulations reveal a reduction in heating energy demand of approximately **22%,** confirming the effectiveness of low-impact strategies. Improved airtightness further enhanced performance, highlighting infiltration as a major source of heat loss. Optimized shading produced moderate but consistent improvements in seasonal thermal response.

The second scenario examined the impact of reduced infiltration rates through improved airtightness measures, addressing one of the primary sources of heat loss in traditional dwellings. The intervention included improved sealing of window and door junctions and reduction of uncontrolled air leakage while preserving the original architectural appearance. The simulation results indicate a noticeable decrease in heating energy demand, confirming that uncontrolled air leakage significantly affects the thermal performance of vernacular houses. The reduction of infiltration rates resulted in an additional decrease in heating energy demand of approximately **12%,** confirming the significance of uncontrolled air leakage in traditional buildings.

The third scenario evaluated the influence of optimized solar control strategies, including adjustments to shading elements and the functional role of extended eaves. The results reveal moderate yet consistent improvements in thermal behaviour, particularly in transitional and warmer periods, demonstrating the relevance of passive solar regulation. Optimized shading strategies produced a moderate reduction in heating demand of approximately 5%, while contributing to improved seasonal thermal regulation.

5.3 Comparative Performance Assessment

The comparative analysis demonstrates that vernacular houses possess inherent passive advantages that can be effectively enhanced through minimal interventions. The baseline annual heating demand of the representative dwelling was approximately 36 MWh/a. The introduction of selective interior insulation reduced heating demand by approximately 22%, while airtightness improvements contributed an additional reduction of around 11–12%. Optimized shading strategies produced smaller but measurable improvements of approximately 5%, particularly during transitional seasonal periods. These comparative indicators confirm the effectiveness of low-impact passive retrofit strategies in improving the environmental performance of vernacular architecture. The results emphasize the critical role of thermal mass in regulating the environmental behaviour of traditional dwellings. Massive stone walls act as dynamic thermal regulators, while reversible renovation strategies enable measurable efficiency gains without compromising architectural authenticity. These findings support the interpretation of vernacular architecture as an environmentally responsive and inherently circular system (see Table 2).

Table 2. Comparative Performance Assessment

Model Scenario	Envelope Characteristics	Energy Demand Improvement ($kWh/m^2/year$)	Interpretation
Baseline Model	Walls: Thick stone masonry (70 cm) Roof: Timber structure with metal sheet covering Floor: Ground-contact assembly	36 MWh/a	Stable thermal behaviour due to high thermal mass
Scenario 1	Walls: Selective interior insulation applied (Rock wool 5 cm) from 2.0 W/m^2K to 0.6–0.8 W/m^2K	≈22%	Significant reduction of conductive heat losses
Scenario 2	Air exchange: Reduced infiltration (improved airtightness) 1.0–1.5 ACH	≈11% 0.5 ACH	Decrease in infiltration
Scenario 3	Solar control: Optimized shading strategies	≈ 5%	Improvement in seasonal thermal regulation

6 Discussion

The results provide a clear response to the central research question by confirming that the environmental performance of the Sredačka Župa house is fundamentally shaped by its traditional construction logic. The massive stone masonry walls, through their

high thermal mass, generate pronounced thermal inertia, moderating heat transfer and stabilizing indoor temperature variations. Although the baseline model indicates relatively high heating demand, the stable thermal behaviour reveals inherent passive advantages embedded in the compact form, controlled openings, and transitional semi-open spaces. The analysis further demonstrates that minimal and reversible interventions can significantly improve energy efficiency. Selective interior insulation produced the greatest reduction in heating demand (≈22%), while improved airtightness achieved an additional decrease (≈11%), highlighting infiltration as a critical factor. Optimized shading strategies generated moderate but consistent improvements (≈5%), reinforcing the role of passive solar control. Collectively, these findings confirm that traditional passive design strategies play a decisive role in environmental performance and that conservation-sensitive interventions can enhance efficiency without compromising architectural authenticity. Vernacular houses thus emerge as environmentally responsive and inherently circular systems, demonstrating strong compatibility with contemporary sustainability and regenerative renovation principles. However, the study is based on a single representative case study and adopts a strongly place-based methodological approach focused on the specific climatic, material, and morphological characteristics of Sredačka Župa. Therefore, the findings cannot be universally generalized to all vernacular contexts. Nevertheless, the research contributes to the broader discourse on sustainable heritage renovation by demonstrating how passive environmental strategies embedded in traditional architecture can support contemporary circular and regenerative design approaches. The study also provides a transferable methodological framework that may inform future investigations of vernacular settlements in comparable climatic and cultural contexts.

7 Conclusion

This study demonstrates that the vernacular residential architecture of Sredačka Župa possesses significant passive environmental performance potential. The simulation results confirm that traditional construction systems, particularly massive stone masonry walls, play a decisive role in thermal regulation through pronounced thermal inertia. Despite the relatively high heating demand observed in the baseline model, the stable thermal behaviour indicates that these buildings inherently embody climate-responsive design principles.

The analysis further reveals that minimal and reversible interventions can achieve substantial improvements in energy efficiency. Selective interior insulation, improved airtightness, and optimized shading strategies collectively demonstrate that energy optimization can be pursued without compromising architectural authenticity. These findings highlight the compatibility between heritage preservation objectives and contemporary sustainability requirements.

Beyond energy performance, the research reinforces the interpretation of vernacular houses as inherently circular systems. Their reliance on durable local materials, long service life, reparability, and passive climatic adaptation aligns closely with circular economy and regenerative design principles. Rather than representing obsolete construction models, vernacular dwellings demonstrate a latent capacity for environmental optimization and adaptive reuse.

Although the research is limited to a specific vernacular context, its broader contribution lies in illustrating the potential of integrating traditional passive design knowledge into contemporary energy-efficient adaptive reuse strategies. The findings emphasize the relevance of vernacular architecture as a source of climate-responsive and circular design principles that may inspire conservation-sensitive renovation practices in other regions with similar environmental conditions.

The study therefore underscores the importance of integrating heritage-based architectural knowledge into contemporary renovation practices. Traditional buildings should be recognized not only as cultural assets but also as valuable resources for developing resilient, low-impact, and energy-efficient architectural strategies.

NETRACCI: Operationalising Circular Governance in the Built Environment

Niclas Ihren and Moa Turander(✉)

Matters Group, Stockholm, Sweden
moa@mattersgroup.com

Abstract. The transition to a circular and net-zero built environment requires new governance structures that translate sustainability ambitions into operational decisions across the value chain. This paper presents early findings from the Netracci project, a Swedish multi-stakeholder initiative running 2025–2027 involving 20 industrial partners and 3 research institutions. Based on current-state maturity assessments of real estate companies, architects, and suppliers, the paper identifies actor-specific barriers to circularity. Suppliers face challenges in providing verified lifecycle data spanning circular business models, environmental impact, and total cost of ownership. Architects lack competence in translating circular data into design and business cases. Needs owners exhibit a maturity gap characterised by imbalanced capabilities and a narrow focus on reuse over systemic circular strategies. A novel six-dimensional maturity framework reveals that circular maturity lags significantly behind sustainability maturity among needs owners. Three hypotheses guide the research: (1) regulatory focus on supply-side measures has outpaced customer-side readiness; (2) financial governance centred on initial investment constitutes the primary blockage among needs owners; and (3) insufficient ecosystem dialogue prevents coordinated action. The paper concludes with implications for operationalising circular governance across the value chain.

Keywords: Circular Economy · Built Environment · Governance · Maturity Assessment · Lifecycle Thinking · ISO 59000 · Total Cost of Ownership · Digital Product Passport

1 Introduction

The built environment accounts for approximately 40% of global carbon emissions and half of all extracted materials [1]. Translating high-level sustainability ambitions into operational decisions remains a central challenge [2], and governance structures enabling cross-value-chain collaboration are largely absent. Despite growing regulatory pressure—including the Eco-design Directive and Digital Product Passport requirements—circular practices remain niche rather than mainstream.

The Netracci project (2025–2027) was designed to address this gap. It brings together 20 partners from architecture, construction, interiors, real estate, and digital services, alongside research partners from Matters Group, RISE, KTH, and Linköping University, to develop and test a circular governance framework aligned with ISO 59000. Three hypotheses structure the inquiry:

H1 – The Supply-Demand Maturity Gap: Regulatory measures have focused on the supply side, creating an asymmetry where suppliers are more ready to deliver circular products than customers are to procure them.
H2 – The Financial Governance Hypothesis: The primary blockage among needs owners lies in financial governance structures that prioritise initial capital expenditure over total cost of ownership (TCO).
H3 – The Ecosystem Dialogue Hypothesis: Insufficient value-chain dialogue prevents the coordinated action needed for circular transition.

This paper reports early findings from Work Package 2 (WP2), which conducted current-state maturity assessments across all participating organisations.

2 Theoretical Framework

2.1 Circular Economy and Barriers to Transition

The circular economy represents a fundamental shift from linear "take-make-waste" models to systems that prioritise resource retention, value recovery, and regenerative design [3], spanning the R-hierarchy from reuse (R3–R4) through remanufacturing to recycling (R8–R9) [4]. The ISO 59000 series provides a standardised framework emphasising systemic thinking, value creation, and stakeholder collaboration [5]. Kirchherr et al. [2] identified cultural, regulatory, financial, and structural barriers in the EU—often interconnected and requiring simultaneous resolution. The present research builds on this by focusing on governance and actor-specific capabilities within the built environment value chain.

2.2 Maturity Assessment as a Governance Tool

Maturity models offer a structured approach to benchmarking organisational capabilities, identifying gaps, and charting improvement pathways [6, 7]. In the context of circular economy, they help organisations understand their position on the linear-to-circular transition and prioritise interventions accordingly.

2.3 The Netracci Circular Management Maturity Model

The project developed a maturity model tailored to real estate companies and major owner-occupiers, structured across six interconnected dimensions: (1) Strategic Leadership & Investment – assessing whether circularity and net-zero are embedded in core business strategy and financial decision-making; (2) Portfolio & Asset Management – evaluating practical application of circular principles across the asset portfolio; (3) Development & Project Management – how circularity is designed into new assets and refurbishments; (4) Data, Technology & Systems – enabling measurement and data-driven decision-making; (5) Ecosystem & Collaboration – engagement with value chain partners, industry peers, and policymakers; (6) Value Proposition & Market Positioning – how circular strategy translates into tangible value for tenants and investors.

Each dimension is assessed against a five-level maturity scale: Level 1 (Ignorance/Linear) – no awareness of circular economy concepts; Level 2 (Ad hoc/Beginner) – isolated projects, no strategic framework; Level 3 (Structured/Developer) – strategy exists, systematic implementation begins; Level 4 (Excellence/Integrated) – circularity is core to the business model; Level 5 (Pioneering/Systemic) – ecosystem shaping and net-positive impacts. A core premise of the framework is that organisations must achieve balanced maturity across all six dimensions to enable effective circular governance.

3 Methodology

Netracci is structured into six work packages; this paper draws on WP2 (Current State Analysis), which assessed circular capabilities across all partner organisations. Assessments were conducted through questionnaire-based self-assessments supported by document analysis of sustainability reports, procurement policies, project briefs, and governance documents (Table 1). For suppliers, additional data collection followed the Integrated Circularity and Sustainability Model framework, capturing corporate capabilities and product-level specifications across environmental, circularity, social, and financial parameters.

Organisations were grouped into three actor categories: needs owners – real estate companies and large tenants (n = 5); architects – firms involved in commercial and residential design (n = 5); and suppliers – manufacturers of products and materials for interiors and construction (n = 7). This categorisation enabled cross-actor comparison and identification of distinct capability profiles, directly supporting investigation of H1.

Table 1. Key documents collected for validation, mapped to assessment dimensions.

Document Type	Primary Validation Area
Corporate/Sustainability Strategy	Strategic Intent
Green Procurement Policy	Supply Chain Governance
Green Investment Framework	Financial Integration
Net Zero/Circularity Roadmap	Portfolio-Wide Execution
Standard Project Brief Template	Project-Level Governance
Life Cycle Assessment (LCA) Report	Data Use in Design
Annual Sustainability Report	Transparency & Communication
Green Lease / Tenant Fit-out Guide	Tenant Collaboration
Circular Partnership Agreement (MoU)	Ecosystem Collaboration
Evidence of Green Financing	Market Credibility & KPIs

4 Findings

4.1 H1: The Supply-Demand Maturity Gap

Maturity assessments revealed a pattern consistent with H1. Suppliers demonstrated moderate-to-high willingness to deliver circular products; however, their ability to provide verified data across circular business models, environmental lifecycle data, and TCO financial parameters was uneven. Critically, needs owners' readiness to procure circular solutions lagged significantly behind supplier willingness to provide them (Table 2).

Table 2. Supplier circular readiness indicators.

Indicator	Average Score / Response
Circular business model existence	70% have developed some circular offering
Circular offer coverage (% of portfolio)	<30% average
EPD/LCA capability	60% have in-house or external capability
Buy-back/take-back system in place	40% have operational systems
Digital Product Passport roadmap	25% have a concrete timeline
Circular project references	Limited to pilot scale in most cases

> We have circular products ready to go. We have take-back systems. We have refurbishment capabilities. But our customers aren't asking for them, and when they do, they don't have the procurement processes or investment models to value what we're offering. – Supplier representative

4.2 H2: The Financial Governance Hypothesis

All five needs owner organisations showed financial governance structures that consistently favoured initial capital expenditure over lifecycle value. None had mandatory TCO requirements for investment decisions; payback period requirements (typically 3–5 years) conflicted with longer-term circular value realisation; and risk assessment methodologies did not capture risk reductions associated with circular strategies. Procurement remained heavily weighted toward lowest initial price, and circular criteria—where present—were treated as optional.

> *Our investment model is not capable of managing even marginally increased investments, even if that leads to lower TCO. We're measured on project IRR and payback periods. Shifting to TCO is a cultural and financial shift we haven't made yet. – Real estate sustainability manager*

4.3 H3: The Ecosystem Dialogue Hypothesis

The assessment revealed fragmented cross-actor dialogue consistent with H3. Architects lacked a forum to collectively articulate data needs to suppliers; suppliers expressed willingness to develop circular offerings but received unclear market signals; needs owners had circular ambitions but had not communicated these as procurement requirements. No structured mechanisms existed for risk-sharing or circular co-investment.

> *We're all doing what we can within our own spheres. But we're not having the conversations across the table about what's really needed. The questions we need to solve together fall outside the regular procurement dialogue. – Architect representative*

4.4 The Supplier Data Trilemma

Suppliers identified a fundamental barrier: the inability to provide verified data across three categories simultaneously. (1) Circular business model data: take-back systems and product-as-a-service offerings lack standardised documentation, and circular offer coverage (the share of portfolio available with circular commercial terms) averaged below 30%. (2) Environmental lifecycle data: EPDs commonly cover cradle-to-gate (A1–A3) only; data on transport and installation (A4–A5), use stage (B), and end-of-life (C) are frequently absent or based on generic scenarios rather than product-specific information. This prevents accurate whole-life carbon assessment and undermines TCO calculations. (3) TCO financial data: parameters such as expected service life, buy-back percentages, and guarantee coverage risk factors are rarely collected or disclosed.

This data trilemma is a systemic barrier that individual suppliers cannot solve alone—it calls for shared infrastructure and standardised reporting frameworks across the sector.

4.5 Architect Challenges

Architects face a dual challenge. First, they lack competence in interpreting and applying circular product data in design. While trained to optimise for aesthetics and function, integrating circularity metrics into early-stage design is new territory. Second, they are expected to act as advisors translating circular ambitions into financially viable concepts—a shift from initial investment thinking to TCO modelling that is not yet widespread in the profession.

> *We're expected to lead the client into circularity, but we don't have the tools or the training to do it confidently. And even when we get data from suppliers, it's in different formats, different units, and we have no way to compare options systematically. – Architect*

4.6 Needs Owner Maturity Profiles

Across all five needs owner organisations, circular maturity (averaging Level 2–3) was consistently and significantly lower than sustainability maturity (Level 3–4). This reflects

the relative novelty of circular economy as a management concept in real estate. Sustainability has been on corporate agendas for decades, with established metrics, reporting frameworks, and regulatory drivers; circular economy by contrast lacks standardised definitions, mature data infrastructure, and embedded governance mechanisms.

A second pattern was the concentration of circular activity around reuse strategies (R3–R4) rather than more systemic approaches. Many organisations had implemented furniture and fixture reuse pilots, achieving measurable waste reductions. However, engagement with higher-order strategies—design for disassembly (R2), product-as-a-service (R1), or buildings-as-material-banks (R0)—was limited. Beyond the maturity gap, needs owners articulated a critical operational challenge: no systematic mechanism exists to preserve and update product and material data over the asset lifecycle. Digital product passports, where they exist, are not integrated into facility management systems, causing data decay that undermines circular value propositions and prevents buildings from functioning as material banks at end-of-life.

4.7 Cross-Cutting: Data Infrastructure

All actor groups identified fragmented data infrastructure as a major obstacle. Product data, circularity indicators, EPDs, cost parameters, and digital product passports are currently scattered across incompatible systems. Two complementary infrastructure needs were identified: (1) a central credible data repository enabling suppliers to publish verified circular product data once and make it accessible to all authorised procurement processes, reducing transaction costs and improving data quality; and (2) asset lifecycle data management systems for needs owners, integrating BIM, facility management, and digital product passport platforms to track material data over decades and enable eventual material banking when assets are decommissioned.

5 Discussion

5.1 Hypothesis Validation

Preliminary findings provide initial support for all three hypotheses. H1 is supported: the demand-side bottleneck appears significant, though suppliers face their own data challenges. H2 is strongly supported: initial-investment-focused financial governance is the most consistently cited barrier across all needs owner organisations, manifesting in the absence of mandatory TCO requirements, short payback horizons, and procurement processes that systematically exclude lifecycle criteria. H3 is supported: fragmented communication reinforces transactional relationships and prevents the collaborative problem-solving needed for systemic change. The pilot phase of Netracci will provide opportunities to test targeted interventions and to gather longitudinal evidence on each hypothesis.

5.2 From Reuse to Systemic Circularity

The concentration of circular activity around reuse strategies, while valuable, represents an incomplete transition. True circular governance requires engagement with the full R-hierarchy, including design strategies that prevent waste creation (R0–R2) and business

models that retain value at higher levels (R1–R4). This shift demands competence development, new metrics, and willingness to experiment with novel value propositions such as product-as-a-service and design for disassembly. Current efforts anchored in familiar operational improvements—rather than transformative business model innovation—will not alone deliver the systemic change required.

5.3 The Role of Integrated Data Platforms

The Netracci project is developing an integrated data model linking material passports, circular indicators, EPDs, and cost parameters into a BIM-compatible decision-support tool. This addresses the cross-cutting data challenge by enabling supplier capability assessment through corporate maturity scoring; product-level circularity indexing based on R-strategy parameters; environmental impact comparison using standardised EPD modules; and total cost of ownership calculations incorporating service life, warranties, buy-back commitments, and guarantee risk factors. Early pilot planning suggests such tools can reduce the transaction costs of circular procurement and support evidence-based decision-making—but the tool is only as effective as the data it contains, underscoring the need for both complementary data infrastructures identified in Sect. 4.7.

5.4 Actor-Specific Interventions and Emerging Risks

Suppliers require standardised data templates aligned with EN 15804, EN 16810, and ISO 59000, together with access to central data repositories that reduce repeated disclosure burden. Architects need TCO modelling capabilities, circular design guidelines, and access to verified product data through BIM-compatible platforms. Needs owners must build asset lifecycle data infrastructure, broaden their circular focus beyond reuse, reform investment frameworks to capture lifecycle risk reductions, and create governance mechanisms for long-term supplier commitments.

Circular models also introduce new long-term risks alongside risk reductions. Suppliers may be asked to provide take-back commitments for 15 or more years—potentially exceeding their commercial lifespan—requiring governance innovations that extend beyond traditional warranties.

6 Conclusion

This paper has presented early findings from the Netracci project, highlighting actor-specific challenges in operationalising circular governance in the built environment. Suppliers face a data trilemma requiring the simultaneous provision of circular business model data, environmental lifecycle data, and TCO financial parameters—a systemic barrier that exceeds what individual firms can solve alone. Architects lack the competence and tools to integrate circularity metrics into design workflows and business case development. Needs owners exhibit a sustainability-circularity maturity gap, a narrow reuse focus rather than systemic circular strategies, and insufficient data infrastructure to maintain product data across asset lifecycles.

Preliminary evidence supports all three guiding hypotheses: a significant supply-demand maturity asymmetry (H1); financial governance centred on initial expenditure as the primary blockage among needs owners (H2); and fragmented ecosystem dialogue that prevents coordinated action (H3). These findings inform the design of WP5 pilot interventions targeting each hypothesis in commercial real estate settings.

The paper contributes to emerging circular governance literature by demonstrating the need for differentiated actor-specific support, integrated data infrastructures, and new instruments for managing long-term circular commitments. Future work will track longitudinal changes in maturity as pilots progress.

Advancing Circular Construction Through Digital Product Passports

Angel Jimenez-Aranda(✉) and Juan Antonio Ferriz-Papi

University of Salford, Manchester M5 4WT,, UK
a.jimenez-aranda@salford.ac.uk

Abstract. Digital Product Passports (DPPs) are increasingly recognised as a key enabler of sustainability and circularity in the construction sector, offering a structured way to capture, share, and reuse accurate product information across the entire lifecycle of built assets. By providing transparent data on product performance, provenance, environmental impact and compliance, DPPs support responsible procurement, reduce waste, and create new opportunities for reuse and recycling, which are essential principles for achieving circular construction. In this context, SmartScan, a digital tool developed by the University of Salford, demonstrates how DPP-aligned solutions can be implemented in practice. SmartScan connects product barcodes and QR codes through the Global Trade Item Number to verified manufacturer data, including safety documentation, installation guidance, environmental product declarations, and origin information, providing essential information for users across the construction supply chain. This study investigates how SmartScan can contribute to sustainable construction by improving material traceability and enabling more informed decision-making throughout the product lifecycle. Through user testing and analysis of product data flows, the research shows that SmartScan enhances access to environmental information, supports lower-impact material choices, and strengthens opportunities for circularity in procurement, reuse, and end-of-life processes. The findings highlight the value of tools based on global data standards in promoting sustainable and circular practices and illustrate how manufacturers can organise and share their product data to better support the construction supply chain.

Keywords: Digital Product Passports · Circular Economy · Product Traceability · Sustainability · Smart Construction

1 Introduction

The construction sector, encompassing the planning, design, manufacture, construction, operation, maintenance, and demolition of buildings and infrastructure, is central to sustainability and circular economy goals but remains one of the most resource-intensive and waste-generating industries. Buildings and construction account for about 37% of global energy-related carbon emissions and a large share of material consumption, highlighting the need to improve material efficiency and reduce lifecycle impacts in the built environment [1]. Circular economy strategies are increasingly promoted to address

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 20–28, 2026.
https://doi.org/10.1007/978-3-032-34930-9_3

these challenges through improved resource efficiency, reuse of building components, and longer product lifetimes [2, 3].

Digital technologies are recognised as key enablers of circular construction. Tools such as Building Information Modelling (BIM), the Internet of Things (IoT), artificial intelligence (AI), and digital product information systems can enhance lifecycle information management and transparency across construction supply chains [4, 5]. They support material traceability, collaboration, and data-driven decision-making across design, procurement, construction, and operation phases [6]. However, adoption remains limited because product and material information is often incomplete, difficult to access, or disconnected from the physical products installed in buildings.

A key barrier is the lack of reliable and interoperable product information across the lifecycle of built assets. Circular decision-making requires knowledge of installed products, including their composition, provenance, environmental performance, and end-of-life options. In practice, this information is fragmented across manufacturer documentation, project systems, and static files, limiting integration with digital tools and disrupting lifecycle information continuity [3, 4]. This fragmentation restricts opportunities for reuse, refurbishment, and recycling of building components [2, 3].

Digital Product Passports (DPPs) have emerged as a promising approach to addressing these information gaps [7–10]. DPPs provide structured digital identities for products containing data on composition, technical characteristics, environmental performance, and end-of-life management. By enabling persistent access to product information, DPPs can improve transparency and traceability across supply chains and support sustainable procurement, maintenance, and material recovery [11].

Policy developments are accelerating DPP adoption. The Ecodesign for Sustainable Products Regulation (ESPR) [12] introduced by the European Commission establishes a framework for digital product passports across multiple product groups. Complementary initiatives, including revisions to the Construction Products Regulation, aim to strengthen digital product information requirements in construction supply chains.

Standardisation efforts for Digital Product Passports (DPPs) are still evolving, with ongoing work across European and international standardisation bodies to define common data structures, interoperability requirements, and sustainability-related information for construction products. In particular, CEN/TC 350/SC1/WG4 is currently working on the definition of product properties with circularity significance that should be integrated into a DPP dataset, supporting greater transparency, traceability, and circular economy practices within the construction sector.

The effectiveness of DPPs depends on global data standards and digital identification mechanisms linking physical products to digital information. Standardised identifiers allow products to be uniquely identified and connected to verified data repositories, improving interoperability and integration with procurement and asset-management systems [13].

Despite increasing attention to DPPs, empirical evidence on operational DPP-aligned tools in construction remains limited. Most research focuses on conceptual frameworks or regulatory aspects rather than practical implementations and their impact on procurement, material selection, reuse, and end-of-life decisions.

This study addresses this gap by examining SmartScan, a digital tool that aligns with DPP principles and links physical construction products with verified manufacturer data through digital identifiers. By connecting product identifiers encapsulated in barcodes and QR codes to product records, SmartScan enables access to safety documentation, installation guidance, environmental product declarations, and provenance information. This research investigates how SmartScan improves material traceability and access to lifecycle-relevant product information.

2 Methodology

This study adopts an exploratory case study approach to investigate how a DPP–aligned digital tool can support sustainable and circular practices in the construction sector. Given the early stage of DPP adoption in construction, an exploratory design enables in-depth analysis of processes, user interactions, and data flows that would be difficult to capture through large-scale quantitative methods.

SmartScan is a digital tool developed by the University of Salford that links physical construction products to verified digital information. At its core, the system connects the Global Trade Item Number (GTIN) encapsulated in barcodes and QR codes with a digital data layer. When a product is scanned, users are directed to aninterface that provides access to manufacturer-verified product information (see Fig. 1).

Fig. 1. Screenshot of a product information page in SmartScan

The system architecture is designed to support interoperability and data integrity. Rather than storing all information locally, SmartScan functions as a connector between

physical identifiers and authoritative data sources maintained by manufacturers or trusted platforms. This approach reduces duplication and supports the principle of a single source of truth for product information. The types of data accessible through SmartScan include safety documentation, installation and maintenance guidance, environmental product declarations (EPDs), and provenance information.

SmartScan aligns with key DPP principles by enabling persistent linkage between products and their digital records, supporting multi-stakeholder access to information, and facilitating lifecycle-oriented data use. Although it does not represent a fully standardised DPP as defined in emerging regulations, it operationalises many of the functional requirements associated with DPPs, particularly in relation to traceability, transparency, and lifecycle accessibility.

In the study, data collection focused on two complementary components: user testing and analysis of product data flows. User testing was conducted with participants representing different roles within the construction supply chain who interact with product information at different lifecycle stages. Participants were asked to use SmartScan to access product information in simulated scenarios, such as checking installation requirements, verifying safety documentation, or reviewing environmental performance data. Observations were recorded alongside semi-structured feedback on usability, clarity, and perceived value.

In parallel, the study analysed how product data flows through the SmartScan system, mapping the key information categories accessible through the platform against lifecycle stages aligned with ISO 19650 principles. This involved examining the types of data made available, how they are structured, and how they are accessed at different points in the lifecycle. This analysis enabled assessment of both the technical capabilities of the tool and its relevance to sustainability-oriented decision-making.

3 Results

3.1 User Testing

User testing was conducted to assess the effectiveness, usability, and user satisfaction associated with the SmartScan digital platform. The evaluation aimed to simulate realistic usage scenarios and to identify design considerations, usability barriers, and opportunities for system improvement. Insights obtained from this process informed iterative refinements to the digital solution.

To measure user satisfaction, the Post-Study System Usability Questionnaire (PSSUQ) [14] was administered after participants completed a predefined set of tasks. The testing environment included both laptops and smartphones, connected to a smart screen that enabled monitoring of user interactions during task execution. Ethical approval for the usability study was obtained prior to testing, and all participants provided informed consent.

A total of 14 participants took part in the evaluation. Participants completed ten tasks, equally divided between laptop-based and smartphone-based interactions, allowing the research team to assess usability across different device contexts. Data were collected on task completion processes, user responses, and observed interaction patterns, enabling the identification of usability issues and user preferences.

User satisfaction was evaluated using four PSSUQ dimensions. System usefulness (SYSUSE) recorded score of 1.61 ± 0.74, suggesting that users perceived the platform as highly effective for locating and accessing product information. Information quality (INFOQUAL) scored 1.62 ± 0.57, indicating that the content provided by the system was clear, relevant, and aligned with user expectations. Interface quality (INTERQUAL) achieved a mean score of 1.61 ± 0.85, reflecting positive perceptions of the system interface and interaction design. The overall satisfaction score (OVERALL) of 1.60 ± 0.58 indicates a consistently positive user experience across the evaluated tasks. Taken together, these results demonstrate that the SmartScan platform performs strongly in terms of usability and user acceptance.

In addition to the questionnaire results, qualitative feedback was collected during the testing sessions. Overall, the feedback confirmed that users found the platform useful, accessible, and visually well designed, particularly appreciating the ability to reduce time required to locate and access relevant product information. Some challenges related to product comparison and barcode scanning were also identified, helping to inform further improvements to the platform's design and usability.

3.2 Product Data Flow and Lifecycle Information Availability

To evaluate the capability of SmartScan in supporting lifecycle information management, the product data made available through the system was analysed in comparison with principles defined in ISO 19650, the international standard for the organisation and digitisation of information about buildings and civil engineering works using Building Information Modelling (BIM). ISO 19650 establishes that structured information should be produced, managed, and exchanged consistently throughout the lifecycle of built assets to support decision-making, regulatory compliance, and operational efficiency. While ISO 19650 does not explicitly define discrete lifecycle phases, it provides a framework for managing information across the delivery phase, which encompasses design and construction, and the operational phase, covering asset management, maintenance, and end-of-life activities.

To contextualise SmartScan's product data flows, Table 1 was developed that maps the key information categories accessible through the platform against lifecycle stages aligned with ISO 19650 principles. These stages include concept/pre-design, design, procurement, construction/installation, operation/maintenance, and end-of-life /deconstruction.

The analysis highlights that SmartScan delivers structured, accessible information corresponding to the needs of each lifecycle stage. During the delivery phase, the platform supports sustainable material selection, regulatory compliance, and supplier verification by providing access to EPDs, technical specifications, and certifications. During the operational phase, SmartScan maintains access to installation instructions, maintenance guidance, warranties, and provenance information, supporting asset management and enabling circular construction practices such as refurbishment, reuse, and responsible deconstruction.

Overall, the adapted table demonstrates that SmartScan can bridge critical information gaps across the construction lifecycle, enabling traceability, continuity of information, and sustainability-oriented decision-making. By systematically linking physical products to verified digital records, SmartScan illustrates how DPP principles can be operationalised in practice while remaining consistent with ISO 19650 information management frameworks.

Table 1. SmartScan product data mapped to lifecycle stages.

Lifecycle Phase	Typical Information Required	Relevance to SmartScan
Concept / Pre-design (Delivery)	Sustainability targets, project requirements, high-level material performance data, environmental objectives, embodied carbon targets	Provides EPDs and material composition for early sustainability decisions
Design (Delivery)	Product specifications, environmental performance metrics, compliance documentation, certifications, dimensional and technical data	Supports product selection and integration of verified environmental data
Procurement (Delivery)	Supplier information, product certifications, logistics requirements, pricing data, installation prerequisites	Consolidates manufacturer data and certifications for procurement
Construction / Installation (Delivery)	Installation guidance, safety documentation, on-site handling instructions, product identification (QR/Barcode), delivery and logistics records	Links products to installation and safety documents
Operation / Maintenance (Operational)	Maintenance schedules, warranties, asset registers, performance records, service manuals	Maintains access to installation and maintenance information
End-of-life / Deconstruction (Operational)	Product composition, recyclability data, origin/manufacturer information, potential for reuse or remanufacturing	Enables traceability and supports reuse or recycling decisions

3.3 Implications for Sustainability and Circular Construction

The analysis of SmartScan demonstrates clear implications for promoting sustainable and circular practices within the construction sector. By providing structured, accessible product data, the platform supports more informed decision-making throughout the asset

lifecycle, particularly in areas critical to reducing environmental impact and enhancing material circularity. Access to EPDs and technical specifications allows designers and procurement teams to compare materials based on embodied carbon, recyclability, and compliance, facilitating low-impact material selection.

During the operational phase, the platform's availability of maintenance, provenance, and manufacturer data helps facility managers and contractors plan for efficient repairs, refurbishment, or component replacement, extending asset lifespans and reducing unnecessary waste. At the end-of-life stage, provenance and product composition data enable deconstruction teams to identify materials suitable for reuse or high-value recycling, supporting circular construction principles.

SmartScan also illustrates how digital product identification and global data standards can bridge information gaps that typically hinder sustainability initiatives. By linking physical products to verified digital records, the platform ensures that environmental and compliance information remains accessible and trustworthy, mitigating the risk of data loss across project handovers or organizational transitions.

Overall, these capabilities suggest that operational DPP–aligned tools like SmartScan can enhance traceability, reduce material waste, and strengthen the practical implementation of circular strategies, providing measurable support for sustainability objectives across construction projects.

4 Conclusions

This study investigated the usability and functionality of SmartScan, a digital tool designed to align with DPP principles and support sustainability and circularity in the construction sector. Through user testing and product data flow analysis, the research provides empirical insights into how a solution aligned with DPP application can enhance access to product information and inform decision-making across the building lifecycle.

The findings demonstrate that SmartScan enables stakeholders to retrieve relevant information throughout the product lifecycle, from procurement and installation to operation and end-of-life management.

SmartScan also supports sustainability and circular construction practices by improving traceability and enabling evidence-based decision-making. The system allows users to compare products, select lower-impact options, and plan for reuse, refurbishment, and responsible end-of-life management. By linking products to verifiable information, the system reduces data fragmentation and strengthens transparency and trust across construction supply chains. These results illustrate how global data standards and digital identification mechanisms, such as GTINs, can underpin interoperable, lifecycle-oriented product data management.

The practical implications of this study suggest that manufacturers, designers, contractors, and facility managers can adopt DPP-aligned tools like SmartScan to streamline access to product information, support compliance verification, and enhance circularity in building projects. From a policy perspective, these findings reinforce the importance of regulatory initiatives, including the Ecodesign for Sustainable Products Regulation and the Construction Product Regulations, which encourage digitalisation and standardisation of product data to promote sustainable construction practices.

Abstract. The article presents a case study on restoring an industrial building damaged by a missile strike during the armed aggression against Ukraine. The study shows how using existing structural elements in reconstruction can reduce costs, shorten schedules, and minimise environmental impact. The methodology includes assessing the building's life-cycle stages (design, construction, and operation) and analysing missile-strike damage to inform the restoration project. Visual inspections and instrumental measurements determined the building's technical condition and residual deformations. A restoration project was developed based on this data. The project retained the lower parts of the columns, their foundation nodes, foundations, plinth walls, and concrete floor. Damaged steel frames and cladding structures were replaced. Reusing the foundations, plinth walls, and concrete floor lowers construction costs and time, reduces construction waste (about 900 tons of concrete), and decreases embodied energy and CO_2 emissions (GWP $\approx$ 75,000 kg CO_2-eq and PENRT $\approx$ 640,000 MJ) compared to total demolition. The results confirm the technical feasibility and practicality of partial structural reuse in post-war reconstruction, supporting circular economy principles.

Keywords: Building Restoration · Airstrike Damage · Structural Reuse · Steel Frames · Foundations

1 Introduction

In real construction practice, it is extremely rare to encounter cases where a single design and research team can track the entire life cycle of a building – from its design stage to its reconstruction or demolition – as the life cycle of modern buildings ranges from 30 to 100 years, which often equals or exceeds the duration of a person's professional activity. At the same time, emergency situations can shorten a building's life cycle. In such cases, it is rational to involve the original authors of the primary design in the restoration of these buildings, as they are intimately familiar with the building's history.

The development of specific solutions and comprehensive general methodologies for the restoration of infrastructure destroyed by war must be carried out with significant attention to security [1]. For damage to building envelopes – walls or the infill of window and door openings – researchers are developing solutions for rapid, reliable restoration to return buildings to operational readiness [2, 3]. The main advantage of the technology proposed in [2] lies in its high assembly speed, without the need for heavy, specialised equipment, which is critical in dense urban areas and for the urgent return of buildings to operation. Article [3] conceptualises the term "wartime circularity," and the study demonstrates how urgent needs transform building components (used windows) that were considered waste into a vital resource. Given the scale of destruction and the resulting significant amount of construction waste, the need to transition from a traditional linear consumption model to a circular system that minimises waste and maximises resource efficiency at all stages of the building life cycle is particularly acute [4, 5]. Studies [5, 6] aim to optimise the accounting for and reuse of construction waste generated by war-related destruction in Ukraine.

Given the above, minimising construction waste and the possible reuse of materials, structures, and building components when designing the restoration of damaged objects is an urgent task.

2 Object of Study and Description of its Life Cycle

The object of study is an industrial warehouse building with a storage temperature regime of 0 °C. The building's life cycle (2018–2023) consisted of the following stages:

1. **Feasibility Study, 2018.** The building was designed in accordance with the forecasted indicators of the enterprise's technological needs for storing chilled products. According to the developed concept, a rectangular frame building was designed with two spans (2 × 20 m), overall plan dimensions of 40 × 35 m, and a height of 9.15 m to the bottom of the load-bearing roof structures (Fig. 1, left). Also, at this stage, an attached tiered rack for equipment placement was installed. The dimensions of the rack were 18.0 × 3.5 m. Preliminary solutions included the possibility of constructing an extension for an expedition zone.
2. **Development of the Working Project, 2019.** During the design process, a compromise space-planning solution was achieved by implementing a single-span (32 m) building.

   This led to optimising storage space allocation, reducing construction costs, and introducing variability in technological solutions for rack positioning. The building frame was reduced to dimensions of 32 × 29 m (Fig. 1, right). The use of steel frames with variable cross-sections allowed for a significant reduction in building height. An increase in the metal intensity of the building frame from 45 kg/m^2 (when using open-web trusses with a height of 4.5 m) to 97 kg/m^2 (when using variable cross-section beams with a height from the bottom of the eave node to the ridge of 3 m) proved to be economically feasible, considering the substantial reduction (approximately 1500 m^3) in the refrigerated volume of the warehouse.
3. **Building Construction, 2019–2020.** Construction began in mid-2019. The building was commissioned in the spring of 2020 (Fig. 2, left).

4. **Building Reconstruction, 2020–2021.** During the first season of the building's operation, the optimality of the frame's space-planning solution was confirmed, enabling changes to the layout of product storage systems without redesigning the floor plan. To further optimise technological processes, a reconstruction was designed and completed by the end of 2021 (Fig. 2, right), extending the expedition zone.
5. **Building Operation, 2022–2023.** The warehouse building is conventionally divided into three parts: the warehouse itself, an extension for product dispatch (expedition), and a technological extension for placing engineering equipment (tiered rack). In terms of space planning, the warehouse building was a rectangular frame building with overall plan dimensions of 28.6 × 32.0 m and a height to the bottom of the load-bearing roof structures of 9.3–11.2 m. The size of the tiered rack was 22.5 m × 3.6 m. The expedition zone was rectangular, with overall plan dimensions of 10.0 x 22.5 m and a height to the bottom of the load-bearing roof structures of 4.8 m. Foundations: monolithic reinforced concrete made of class C20/25 concrete on a natural base. The warehouse building frame: a metal frame in the form of a single-span portal. Columns and rafters: variable I-section, welded. Cross-section of main columns: flanges - 350 × 20 mm, webs - 300–950 × 12 mm. Rafters: flanges - 300 × 16 mm, web – 300–580 × 12 mm. The frame's spatial rigidity is ensured by a system of vertical and horizontal bracing. Tiered rack: a separate two-level steel frame. The building floor: 200 mm reinforced concrete of class C20/25 with a "topping" finish and a 50 mm layer of extruded polystyrene thermal insulation. External walls of the warehouse: 160 mm thick wall sandwich panels with a thermal conductivity coefficient of 0.022 W/m × K. Warehouse roof (including expedition): 160 mm thick roof sandwich panels with a thermal conductivity coefficient of 0.022 W/m × K. Doors and gates: metal, thermally insulated.
6. **Emergency Situation and Building Destruction, 2023.** In the autumn of 2023, during the armed aggression against Ukraine, a missile strike was carried out, resulting in significant destruction of the building. Emergency loads on the warehouse structures occurred due to a deflagration explosion of missile fuel inside the building. The blast wave caused additional damage to the main structures from fragments of other structures and the warhead, leading to local weakening of the cross-sections of the building elements. The overall stability of the main warehouse structures at the time of the inspection was maintained; the frame structures did not collapse. The duration of the fire, caused by the combustion of missile fuel residues, did not exceed 15–20 min.
7. **Assessment of the Technical Condition of the Main Building Structures, 2023.** This stage of the life cycle is described in more detail in Sect. 3 of this work.
8. **Project for the Restoration of the Building with the Reuse of Preserved Parts, 2023–2024.** This stage of the life cycle is described in more detail in Sect. 4 of this work.

Fig. 2. Constructed warehouse building with a tiered rack and an attached expedition zone.

3 Description of the Consequences of the Missile Strike and Structural Damage

The epicentre of the explosion was located in the main part of the building. During the explosion in the warehouse section, the wall and roof sandwich panels collapsed, effectively acting as blast-relief structures (even though they were not designed for this type of impact). The blast wave propagated, partially offset on one side by the deformation and displacement of racks filled with products (bulk density of 1–1.5 t/m^3), while on the other side, it created conditions for the directed action of the accidental load on the building structures. Consequently, the load-bearing structures of the tiered rack sustained the greatest impact, leading to excessive deformations, with displacements of its upper part exceeding 600–700 mm.

The warehouse roof and end facades became other directions of the blast wave's targeted impact. The most significant damage was noted in the load-bearing roof structures: general bending and distortion of the rafters, tearing of individual wall or flange sections of the beams, and the tearing away of entire rafter fragments. The roof purlins sustained significant bending (exceeding 1/200 of their length). Approximately 40% of the purlins collapsed. Based on the visual inspection results, the technical condition of the rafters, purlins, vertical and horizontal bracing, and engineering networks was found to be critical (Fig. 3).

Fig. 3. Consequences of the missile strike on the warehouse part of the building.

Fig. 4. Damage to the columns.

Only the foundation structures, the floor, and the fire-fighting water supply networks at the building's entry point were found to be in relatively satisfactory condition, which is explained by the shielding of this area by the monolithic structure of the warehouse plinth wall. To determine the technical condition of the main frame columns and a portion of the gable columns with the aim of maximising their preservation, it was decided to establish the columns' deviations from the vertical and their design positions.

During instrumental measurements, the dimensions of damage to the structural elements were established:

– concrete foundation structures: spalling of the concrete cover layer and protruding parts of the plinth measuring 100 × 100 mm; crack propagation around the columns with lengths of 100–300 mm and opening widths of a = 0.2–5.0 mm; separation of the plinth walls from the floor structure;

– concrete floor structure: spalling of the surface concrete cover layer (impact depth up to 20 mm); punctures in areas where structures fell or fragments penetrated;
– steel frame columns (Fig. 4): overall bending of elements up to 700 mm (for the tiered rack columns), local flange buckling (up to 100 mm), cross-sectional twisting, and through-punctures by fragments (up to 20 mm in diameter);
– steel frame rafters (Fig. 3): damage similar to that of the columns but with significantly larger defect dimensions; approximately 30% of purlins collapsed; torn flanges and webs of the main beams (on 2 frames); and a total absence of a fragment of one of the rafters over a length of about 3 m.

4 Method of Building Restoration with the Reuse of its Parts and Assessment of Environmental Efficiency Indicators

The main idea of the warehouse building restoration project was to preserve as many elements and structures as possible that survived the emergency beyond design loads, thereby saving funds, reducing construction time, and minimising environmental impact.

Based on the technical inspection results, elements in a critical state were dismantled: building envelopes, technological equipment, engineering networks, the entire structure of the technological tiered rack, and the roof purlins. Concrete elements were cleaned of organic decomposition products (food products stored in the warehouse), soot, carbon deposits (from the fire), and residues of toxic missile fuel. A geodetic survey conducted before partial dismantling established deviations of the columns from their design position at the eave node level of 20–30 mm.

The dismantling of the damaged tiered rack frames and the expedition roof beams revealed that the rigidly fixed columns had significant residual stresses resulting from their combined action within the deformed structural scheme of the building frame as a whole. Therefore, column positions were repeatedly measured after the complete dismantling of the rafters in the main part of the warehouse (Fig. 5).

Fig. 5. Condition of the building frame after the dismantling of the roof structures.

The point cloud of the steel columns' actual positions was compared with the frame design model. The deviation of the top of the main frame columns after their release from

the rafters showed significant residual deformations, including twisting of the column cross-sections and deviations from the design position of 30–70 mm. The gable posts sustained deviations of up to 400–500 mm with bends along the length of the element up to 150 mm. At the same time, the position of the lower parts of the columns (at a height of up to 1 m from the floor level) practically coincided with the design position, and deviations did not exceed ±5 mm.

Based on the survey results, a building restoration project was developed, which included the following measures:

- cutting the existing main columns of the building at a height of 1 m from the floor level, gable columns at a height of 300 mm, and expedition columns at 500 mm;
- development of connection nodes for the new building frame with the remains of the existing columns;
- all foundations, the plinth wall, and the building's concrete floor were left intact. The project provided for local repair of the floor structure and restoration of the surface with epoxy self-levelling compounds.

The use of existing lower parts of the columns, all foundations, the plinth wall, and the concrete floor in the restored building reduces the cost of reconstruction, the duration of construction work, and the amount of construction waste (approximately 900 tons of concrete) compared to complete demolition and new construction. Even a partial decision to fully replace the frame columns would have necessitated dismantling more than 70% of the entire floor structure and most anchor bolts, requiring their replacement with chemical anchors, which in turn could affect the overall reliability of the restored building.

To quantify the environmental impact, environmental performance indicators were used: primary energy consumption, expressed as total non-renewable primary energy (PENRT, MJ), and global warming potential (GWP, kg CO_2-eq). PENRT and GWP were chosen because they directly quantify the demand for non-renewable energy sources and greenhouse gas emissions, which are the main drivers of climate change in the built environment. These indicators were calculated for all foundations, the plinth wall, and the concrete floor of the building based on data from established databases (Ökobaudat [7]) according to a simplified scheme (phases A1–A3 "cradle-to-gate"), based on the assumption that the building would have been completely dismantled and rebuilt in the same dimensions and structures.

For the total volume of construction materials – concrete classes C8/10, C12/15, C20/25, steel (reinforcement and plate elements), and extruded polystyrene for all foundations, the plinth wall, and the concrete floor of the building – the obtained indicators were PENRT $\approx$ 640,000 MJ and GWP $\approx$ 75,000 kg CO_2-eq.

Thus, even a simplified analysis of environmental indicators demonstrated the expediency of the structural reuse strategy for post-war reconstruction, aligning with the principles of the circular economy.

5 Conclusions

The study, conducted on the example of a warehouse building damaged by an explosion, confirmed the technical feasibility and economic and environmental expediency of the strategy for the partial reuse of existing structural elements in the reconstruction of buildings and structures. This approach requires greater costs for technical inspection, full control by the design organisation over demolition, and the execution of intermediate variable calculations for the installation of a new structural system with maximum use of preserved elements from the previous building.

The connection nodes of the steel columns to the foundations, the monolithic reinforced concrete foundations themselves, the plinth wall, and the concrete floor maintained their load-bearing capacity and suitability for continued operation after sustaining significant, beyond-design emergency loads. Using these elements in the restored building made it possible to significantly reduce the volume and duration of construction work; the amount of construction waste generated (≈900 t of concrete); non-renewable primary energy consumption (PENRT ≈ 640,000 MJ); and lower the global warming potential (GWP ≈ 75,000 kg CO_2-eq) compared to the option of complete demolition and new construction of these structures. The approach demonstrated in this work can serve as an important tool for reducing economic, resource, and environmental losses during large-scale post-war reconstruction in Ukraine or in the restoration of buildings and structures affected by other emergencies.

Abstract. The paper presents a simplified rapid assessment method for evaluating the load-bearing capacity of hot-rolled steel beams (I-beams, channels, and Z-sections) with initial horizontal curvature. The main objective of the work is to assess the technical feasibility of reusing such elements in new construction and reconstruction projects. This allows for transforming damaged or deformed steel beams from waste into a valuable resource, significantly extending their life cycle and reducing the need to produce new steel structures. The computational approach is based on accounting for additional torsional stresses arising from geometric imperfections. Experimental studies of beams with a span of 1.5 m and significant deviations (40–60 mm) confirmed that, even with deformations exceeding regulatory tolerances, the elements maintain a sufficient safety margin for continued operation. The proposed methodology provides engineers with a reliable tool for rapid decision-making on the safe reintegration of non-ideal steel profiles into construction production, a key step towards implementing circular economy strategies.

Keywords: Steel Thin-Walled Beams · Torsion · Curved Beams · Damages · Structural Reuse · Life Cycle Extension · Circular Building Components

1 Introduction

Recent trends in building science are increasingly focused on reducing greenhouse gas emissions at all stages of construction – from the manufacturing of building materials and structures to their disposal. One method for reducing CO_2 emissions and economic costs is the reuse of elements. At the same time, until the development of the second generation of Eurocodes [1], the very concept of an "existing" structure was practically unregulated, as it must first exist to be reused. This necessitates a fundamental shift in the design approach, because when designing new structures, engineers rely on idealistic concepts of elements – their shape, physical and mechanical properties, etc. The geometry of structures is assumed to be virtually ideal, with some influence from "accidental" geometric imperfections. Such an approach cannot be applied to existing structures, as

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 38–46, 2026.
https://doi.org/10.1007/978-3-032-34930-9_5

in most cases, engineers can clearly determine both the materials' physical and mechanical properties and the structure's geometric parameters. After assessing the technical condition of an existing structure, a conclusion can be drawn regarding its compliance with EN 1993 [2] and EN 1090-2 [3]. In case of compliance, reuse is possible. Full compliance of an existing structural element with the requirements of current standards is more often the exception than the rule, as in most cases, the need for dismantling arises for structures in unsatisfactory condition or after significant accidental impacts – fire, earthquake, explosions. Wars also result in a large number of elements, including steel ones, that can be reused, even though they may not meet the requirements of EN 1090-2 [3]. One common defect of steel beams is curvature in the horizontal plane. Analysis of regulatory documents from other countries [4, 5] indicates that the use of curved structures is entirely possible – for example, for buildings with low consequence classes.

One of the main barriers to the large-scale reuse of steel elements is the lack of simple, rapid, and accessible methods for assessing the load-bearing capacity of non-ideal profiles (e.g., curved or damaged) [6, 7]. Modern approaches to circular construction actively implement the concept of material passports [8], which record all physical, mechanical, and geometric characteristics of elements for their safe reintegration after dismantling. The simplified methodology proposed in this work can be an important component of the algorithm for assessing the suitability of steel beams for inclusion in such a passport: it allows rapid on-site determination of the load-bearing capacity of a curved element and confirms its compliance with reuse requirements [9]. Furthermore, the reuse of steel is significantly more efficient than recycling, as it allows for the preservation of almost all embodied energy without the energy costs of remelting. According to current meta-analyses, direct reuse reduces the global warming potential (GWP) by 40% compared to recycling and by up to 97% compared to producing new steel, providing embodied energy savings of 90–95% [10, 11]. Therefore, the aim of this work is to present a simplified methodology for assessing the strength of a steel beam with deviations from straightness in the plane perpendicular to the bending plane for the purpose of its reuse.

2 Simplified Methodology for the Strength Verification of Beams with Curvatures

Modern methods for analysing steel structures using the finite element method enable calculations of structures with various types of imperfections and damage. At the same time, the cost of such calculations can exceed that of a new structure, not to mention the cost of existing elements. To evaluate the strength of existing structures, it is advisable to use rapid assessment methods that enable on-site decision-making on the feasibility of preserving a damaged element and its careful dismantling.

The issue of calculating steel beams with initial curvature in the horizontal plane (Fig. 1) was considered by A.R. Rzhanitsyn [12]. Based on the theory of thin-walled rods by V.Z. Vlasov [13], he proposed a theory for calculating I-beams with horizontal curvature. The goal set by A.R. Rzhanitsyn was to maximise the utilisation of steel beams damaged during the Second World War. Work [12] describes in detail the procedure for

determining the additional forces arising in a steel I-beam that has received an initial horizontal curvature. The beam's curvature was assumed to be a parabola. However, this problem remained undescribed for beams with channel and Z-sections.

The work by Hudz S. et al. [14] is dedicated to the theoretical solution of the problem of finding the allowable curvature of beams.

Fig. 1. Examples of beams with overall out-of-plane curvature from the moment action: a) I-beam roof purlins after a fire; b) channel purlins after a fire.

In this work, the authors have supplemented the methodology proposed by A.R. Rzhanitsyn for I-beams with recommendations for the analysis of steel beams with channel and Z-sections and have also verified it experimentally.

In work [12], the author established the principle that in a beam with horizontal curvature, in addition to normal stresses from bending, torsional stresses also arise, i.e.:

$$\sigma = \sigma_{bend} + \sigma_{\omega}, \tag{1}$$

where σ_{bend} – normal stresses arising from bending, σ_{ω} – normal stresses arising from the warping (torsion) of the cross-section.

In the general case, the warping stresses are determined by the formula:

$$\sigma_{\varpi} = -E \cdot \theta'' \cdot \varpi, \tag{2}$$

where E – modulus of elasticity of steel, θ'' – second derivative of the twist angle function, ω – sectorial area at the point where the stress is determined.

The laws for determining additional torsional stresses, as presented in [12], are shown in Table 1.

Table 1. Additional torsional stresses in the beam.

	Type of load	
	Concentrated force at mid-span	Uniformly distributed load
σ_{ϖ}	$2 \cdot \frac{P \cdot f}{\ell} \cdot \frac{E}{G} \cdot \frac{\omega}{I_t} \cdot v$	$q \cdot f \cdot \frac{E}{G} \cdot \frac{\omega}{I_t} \cdot v$
v	$1 - \frac{th\left(k\ell/2\right)}{k\ell/2}$	$1 - \frac{th\left(k\ell/2\right)}{k\ell/4} \cdot \frac{th\left(k\ell/2\right)}{k\ell/4}$

In Table 1: P – concentrated force; q – uniformly distributed load; f – beam camber (deflection arrow); G – shear modulus; $k = \sqrt{\frac{GI_t}{EI_{\varpi}}}$ – torsional characteristic; It, I_{ω} – torsion constant and sectorial moment of inertia, respectively; ℓ – beam span.

While the coefficient v in Table 1 accounts for the type of loading, the sectorial area ω accounts for changes in stress due on the type of cross-section. This is particularly evident from formula (2). By multiplying the ω diagram by the constants E and θ'' (for a specific load value), we obtain the σω diagram.

For the cross-sections considered in the article (Fig. 2), the sectorial area diagrams are shown in Fig. 3.

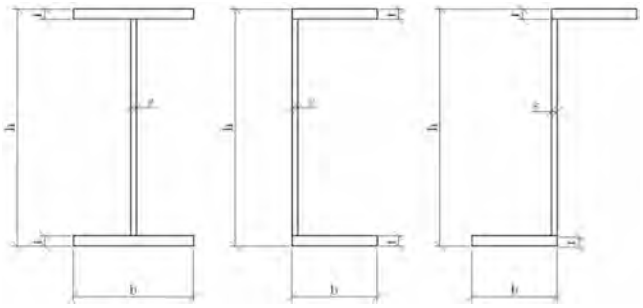

Fig. 2. Beam cross-section diagrams.

In Fig. 3b, the parameter α_x is the distance to the centre of torsion, which is determined by the formula

$$\alpha_x = -\frac{b^2 \cdot t}{2 \cdot b \cdot t + \frac{h \cdot s}{3}} \tag{3}$$

where *b, t, h*, and *s* are the geometric parameters shown in Fig. 2.

In Fig. 3c, the parameter d is the distance from the web face to the zero sectorial coordinate, determined by the formula

$$d = \frac{b^2 \cdot t}{h \cdot s + 2 \cdot b \cdot t}, \tag{4}$$

where *b, t, h*, and *s* are the geometric parameters shown in Fig. 2.

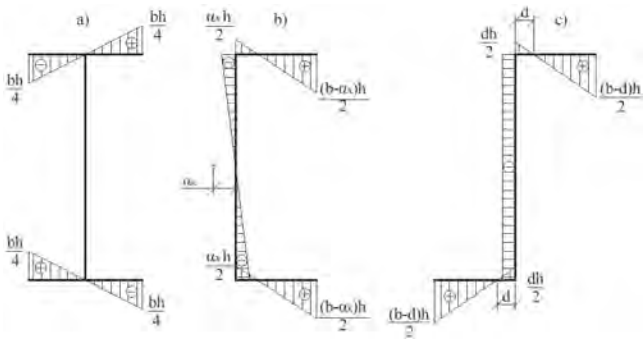

Fig. 3. Sectorial area diagrams for different types of cross-sections.

3 Experimental Verification of the Proposed Methodology

To verify the presented methodology for calculating steel beams with horizontal curvature, tests were conducted on three steel beam specimens. The specimens were made of hot-rolled I-beams No. 10 and No. 12 [15]. The overall bending of the beams ranged from 4 to 6 cm. The beam spans were 1.58 m, 1.59 m, and 1.61 m. The testing of the specimens was carried out on a special setup (Figs. 4 and 5) that allowed the application of a concentrated force without preventing torsional deformations.

The twisting of the cross-section was measured using an optical quadrant. During the experiment, a twist of the beam cross-section with a maximum angle of 8°19′ was recorded.

According to the experimental data, the maximum stress in the cross-section of specimen B1 (I-beam No. 10, deviation from straightness ($d_{fs} = 4$ cm) was 109.2 MPa, 163.8 MPa, and 254.1 MPa (assuming Hooke's law) under loads of 10 kN (moment in the section M = 3.75 kNm), 15 kN (M = 7.5 kNm), and 20 kN (M = 11.25 kNm), respectively, which is 36% higher than the stresses in a non-curved beam.

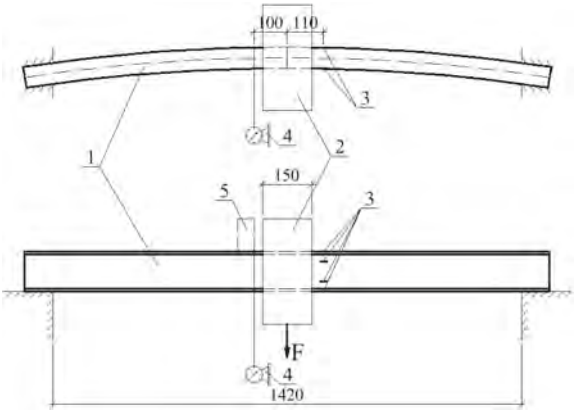

Fig. 4. Diagram of the experimental setup for the bending-with-torsion test: 1 – tested specimen, 2 – steel ring, 3 – strain gauges, 4 – deflection gauges, 5 – optical quadrant.

Fig. 5. Photo of the experimental setup.

When comparing the diagrams for specimens B2 (I-beam No. 12, $d_{fs} = 6$ cm) and B3 (I-beam No. 12, $d_{fs} = 4$ cm), it can be concluded that with a slight increase in horizontal bending (from 4 cm to 6 cm), normal stresses increase significantly (by 26%).

When plotting diagrams based on the experimental data, the development of stresses due to cross-sectional torsion in the I-beam flanges is clearly visible. In pure bending, the theoretical stress diagram in the I-beam flanges would have the shape of a rectangle. Adding the diagram shown in Fig. 3a yields a trapezoidal diagram, as observed during the experimental studies (Fig. 6).

The results of stress calculations using the simplified methodology, compared with those from strain gauges, for specimens B1 and B2 (under a concentrated force F = 10 kN at mid-span) are presented in Fig. 6. The results correlate well, and the remaining discrepancies are due to the accuracy of the measuring instruments and the impossibility of creating ideal conditions for such an experiment.

All of the above leads to the conclusion that the calculation methodology presented in Sect. 2 for analysing steel beams with initial horizontal bending is sufficiently accurate and can be recommended to engineers for further application in the practice of new construction and in the verification calculations of steel beams in operation.

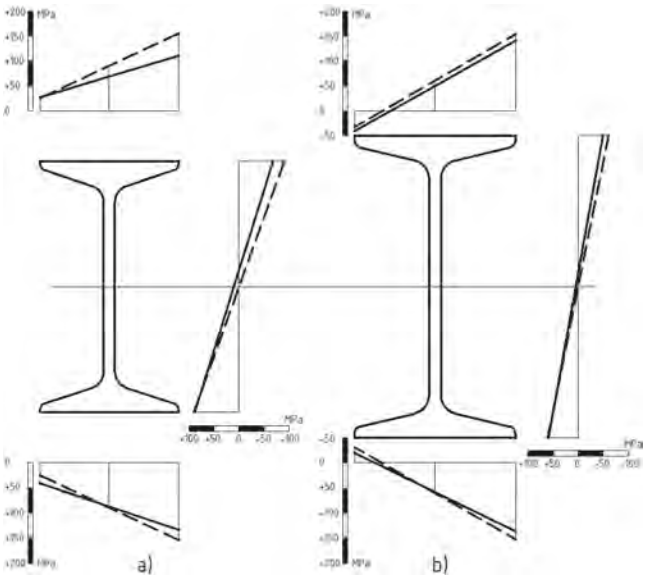

Fig. 6. Diagram of normal stresses in the cross-section of a curved beam under a load of 10 kN: a) specimen B1, b) specimen B2.

4 Conclusions

The methodology presented in this work allows the determination of stresses in beams that have developed a smooth curvature (described by a parabolic function). The methodology can be used both for beams damaged under load and for the calculation of new curvilinear beams. The calculation can be performed for three types of beam cross-sections – I-beam, channel, and Z-section – as well as for the two most common types of loading: a concentrated force at mid-span and a uniformly distributed load. The assumptions underlying the emergence of torsional normal stresses in the methodology were confirmed by experimental studies. The implementation and use of this methodology in the practice of sustainable construction allows for reduced costs in expert assessments of the technical condition of steel beams with this type of damage. It also shortens the decision-making time regarding the possibility of reusing beams with horizontal bends.

By implementing the proposed rapid assessment method, it is possible to significantly increase the share of direct reuse of steel beams. According to surveys of demolition companies in the UK and Europe, currently only about 5% of steel elements are directly reused, while the rest are sent for remelting [16]. The use of simple assessment tools like the one proposed will allow for the saving of thousands of tons of steel from remelting annually in just one region, transforming potential waste into a valuable resource for

new construction and renovation. The embodied energy savings from reusing one steel beam compared to producing a new one reach 90–97%, and compared to recycling, 40–80%. This directly reduces the whole-life carbon of buildings and contributes to achieving circular economy goals, overcoming barriers related to material passports, and transitioning from a linear to a regenerative construction model [10, 11]. Salvaged and reused steel beams reduce both economic costs and the construction process's carbon footprint.

Abstract. For modular building envelope construction in Canada, panelization is implemented through multiple manufacturing methods. While panelized systems can reduce construction time and cost, less well known is their end-of-life (EoL) impacts and reuse potential after building demolition. Current Canadian construction and demolition of panels tend towards landfilling rather than reuse. Modular panel manufacturing methods include fused panels where insulation is permanently attached to a sheathing board, such as sandwich insulation panels, or prefabricated panels which allow for full component disassembly at EoL. This paper compares EoL performance between these two methods, where both panels use cement fibre boards as the sheathing component. Using publicly available environmental product declaration data, life cycle assessment (LCA) EoL impacts are calculated for the demolition scenarios for the same functional unit. Exploring future circularity potential through a literature review of strengths, weaknesses, opportunities, and threats (SWOT) analysis clarifies the end of life and reuse potential of both panel types. A discussion of Canadian policies, markets, construction practices, and material quality assessments required for reuse identifies barriers and future opportunities.

Keywords: modular construction · sheathing panel · reuse · building envelope · end-of-life

1 Introduction

Considerations of end-of-life (EoL) impacts and circularity for modular building elements are in early development in Canada, with modular building still a relatively novel practice in industry [1]. How a modular panel manufacturing practice impacts the EoL circularity is essential for understanding the long-term impact of new building techniques. This study analyzes the EoL impacts of two different panel designs that serve the same function of a building sheathing panel, one with an encapsulated (fused) design and the other with a built-up panel designed for disassembly (DfD).

Circularity with respect to buildings aims to reduce new material production and use by integrating existing building materials into new constructions through recovery, retention, and reuse [2]. Consideration of how materials are reused at the end of life, and reducing demolition waste are integrated into strategies for future building codes and environmental policies [3].

Parallel to the research and development of circular economy practices in building construction is the development of modular integrated construction, or prefabricated construction methods [4]. Prefabricated components, such as structurally insulated panels with an exterior sheathing board and insulation, are becoming more common in Canadian buildings as a method of modular construction [4].

While modular construction principles may allow for reduced construction waste, given the greater potential for automation and factory/off-site manufacturing [5], there has been little focus on EoL impacts of modular components. A concern is that some of the focus on assembly speed and energy performance of prefabricated components may limit circularity [4]. Quantitative analysis of the EoL impacts of modular buildings is limited. Wen et al. [6] conducted a case study of high rise steel framed buildings in Hong Kong comparing the EoL impacts of a modular constructed system with a built-on-site case. Findings indicated carbon emission reductions for the modular case, with even more reductions if materials could be reused. The EoL transportation emissions materials were still significant in both cases [6]. More research concerning EoL and circularity of materials would fill a gap in understanding the impacts of this modular construction trend.

This research examines sheathing panels, a sub-component of a modular system, that can be used in new construction or building retrofit projects. The panels have integrated insulation, structural support, air and vapour barriers, and fire resistance that would be seen in multi-unit residential, commercial, or industrial buildings. Sheathing panels are used in Canadian buildings since both thermal performance and construction efficiency are desirable in the Canadian construction industry [7]. There are guidelines and standards for mechanical and thermal performance of structural insulated panel (SIP) systems in Canada, but there is a lack of regulation for LCA and EoL performance reporting for these applications [7]. Sheathing panels can either be constructed of exterior sheathing with a fused insulation [7], or as a built up panel with bio-based insulation [8, 9].

This paper focuses on EoL impacts of building envelope panels using exterior fibre cement sheathing boards, including boards containing Magnesium Oxide (MgO) for construction in North America [10]. The sheathing boards were components of a cradle-to-gate LCA in British Columbia by Li et al. [11], which compared MgO SIP systems to framed-in-place sheathing panels. Given the high environmental impact of initial raw material production [6], especially in cement, reuse of modular panel systems or components can reduce the long term environmental impact of buildings.

In Canada, construction material reuse focuses mainly on individual building components such as structural steel, framing materials, and masonry [12]. Material reuse in buildings in Canada varies regionally and tends toward project specific initiatives [1]. For some municipalities, there are guidelines for reducing construction waste and for careful deconstruction, such as Vancouver's diversion threshold of 75% for clean wood [1]. Incentives for material circularity in Canada do exist, such as the Canadian

Standards Association (CSA) guideline CSA-Z782–06 for design for disassembly and adaptability in buildings [13]. Prefabrication companies are also involved in adaptive reuse and circularity, but not yet at a level of market maturity [1].

Given the early development in building circularity economy practices in Canada, and varying modular construction methods, this paper aims to determine EoL impacts of two modular sheathing panel designs, with either existing demolition ("business-as-usual") or circular reuse paths.

2 Materials and Methods

Quantitative and qualitative methods were used to consider the EoL impacts of both modular panel systems. The business-as-usual EoL scenario for the panels is examined using quantitative methods. A future scenario, using circular economy principles, is explored using a qualitative literature synthesis in the form of a SWOT analysis.

The modular panel construction methods are referred to as (1) a 'fused panel' and, (2) a 'design for disassembly (DfD) panel'. The fused panel is a sheathing board where insulation is permanently attached to a panel coated with air and vapour barriers. The DfD modular panel design is built of individual elements. That is, it is designed for disassembly into individual components at the end of life, including exterior vapour barrier, sheathing, lightweight steel framing, and insulation.

The design for the DfD panel was adapted from the cellulose retrofit panels previously tested and reported on by Natural Resources Canada [8, 9]. Panel components and the weight of functional units are given in Table 1.

Table 1. Panel composition with EPD reference by material

System	Fused panel	DfD panel
Materials	MgO sheathing board, polyurethane rigid insulation foam (PUR) [14]	Gypsum core fiberglass sheathing board [15], loose fill cellulose [16], membrane [17], steel framing [18]
Panel mass per functional unit	9.2 kg	9.92 kg

For the quantitative analysis, EoL stage LCA impacts (C1-C4) are calculated based on environmental product declaration (EPD) values. The masses of construction waste and recyclable material for each panel design are also determined. Panel designs are based on a functional unit of 1 m^2, with a thermal resistance (R value) of 1 m^2K/W. EPDs collected used TRACI 2.1 methods for North American markets, in accordance with ISO 14025 and ISO 14044. Where possible, product specific EPDs were used, for the fused panel [14], sheathing board [15], cellulose [16], and membrane [17], but a sectorial average EPD was used for the framing [18].

There can be high uncertainty in the EoL LCA data [6], so this paper provides comparisons between systems, rather than an absolute authority on environmental impacts of each system.

The qualitative impacts in a circular economy EoL scenario are considered through a literature review grounded in the strength, weakness, opportunities and threats (SWOT) analysis method. Many SWOT analyses of building construction use a combination of a literature review and surveys, such as Sesana et al. [19]. This project uses a literature review for SWOT analysis, with potential future work to develop research questions and surveys for the architecture, engineering, and construction (AEC) industry.

3 Results and Analysis

3.1 Business-As-Usual EoL Scenario

For EoL environmental impact, LCA impacts for scopes C1 to C4 were calculated for both panel designs as seen in Table 2.

Table 2. EoL impacts for LCA scope C1, C2, C3, C4 inclusive

Impact Category	Fused	DfD
Global warming potential (GWP) [kg CO_2 eq.]	2.12E-01	1.29E+00
Ozone depletion potential (ODP) [kg CFC-11 eq.]	5.49E-05	6.67E-09
Acidification potential (AP) [kg SO_2 eq.]	4.46E-09	2.20E-03
Eutrophication potential (EP) [kg N eq.]	7.08E-04	2.25E-03
Smog formation potential (SFP) [kg O_3 eq.]	1.60E-02	4.33E-02
Abiotic Depletion Potential -fossil fuels (ADPF) [MJ]	1.4E+00	1.08E+00

Depending on the impact category, each panel design can perform better than the other, as visualized in Fig. 1, with impact value max normalized using Eq. (1), where NV is the normalized value, V is the value given for the panel in Table 2, and V_{max} is the maximum value for impact category between the two panel designs.

$$NV = V/V_{\max} \tag{1}$$

In terms of GWP, the fused panel has a lower environmental impact, likely due to the lack of steel framing. The fused panel has higher ADPF impacts, and the DfD panel has a higher GWP impact.

Transport of demolished materials can be a significant factor in EoL impacts [6], so the mass of waste was calculated for each scenario, as seen in Table 3, using stated waste and recycling rates from EPD documents.

For the fused panel, screws that would be included in the functional unit were partially recycled but the rest of the construction waste is going to the landfill. For the DfD panel, 92% recycled steel was assumed based on the product EPD. Even though the design for disassembly panel could theoretically have higher recycling or reuse rates by disassembly of individual components, this base EoL scenario assumed that contractors would still follow typical landfilling practices for the fibre cement board, cellulose insulation, and membrane. The overall masses of waste to landfill for each panel are within 1.2% of each other (9.22 kg vs. 9.33 kg).

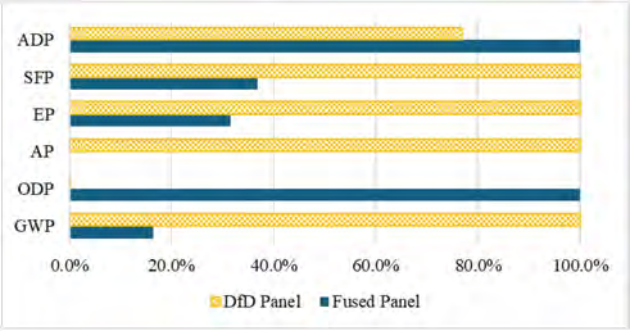

Fig. 1. Normalized LCA EoL impacts by panel

Table 3. Panel Waste Quantities

	Fused panel [14]	DfD panel
Mass as mixed construction waste [kg]	9.27	9.92
Waste to landfill [kg]	9.22	9.33
Waste to recycling [kg]	0.053	0.460
% Total mass recycled	0.58%	4.64%

3.2 Circular Economy End-of-Life Scenario

This synthesis of threats and weaknesses drew upon barriers discussed by Wuni and Shen [20] in their review of barriers to adaptation of modularity in construction. Both panel designs would experience shared barriers to reuse in circular applications such as costing accuracy [1], risk aversion by contractors and customers, or excessive regulation on used materials [21]. Still, there are differences in how each panel could be used in circular applications, as described in Tables 4 and 5.

Table 4. SWOT of circularity of fused panel

Strengths	Labour savings in demolition – full panels, ease of reuse for complete panel
Weaknesses	Damage risk in disassembly which may result in the full panel becoming unusable (process barrier), minimal recyclable materials (technical barrier)
Opportunities	Material traceability for a panel market as fused panels can be more easily stored and transported as complete products, minimizing perceived risk [21]
Threats	Lack of market for fused panels (financial barrier), lack of material testing standards for full panel (knowledge and process barriers) [1]

The fused panel best case scenario for circularity is full reuse of all panels; a more likely scenario is to reuse and storage of the largest undamaged panels with debonding of

cement fibre boards and insulation to downcycle materials where possible [1]. Worst case for the fused panel is even with reuse as a goal, materials are damaged and can only be landfilled. As a building element, the fused panel can be easily traced, as all components are together in the panel. DfD panel is designed for adaptation and flexibility; individual components will require more care to ensure traceability but are easier to reuse in multiple applications.

Table 5. SWOT of circularity of DfD panel

Strengths	Components can be reconfigured for different applications if select parts of the panel are damaged [6], lighter weight of materials, reducing individual transport impacts
Weaknesses	Increased labour time in disassembly [21], potential breakage and damage of fibre cement sheathing during deconstruction (technical barrier)
Opportunities	Simpler market for individual components compared to whole panel (aesthetic barrier and use flexibility)
Threats	More documentation for a material bank required for each component (process barrier)

In terms of circularity, many researchers assume when conducting quantitative EoL analysis that a market for materials will exist (e.g., see Wen et al. [6]). This is a threat for the fused panel, as the complete panel component is less likely to be in demand across a broad range of building applications compared to individual elements in the DfD panel.

The central difference between the two panel designs is the level of disassembly possible – the strength of the fused panel is in its traceability as a single component. The fused panel may be faster to deconstruct as a single piece without damage to the cement fibre board compared to the DfD panel. If the DfD panel requires full disassembly there are weaknesses in the time to deconstruct, and a threat with traceability.

Expanding on this analysis, future research could survey stakeholders in the AEC industry regarding priorities for material reuse related to modular panels. A survey could explore whether traceability and storage (fused panel) or full material reuse and ease of recycling (DfD) is more desirable. As new panel designs and manufacturing methods are introduced, it is essential that new materials are not having high impacts to the environment, or create an environmental burden at end of life [3].

4 Conclusion

EoL scenarios for two novel modular panel designs in Canada using current landfilling scenario and circular economy potentials in future practice were presented.

The current practice EoL scenario based on publicly available EPD data showed the environmental impacts in the C1 through C4 scope were close in scale, with no design having the least impact in all LCA categories. This quantitative analysis is limited by EPD availability for materials that includes C1-C4 impacts.

While the current EoL accounting did not conclusively determine if one panel design was preferred, the circular economy analysis for EoL raised important questions on how diverging priorities of stakeholders will influence which panel is desired. While fused panels may not have a guaranteed market, they are more traceable and faster to deconstruct. A DfD style panel may be slower to deconstruct, with more potential for damage to the cement sheathing board, but it will likely have a better reuse market for individual components and potentially reduce transportation impacts through reduced weight of individual components.

This is an early exploration of the EoL scenarios for modular panels. Further research on circularity in initial designs using prefabricated panels is recommended, especially direct consultation of the AEC industry and on-site experience.

Enhancing Natural Fibre Textile Reinforcement – Effects of Impregnation Materials and Methods

Malte Kaliske(✉) and Marcus Ricker

Chair of Structural Concrete, TU Dortmund University, Dortmund, Germany
malte.kaliske@tu-dortmund.de

Abstract. In recent years, the importance of non-metallic reinforcement made of natural fibres has been gaining relevance. Previous investigations have suggested that impregnation is a critical aspect for the mechanical and long-term performance of concrete components reinforced with natural fibres.

This study aims to understand the influence of distinct impregnation methods and materials, namely mechanical rolling and vacuum impregnation, on the mechanical performance, bonding behaviour, and durability of natural fibre yarns intended for textile-reinforced concrete.

To this, reinforcements made of sisal, hemp, and flax yarns, as well as selected hybrid configurations, were systematically examined. The tensile properties were determined prior to textile production in accordance with a standardised fibre strand testing procedure. Multiple specimens were tested to capture the material variability and to evaluate the resulting variation in stiffness and strength.

The results indicate that strength, stiffness, and scatter varied substantially depending on material and processing method. Vacuum impregnation increased the modulus of elasticity from 1.8 up to 2.2 times compared to the rolling impregnation with notable differences across yarn types and combinations. Additionally, the results suggest that appropriate pairing of yarn material and impregnation technique can significantly enhance load-bearing capacity and control deformability.

This study provides a systematic comparison of impregnation techniques for various natural fibre yarns, showing how these methods interact and influence mechanical performance. The comparison supports the selection and combination of suitable yarns and impregnation techniques for textile reinforcements in structural concrete. It also identifies opportunities for further optimizing natural fibre reinforcement systems to achieve durable and structurally efficient concrete components.

Keywords: Natural fibre textile reinforcement · Textile-reinforced concrete · Impregnation methods

1 Introduction

In recent years, the importance of non-metallic reinforcement in concrete construction has steadily increased, with synthetic fibres such as carbon, glass, and basalt being predominantly used (e.g. [1–3].). Although these materials exhibit excellent mechanical

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 56–63, 2026.
https://doi.org/10.1007/978-3-032-34930-9_7

properties and high resistance to corrosion, their production is often energy-intensive, costly, and associated with a considerable CO_2 footprint [1, 2, 4, 5]. Against this backdrop, natural fibres have increasingly come into focus as a sustainable and cost-effective alternative [1, 6, 7]. Plant-based fibres such as hemp, flax, and sisal are widely available in multiple geographic regions, are environmentally-friendly, thereby, offering the potential to replace conventional synthetic fibres in various composite materials [6, 7].

Despite these benefits, the widespread application of natural-fibre textiles in reinforcement technology still faces significant challenges due to their mechanical performance and durability [1, 6, 7]. A central issue is the degradation of the fibres in the highly alkaline environment of concrete, which can reduce their long-term bond and load-carrying capacity [6, 7]. Furthermore, natural variations in fibre thickness, purity, and inherent mechanical properties increase the complexity of their industrial production process, leading to increased variability in material characteristics [6–8]. To overcome these shortcomings, the impregnation of textiles is essential to improve the internal cohesion of the fibres and to protect them from external chemical influences. Impregnation is also relevant for the handling and placement of the textiles into [6–8]. Natural fibres exhibit inherent material variability, including variations in thickness, purity, and mechanical properties due to their botanical origin and cultivation conditions. This variability complicates industrial textile processing and increases scatter in material properties, ultimately affecting mechanical performance and structural reliability [6, 8]. To ensure their long-term durability, an impregnation process is indispensable. Impregnation not only enhances the internal bond between the individual filaments but also provides a protective barrier against the chemically aggressive and highly alkaline environment of concrete. Without this protection, the fibres would deteriorate rapidly, limiting their structural applicability.

This study examines the mechanical behaviour of sisal, hemp, and flax yarns for use in textile reinforced concrete. It focuses on the influence of impregnation materials and methods, comparing mechanical rolling and vacuum techniques, using standardized yarn tow tests, as those described in [9], to determine tensile strength and elastic modulus. The results support the targeted design of natural fibre reinforcements with controlled deformability for structural concrete applications.

2 Materials and Methods

2.1 Natural Fibre Yarns

The selection of natural fibre yarns for textile reinforcement focused on sustainable alternatives such as hemp, flax, and sisal. To function effectively in concrete reinforcement, these yarns must exhibit high tensile strength and a high modulus of elasticity.

The mechanical properties of the investigated unimpregnated yarns are summarised in Table 1.

For this study, the yarns with the largest cross-sectional areas—specifically Hemp 3333 tex, Sisal 4545 tex, and Flax 3000 tex—were selected for further processing. This selection ensures that the reinforcement can carry sufficient tensile forces after cracking. A larger yarn diameter improves tensile load uptake and thus enhances force transfer to the concrete matrix.

Table 1 Mechanical properties of unimpregnated yarns

Fibre Type	Fineness [tex]	Number of Test specimens	Cross-sectional area [mm^2]	Mean Tensile Strength [MPa]	CV [%]	Mean Modulus of Elasticity [GPa]
Hemp	3333	9	1.5	156.61	7.5	5.95
Hemp	2222	10	2.3	102.14	5.2	4.17
Sisal	4545	10	1.9	173.74	12.9	7.47
Sisal	2222	10	3.9	206.71	17.6	8.98
Jute	2222	10	1.5	149.73	8.1	9.60
Flax	3000	12	2.1	158.18	19.0	7.81

2.2 Impregnation Materials

Impregnation of natural fibre textiles is essential for use in cementitious matrices, providing filament bonding and alkaline protection. This study compares several impregnation systems to balance mechanical performance, bond behaviour, and sustainability, using the bio-based epoxy GreenPoxy 56 as a reference against TECOSIT polymer dispersions (CHT Germany).

The GreenPoxy 56 reference system is characterised by a high bio-based carbon content of up to 56% and delivers good mechanical properties in terms of tensile and flexural strength [10]. Due to its high diffusion density, it acts as an effective barrier against chemical degradation of natural fibres [11]. In practical application, the system manifests itself as reactive. This results in significant exothermicity, especially with larger batches. In addition, it should be noted that these thermosetting systems exhibit characteristic brittle fracture behaviour without additional modification [11].

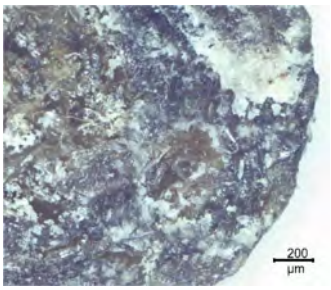
Specialised polyacrylate-based dispersions, such as TECOSIT CC 1000, were also examined. These systems provide an effective moisture barrier and improve mechanical adhesion [8], although their matrix stiffness is lower than that of high-strength epoxies because they prioritise interface optimisation over forming a highly rigid structure. The TECOSIT CC 7030 and CC 7021 variants allow universal application and precise control of film formation through adjustable glass-transition temperatures. As aqueous systems, they offer a closed barrier against external influences while maintaining practical handling [12].

2.3 Impregnation Processes

In this study, four impregnation variants (VR1–VR4) were systematically examined to assess their effects on wetting quality, structural integrity and the mechanical properties of fibre yarns. The initial variant (VR1) employs a custom-built impregnation device in which the yarn passes over multiple deflection rollers. Upstream and downstream rollers ensure uniform low-tension guidance, while rubber-coated rollers reduce local

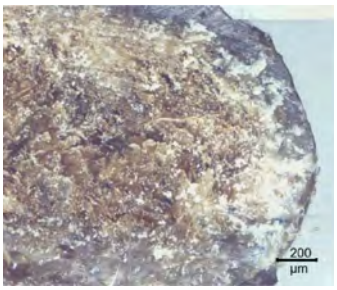
tension peaks and promote homogeneous impregnation. This setup enables consistent impregnation while minimising mechanical stress on natural fibres.

Variants VR2 and VR3 are based on the mechanical incorporation of the impregnation media using profiled steel or acrylic rollers. The application of transverse pressure by the rollers facilitates deeper penetration of the impregnation compound into the yarn cross-section, thereby, reducing voids and improving wetting of individual filaments [13, 14]. However, previous investigations have shown that the applied pressure can induce localised fibre damage, resulting in a significant reduction in the modulus of elasticity [15, 17]. This decrease in stiffness is consistent with studies on the treatment of natural fibre bundles, which indicate that lateral compressive loads can cause microscopic fibre breaks or delamination [16, 17].



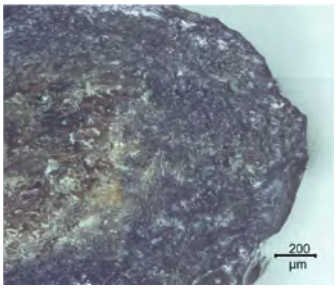
VR4 applies vacuum impregnation, in which the yarns are fully wetted in a vacuum chamber at 20–30 mbar and 20 °C. This method allows the impregnation medium to penetrate deeply into the fibre bundle without mechanical pressure. Microscopic images of VR4 Fig. 1 show a homogeneous matrix–fibre structure, low porosity and a distinct boundary zone without protruding filaments. No structural fibre damage is evident, corresponding to comparatively high elastic modulus values and more consistent mechanical performance. The benefits of low-pressure or pressure-free impregnation are likewise reported in studies on mineral or polymer impregnation of fibre bundles (e.g. [14, 18].).

A direct comparison of the four variants (Fig. 1) shows that VR1 and VR4 are the least invasive and most effective in maintaining yarn integrity. VR1 benefits from controlled, low-stress mechanical guidance, whereas VR4 ensures uniform wetting without fibre damage. By contrast, VR2 and VR3 achieve extensive cross-sectional wetting but compromise structural integrity and stiffness. The findings underline that impregnation of natural fibres requires a careful balance between complete saturation and mechanical protection. This balance is particularly important for textile-reinforced concrete, where both the load-bearing capacity of the textile reinforcement and its durability under alkaline exposure are essential.



VR1 exhibits uneven impregnation with significant cavities due to insufficient fibre wetting. Mechanical impregnation in VR2 and VR3 improves wetting and reduces cavities, while vacuum impregnation in VR4 yields the highest-quality cross-sections with complete wetting and a homogeneous fibre–matrix structure.

For the GreenPoxy epoxy system, investigations focused on VR1, which met the mechanical requirements and rendered further process variations unnecessary (see Fig. 2). Microscopic analysis of the resulting cross-sections shows nearly complete resin penetration, consistent filament wetting and an absence of interstitial voids. The composite exhibits a clear boundary zone, indicating full filament integration into the consolidated matrix.



Sisal represents a special case: impregnation with Tecosit CC1000, Tecosit 7030, or Tecosit 7021 was unsuccessful because the low viscosity of these resins caused the yarn to untwist, which made the fibres lose their cohesion and thus partially destroyed the fibre composite structure.

3 Results and Discussion

Figure 3 compares the mechanical properties of untreated and impregnated natural fibre yarns, demonstrating the performance enhancement achieved through impregnation. Untreated yarns exhibit low tensile strength and stiffness due to the absence of internal fibre bonding: Hemp (3333 tex) achieved a tensile strength of 156.6 MPa and an elasticity modulus of 5.95 GPa, while flax (3000 tex) achieved 158.2 MPa and 7.81 GPa. Impregnation using the standard VR1 process significantly increased these values. Hemp–GreenPoxy attained 471.5 MPa and 33.57 GPa, and flax–Greenpoxy 392.4 MPa and 29.8 GPa.

These results confirm that impregnation activates the load-bearing potential of natural fibre yarns, preventing premature twisting failure and promoting failure of the fibres within the yarn.

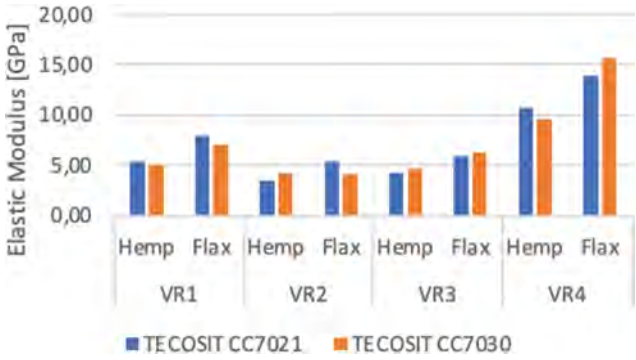

Fig. 3 Influence of the impregnation method (VR1-VR4) on the modulus of elasticity of flax and hemp yarn.

Across all variants, flax exhibited a slightly higher modulus of elasticity than hemp due to its greater intrinsic fibre stiffness. VR1 produced intermediate modulus values, with flax reaching 7.89 GPa (CC7021) and 7.06 GPa (CC7030), both exceeding the corresponding hemp results. VR2 yielded the lowest stiffness overall: hemp achieved 3.48 GPa (CC7021) and 4.26 GPa (CC7030), while flax reached 5.42 GPa (CC7021) and 4.15 GPa (CC7030), indicating insufficient wetting or increased defect sensitivity during impregnation.

With VR3, stiffness increased, giving comparable results for both rolling-based methods. Hemp ranged from 4.22 to 4.60 GPa, and flax from 5.97 to 6.33 GPa. The highest stiffness values occurred in VR4: hemp reached 10.68–9.56 GPa and flax 13.96–15.66 GPa, representing the highest values in the dataset.

The impregnation method strongly influences mechanical performance. In VR2 and VR3, transverse roller pressure damages filaments and reduces stiffness, whereas vacuum impregnation (VR4) at 20–30 mbar achieves complete, gentle wetting of the yarn cross-section. For flax–acrylate 7021, stiffness increased from 5.42–5.97 GPa (rolling) to 13.96 GPa (VR4), an improvement by a factor of 1.8–2.2. This demonstrates that both matrix selection and process mechanics determine the effective utilisation of the fibres.

Load-deformation behaviour is governed by yarn type, matrix properties, and processing conditions. While epoxy systems provide the highest strength, polymer dispersions improve wetting and reduce porosity, offering a balanced performance. For flax yarns impregnated with TECOSIT CC1000 in VR4, a tensile strength of 244.1 MPa and a modulus of 22.41 GPa indicate a favourable stiffness to deformation ratio. Overall, impregnation type, particularly vacuum impregnation, strongly influences mechanical performance, enabling natural fibre reinforcements in textile reinforced concrete to achieve high load capacity and controlled deformability when material and process parameters are optimized.

4 Conclusion

This study demonstrates that impregnation is crucial for enhancing the mechanical performance of natural fibre yarns used as concrete reinforcement. Among the investigated techniques, vacuum impregnation proved most effective, increasing the modulus of elasticity by a factor of 1.8–2.2 compared to mechanical rolling while ensuring uniform fibre wetting and minimal structural damage. Flax yarns showed the greatest improvements in stiffness and strength, whereas sisal required careful processing due to structural sensitivity. Overall, vacuum impregnation combined with bio-based resins such as GreenPoxy offers a promising route toward durable, high-performance, and sustainable textile reinforcements for structural concrete applications.

Abstract. This research analyzes the feasibility of obtaining a real Construction and Demolition Waste (CDW) footprint by quantifying and analyzing waste generated in two residential developments. The aim is for the CDW footprint obtained during construction to serve as a reference for similar future projects, enabling more accurate waste management estimates. The methodology combines theoretical estimation and quantitative measurement of construction waste, comparing planned estimates with actual on-site data.

Calculating the CDW footprint revealed significant discrepancies between EGR and PGR estimates and actual waste: up to 18% and 27% less, respectively, for non-hazardous waste, and 400–900 times more than actual for hazardous waste. For Level I CDW, primarily generated during excavation, the footprint ranged from 3.83 m^3/m^2 B/R for one basement to 4.60 m^3/m^2 B/R for two basements. For Level II CDW, the footprint depended on the construction system: 0.50 m^3/m^2 S/R for traditional construction and 0.30 m^3/m^2 S/R for prefabricated or industrialized elements. Hazardous CDW was quantified in mass due to a lack of volumetric data, showing lower values in industrialized constructions (0.000046 t/m^2 S/R) than in traditional ones (0.000075 t/m^2 S/R).

These findings support compliance with current regulations and provide data-driven benchmarks that promote waste minimization and eco-efficient construction practices.

1 Introduction

The implementation of new regulations and revisions of existing frameworks have advanced European targets for waste management, industrial sustainability, and the transition to a circular economy [1–9]. Reliable, real-world data remain essential to assess the effectiveness of these measures and to monitor progress [10–16].

Construction and demolition waste (CDW) requires proper traceability to prevent malpractice and verify circular economy practices, including reuse, recycling, and recovery, as mandated by legislation [17]. CDW represents the largest waste stream in the European Union, comprising approximately one-third of total waste generation [1].

The CDW footprint provides detailed information on waste generation and management, enabling strategies to reduce waste in the design phase, improve recycling and recovery during construction, and promote reuse, especially in demolition. It also contributes to reducing the ecological footprint, a measure of human impact on the environment [18].

Spain has recently updated its regulatory framework with Ley 7/2022, replacing Ley 22/2011 and repealing Orden MAM/304/2002. This law transposes European Directives (EU) 2018/851 and (EU) 2019/904 [2–6]. The law prioritizes waste prevention, reduces landfill disposal, ensures proper management of hazardous and non-hazardous waste, and assigns responsibilities to regional authorities for authorization, inspection, and data management. Digital tools are essential to ensure traceability and interoperability across administrative levels.

Despite regulatory advances and the proliferation of initiatives, significant uncertainties remain regarding the estimation of actual CDW generation, as well as the influence of building typology and the degree of industrialization on these rates. Recent studies highlight the need to validate and refine existing calculation methods through systematic comparisons with experimental on-site data.

In this context, the present study examines the accuracy of current CDW estimation methods used in Waste Management Studies (EGR) and Waste Management Plans (PGR), by comparing theoretical estimates with in situ experimental measurements and analysing the role of construction typology and industrialization level in waste generation.

2 Methodology

Conventional CDW estimation methods are generally based on standardized datasets, often producing generic values that may not reflect real on-site waste generation. Historically, regional construction practices played a major role in shaping waste outputs; in contemporary contexts, building typology and degree of industrialization have emerged as primary determining factors.

To address these limitations, a two-stage methodological framework was implemented, combining theoretical estimation with experimental validation. In the first stage, CDW generation was estimated using the indicators and coefficients defined in the corresponding Waste Management Studies (EGR) and Waste Management Plans (PGR). These documents provided project-level forecasts disaggregated by waste category and referenced surface area or built volume.

In the second stage, experimental data were collected directly on site. Waste was segregated by fraction, classified according to the applicable European waste codes, and weighed using calibrated equipment. The total CDW mass was subsequently normalized by constructed floor area to obtain standardized generation rates (e.g., $t \cdot m^{-2}$), enabling comparison with theoretical values.

The empirical study was conducted on two residential construction projects with comparable characteristics in terms of size, location, and regulatory context but differing in construction system and industrialization level. This design allows isolating the effect of construction typology and industrialization on CDW generation while ensuring that external boundary conditions remain as similar as possible. A comparative analysis was then carried out to assess deviations between theoretical and measured values and to identify systematic biases in current estimation practices.

2.1 Theoretical Estimation

The EEH-AURREZTEN tool developed by Ihobe was used and specifically adapted to comply with the regional regulatory requirements set out in Orden 2726/2009. This tool enables the standardized estimation and characterization of construction and demolition waste (CDW) at project level. In this study, it was applied to both the Waste Management Studies (EGR) and the Waste Management Plans (PGR) associated with the selected residential projects.

Using adapted EEH-AURREZTEN tool, the estimates reported in the EGR and PGR were systematically assessed for several key parameters: total waste generation (in terms of both mass and volume), material densities, waste classification by fraction and hazard level, proposed management and treatment routes (reuse, recycling, recovery, or disposal), and the associated management costs. In addition, the influence of these estimates on the overall construction budget (Construction Cost Estimate, PEM) was examined, in order to quantify the economic relevance of CDW management within the project's financial framework.

2.2 Experimental Data Collection

An experimental approach was implemented based on the systematic collection of on-site data throughout the entire construction process, from initial earthworks to completion. This continuous monitoring enabled a detailed and temporally resolved characterization of construction and demolition waste (CDW) generation at project level (Fig. 1).

The primary sources of information were:

- waste dispatch records, documenting each removal event, the type of container used, declared waste type, and estimated or measured volume;
- certificates issued by authorized treatment facilities, specifying the mass of waste received, the corresponding European Waste Catalogue (EWC/LER) codes, and the final treatment option;
- construction progress certifications, which provided a reliable record of executed work, allowing the allocation of waste flows to specific construction stages and work packages.

These datasets were cross-checked and harmonized to obtain consistent, project-wide waste balances. The combination of volumetric information from dispatch records and gravimetric data from facility certificates enabled the quantification of actual CDW in both mass and volume, and the derivation of effective material density coefficients for each waste fraction. All recorded flows were classified according to EWC/LER codes, and assigned to specific management routes (on-site reuse, off-site recycling, recovery, or landfill disposal).

Finally, unit costs reported in the treatment certificates and transport invoices were used to calculate the economic costs associated with each waste stream. These were then aggregated and related to the construction budget (PEM), allowing assessment of the budgetary impact of CDW management and comparison with the cost assumptions made in the project's waste management planning documents.

Fig. 1. Vallecas Construction Site (VA001). From left to right: Construction and Demolition Waste (CDW) plasterboard; Non-hazardous mix Level II CDW. Non-stony nature; Hazardous CDW.

2.3 Data Analysis and Comparison

Experimental results were systematically compared with estimates derived from EGR and PGR methods, as well as across the project sample, to evaluate the role of construction typology in CDW generation. The comparison exposed noteworthy divergences and underscored structural limitations of current estimation techniques.

3 Results and Discussion

The calculation of the construction and demolition waste (CDW) footprint provided quantitative evidence of substantial discrepancies between theoretical estimations and observed on-site waste generation at project level (Table 1). These deviations were detected for both non-hazardous and hazardous waste streams, revealing structural limitations in current estimation practices embedded in regulatory planning instruments.

For non-hazardous CDW, the comparison between design-stage documents and measured data showed that the Waste Management Study (EGR) systematically underestimates the total amount of waste generated by approximately 18%. The deviation is even larger for the Waste Management Plan (PGR), which underestimates non-hazardous CDW by up to 27%. Given that both EGR and PGR are mandatory, standardized tools

in the current regulatory framework, these results indicate that they do not adequately reflect real on-site conditions and may lead to insufficient dimensioning of downstream management infrastructure and budgets.

In contrast, for hazardous CDW, the mismatch presents an opposite pattern. Here, the theoretical estimations included in EGR and PGR grossly overestimate the quantities actually generated. Estimated hazardous waste quantities exceed measured values by factors of approximately 400 (EGR) and 900 (PGR), respectively. This overestimation suggests an overly conservative or poorly calibrated approach to hazardous waste forecasting, with potential implications for cost allocation, contracting of specialized treatment services, and the interpretation of compliance with legal thresholds. Together, these findings underscore the need to revise and recalibrate current CDW estimation methodologies to improve their accuracy and reliability.

Table 1. Total CDW estimates versus actual CDW generation.

	EGR	PGR
Non-hazardous CDW	−18% vs. actual	−27% vs. actual
Hazardous CDW	400× actual	900× actual

This systematic overestimation suggests a conservative approach in project documentation, likely driven by regulatory compliance requirements, but it also evidences a lack of precision in forecasting hazardous waste streams.

With respect to Level I waste (uncontaminated soil and inert materials), the CDW footprint is strongly influenced by building configuration, particularly the number of underground levels. The results indicate specific generation rates of 3.83 m^3/m^2 of below-ground built area for buildings with one basement and 4.60 m^3/m^2 for those with two basements. These findings confirm that excavation volume is the primary driver of Level I waste generation, rather than the construction methodology employed (Table 2).

Table 2. Level I waste footprint.

	CDW Footprint Level I (m^3/m^2 B/R)
One basement	3.83
Two basements	4.60

In contrast, Level II waste (including both inert and non-inert fractions) exhibits a clear dependence on construction typology. In buildings executed using conventional construction techniques, the CDW footprint attains 0.50 m^3/m^2 of above-ground built area, whereas this value decreases markedly to 0.30 m^3/m^2 in projects that incorporate prefabricated or industrialized systems (Table 3). This reduction provides quantitative evidence of the effectiveness of construction industrialization strategies in reducing waste generation during the execution phase.

Table 3. Level II waste footprint.

	CDW Footprint Level II non-hazardous (m^3/m^2 S/R)
Traditional	0.50
Industrialized	0.30

A comparable pattern is observed for hazardous Level II waste, although with much lower absolute values. Owing to the absence of reliable volumetric data, these waste streams were quantified exclusively in mass terms. The results indicate a hazardous Level II CDW footprint of 0.000075 t/m^2 for buildings constructed using traditional methods and 0.000046 t/m^2 for projects employing industrialized construction systems (Table 4). Although their contribution to total waste generation is relatively minor, the reduction associated with industrialized processes is consistent with the trends identified for non-hazardous waste, thereby reinforcing the positive influence of construction industrialization on overall waste minimization.

Table 4. Hazardous Level II CDW (mass).

	CDW Footprint Level II hazardous (t/m^2 S/R)
Traditional	0.000075
Industrialized	0.000046

The observed differences are also evident in the economic assessment of CDW management. The results indicate that a higher degree of industrialization leads to a substantial reduction in waste management costs, particularly for Level II inert and hazardous fractions. In the case studies analyzed, savings of approximately €35,700 were recorded for Level II inert waste and €850 for hazardous waste, corresponding to an overall cost reduction of around 20% in the more industrialized project. By contrast, the costs associated with Level I waste and non-inert Level II waste were not significantly affected by construction typology but were instead primarily governed by the volume of excavation.

Overall, the results show that current estimation tools (EGR and PGR) exhibit notable limitations in accurately predicting CDW generation, especially for hazardous waste. Moreover, the findings confirm that construction typology and the degree of industrialization are key determinants of both waste generation and management costs. These insights highlight the need to integrate real on-site data into estimation models and support the adoption of industrialized construction systems as an effective strategy to reduce both environmental impacts and economic costs (Table 5).

These results confirm that the current estimation tools (EGR and PGR) present notable limitations, particularly in the case of hazardous waste. The findings indicate that construction typology and the degree of industrialization are key determinants of both waste generation and associated management costs. Specifically, industrialized

Table 5. Economic assessment.

	Economic savings on total CDW management
Traditional	0%
Industrialized	20%

construction methods substantially reduce material waste, enhance the efficiency of recycling processes, and yield significant economic savings. Overall, these outcomes support the implementation of industrialized systems as an effective strategy to advance circular economy objectives in the construction sector.

4 Conclusions

This study provides a comprehensive assessment of construction and demolition waste (CDW) management within the current regulatory framework. Recent regulations are broadly aligned with European waste management targets; however, their implementation is still at an early stage and will require long-term, region-specific strategies to become fully effective. The findings highlight that digitalization is essential to ensure traceability and operational efficiency across the CDW value chain, and that strict compliance with Law 7/2022 (Spanish Law) is particularly critical for both transporters and waste managers.

Pre-construction review of the Waste Management Study (EGR) and Waste Management Plan (PGR) contributes to more accurate planning and improved stakeholder compliance, while training and awareness-raising activities are shown to enhance appropriate on-site waste management practices. During the construction phase, systematic verification of documentation helps maintain traceability, although a tendency to simplify European Waste Catalogue (EWC/LER) codes is observed in practice. In terms of waste streams, Level I waste (primarily uncontaminated soil and inert materials) predominates in the early project stages, whereas Level II waste increases significantly during the masonry phase. Circular economy practices, such as the reuse of excavated soil, are only partially implemented. Hazardous waste generation is substantially lower than initially estimated, and recycling routes prevail over final disposal.

The results confirm that industrialized construction systems reduce both total waste generation and associated CDW management costs by up to 20%. Overall, progress towards a circular economy in the construction sector depends on the combined effect of regulatory compliance, digitalization, active stakeholder engagement, and the adoption of industrialized processes. Under these conditions, the construction sector can play a decisive role in achieving broader environmental and sustainability objectives.

Abstract. Despite the urgency to transition to a Circular Economy (CE) in construction, circularity principles remain inconsistently implemented and difficult to monitor across stakeholders and regulatory contexts. This study employs Natural Language Processing (NLP) to examine how circular construction is defined, debated, and operationalised across multiple levels and discourses. A multi-level analysis (academic, social media, regulatory levels) is introduced to trace how circularity concepts travel from theory to practice. At the academic level, NLP analysis of 480 articles reveals a conceptual divergence between circularity objectives focused on operational resource efficiency and waste management, and broader sustainability objectives addressing long-term environmental impacts. This conceptual ambiguity can hinder coherent implementation. At the public-discourse level, sentiment analysis shows that 57% of stake-holder opinions on construction circularity are positive, highlighting which concepts resonate and which remain abstract. At the policy level, analysis of CE strategies from 57 countries identifies five implementation clusters based on the 10R hierarchy, demonstrating that adoption patterns are shaped more by institutional capacity than economic development. At the technical level, text-mining of standards in Central Asia shows that many CE principles promoted in academia and policy fail to materialise in operational requirements. This multi-level approach reveals three critical dynamics: (1) vertical disconnects between policy ambitions and technical standards; (2) horizontal variation in national interpretations of circularity; and (3) missing feedback loops between implementation challenges and strategic or research agendas. NLP provides a diagnostic tool enabling stakeholders to identify misalignments and understand how circularity concepts diffuse—or stall—across the construction ecosystem.

1 Introduction

The buildings and construction sector is a major driver of resource use, emissions, and waste. Recent global reporting shows that the sector consumes a large share of energy and contributes significantly to global CO_2 emissions, while relying heavily on materials such as cement and steel that are also major sources of environmental impact (UNEP, 2025). Circular economy (CE) strategies aim to reduce these impacts by extending material lifetimes, keeping value in use, and reducing demand for virgin resources. Despite growing research and policy attention, global circularity is declining: the share of secondary materials in the global economy fell from 9.1% in 2018 to 7.2% in 2023 (CEF, 2024). In construction, this gap is often attributed to fragmented supply chains, unclear responsibilities, and limited incentives. However, these explanations do not fully explain why well-established CE concepts rarely translate to practical and enforceable requirements in day-to-day delivery.

This paper frames the problem as a knowledge translation challenge. In many fields, the movement from research evidence to action is treated as a process with identifiable stages and potential failure points (Graham et al., 2006). In circular construction, ideas typically emerge in research, get interpreted in professional and public discourse, become priorities in policy frameworks, and finally appear as requirements in technical standards and codes. If concepts lose clarity, priority, or enforceability along this chain, implementation remains slow even when the research base is strong.

Computational tools for analysing these processes have advanced rapidly. Natural language processing (NLP) and large language models (LLMs) are increasingly used to extract and structure information from large textual datasets, including policy and regulatory documents. However, most studies still focus on a single level of discourse at a time, such as academic literature (e.g. Aubakirov et al., 2025), stakeholder perceptions (e.g. Tleuken et al., 2024; Karaca et al., 2024), policy studies, or technical regulations (e.g. Tleuken et al., n.d.-b), limiting their ability to explain the implementation gap, which emerges across levels.

To address this limitation, this paper proposes a multi-level diagnostic framework linking four discourse levels: academic literature (Aubakirov et al., 2025), public (Tleuken et al., 2024) and professional (Karaca et al., 2024) discourse, policy documents (Tleuken et al., n.d.-a), and technical standards (Tleuken et al., n.d.-b). Using the 10R hierarchy of circularity strategies as a shared taxonomy, the framework analyses how CE concepts evolve across these levels. Drawing on recent NLP- and LLM-based analyses conducted in these studies, the framework offers a connected evidence base that shows where CE concepts weaken, diverge between contexts, or fail to convert into enforceable technical provisions.

2 Methods

This paper synthesises four prior studies by the authors and collaborators, each applying NLP to a different discourse level in circular construction. Study-specific data collection and validation procedures are detailed in the original publications and summarised here briefly. The main contribution is the cross-level comparison procedure in Sect. 2.1,

which integrates the findings using a shared 10R taxonomy. This section describes the data sources, NLP techniques, and analytical procedures applied at each level of the framework. Because the individual level analyses have been or are being reported in dedicated publications, the methods are presented concisely and readers are referred to those studies for full technical detail. The cross-level comparison method, which is new to this paper, is described in greater depth.

Level 1: Academic Discourse 480 review articles (2021–2024) from Scopus were analysed: 107 on circular construction and 373 on sustainable construction. Three NLP techniques (TF-IDF, TextRank, and Named Entity Recognition) identified distinctive terms and concept clusters, distinguishing circular from sustainable construction vocabulary. Full details in Aubakirov et al. (2025).

Level 2: Public and Professional Discourse Two datasets were used. First, 906 text chunks from seven online platforms were analysed using sentiment analysis (fine-tuned MPNet, $F1 = 0.68$) and topic modelling, yielding eight discourse topics (Tleuken et al., 2024). Second, a survey of 382 stakeholders across seven countries assessed perceptions of circular construction costs and benefits, with XGBoost and SHAP used to identify key influencing factors (Karaca et al., 2024).

Level 3: Policy Discourse CE strategy documents from 57 countries were analysed using the 10R hierarchy, classifying policy content by R-strategy emphasis. Cluster analysis identified five country implementation profiles. Full details in Tleuken et al. (n.d.-a).

Level 4: Technical Standards 165 Kazakhstani construction norms (SNiP) were analysed in Russian using a hybrid human-machine workflow. DeepSeek V3 identified relevant segments, which were manually validated to produce 519 confirmed provisions, each coded by 10R principle, normative strength, and enforcement mechanism. Sentence-BERT embeddings and PCA were used for semantic analysis. Full details in Tleuken et al. (n.d.-b).

2.1 Cross-Level Comparison

The cross-level comparison is the methodological contribution of this paper. First, findings from all four levels were mapped onto the 10R hierarchy as a shared taxonomy (Kirchherr et al., 2018). For Levels 3 and 4, the mapping is direct as the original analyses already use the 10R framework. For Levels 1 and 2, key terms and topics were interpreted and assigned to corresponding strategies (e.g. "design-for-disassembly" maps to Rethink; "waste diversion" maps to Recycle/Recover). Second, the mapped findings were analysed using a gap-identification protocol to detect three patterns: (a) vertical disconnects, where a principle's presence drops sharply between adjacent levels; (b) horizontal variations, where the same principle is emphasised differently across countries at the policy level; and (c) missing feedback loops, where challenges identified at Levels 2 or 4 do not appear to inform the agendas at Levels 1 or 3. Interpretive judgement is required when mapping Levels 1 and 2 to the 10R taxonomy. Both authors independently assigned terms and topics to R-strategies, resolving disagreements through discussion and assigning borderline cases to the more conservative (lower-order R) category.

3 Results

3.1 Levels Overview

Level 1: Academic Discourse Analysis of 480 review articles reveals a clear conceptual split. Circular construction centres on resource efficiency, waste management, and material lifecycle strategies, while sustainable construction is broader, encompassing urban planning, energy performance, and social dimensions. Although often used interchangeably, circular construction focuses on closing material loops whereas sustainable construction addresses wider environmental and social outcomes. This conceptual confusion at the academic level creates a shaky foundation for the levels that follow.

Level 2: Public Discourse Public attitudes are moderately positive (57% positive, 28% neutral, 15% negative). Positive sentiment clusters around innovation and environmental benefits; negative sentiment around cost, implementation difficulty, and feasibility concerns. Stakeholders in countries with stronger CE policy frameworks report more positive expectations. Notably, technical concepts common in academic literature, such as design-for-disassembly or material passports, barely appear in public discourse.

Level 3: Policy Discourse Analysis of CE strategy documents from 57 countries identifies five implementation clusters ranging from downstream revalorisation to upstream life-extension strategies. Cluster membership is shaped more by institutional capacity and regulatory maturity than by GDP. Most countries gravitate toward recycling and recovery as the most accessible entry point, while higher-order strategies like Refuse or Rethink appear mainly in countries with established environmental governance.

Level 4: Technical Standards 519 coded provisions from 165 Kazakhstani construction norms show an uneven distribution across the 10R framework. Reduce dominates ($\approx$150 provisions), while Repurpose, Recover, Refuse, and Remanufacture are weakly represented. Most provisions are recommendatory rather than mandatory, with enforcement mechanisms largely absent, and higher-order circular strategies linguistically dispersed across regulatory texts.

3.2 Cross-Level Synthesis

Cross-level analysis represented in Table 1 reveals three main dynamics:

- Vertical disconnects. Circular strategies widely discussed in academic and policy discourse, such as Refuse, Remanufacture, and Repurpose, are largely absent from technical standards or appear only as non-binding recommendations.
- Horizontal Variation. Policy strategies vary significantly across countries. Differences are shaped primarily by institutional capacity and regulatory traditions rather than economic development level.
- Missing feedback loops. Implementation challenges identified in public dis-course and technical standards, such as cost concerns or enforcement gaps, do not appear to influence academic research agendas or policy design. The knowledge translation process therefore operates largely in a top-down direction.

Table 1. Cross-level concept tracing matrix using the 10R hierarchy.

10R	Level 1: Academic	Level 2: Public	Level 3: Policy	Level 4: Standards
Refuse	Weak–Moderate. Prevention focus; limited operational definition.	Absent.	Variable. Present in "Pre-ventive" cluster countries only.	Weak. <35 clauses; no enforcement.
Rethink	Strong. Design-for-disassembly, modularity.	Absent–Weak. Expert vocabulary doesn't transfer.	Moderate. Preventive and upstream clusters.	Moderate. ~80 clauses; mostly advisory.
Reduce	Strong. Core concept; overlaps with sustainable construction.	Moderate. Efficiency and cost narratives.	Strong. Common entry-point across clusters.	Strong. ~150 clauses; highest mandatory share, but little enforcement.
Reuse	Strong. Material lifecycle reuse.	Weak–Moderate. Practical examples resonate.	Moderate–Strong. Life-extension clusters.	Moderate. ~65 clauses; mostly advisory.
Repair	Moderate. Life extension and maintenance.	Weak. Framed as maintenance, not circularity.	Variable. Some prevention-oriented contexts.	Moderate. 40–50 clauses; only principle with meaningful enforcement (~25%).
Re-furbish	Moderate. Renovation and retrofit.	Weak–Moderate. Re-novation narratives.	Moderate. Downstream life-extension cluster.	Moderate. 40–50 clauses; technical execution partly mandatory.
Remanufacture	Weak. Limited in construction.	Absent.	Weak. Advanced industrial policy countries only.	Absent–Weak. Virtually absent; no enforcement.
Repurpose	Weak. Niche; demolition materials.	Absent.	Weak. Low emphasis across clusters.	Weak. ~15 clauses; advisory only.
Recycle	Strong. Default circular strategy.	Moderate. Waste management framing.	Strong. Central in revalorisation clusters.	Moderate. 40–50 clauses; no binding targets.

(*continued*)

Table 1. (*continued*)

10R	Level 1: Academic	Level 2: Public	Level 3: Policy	Level 4: Standards
Recover	Weak. Lowest-priority in academic framing.	Absent–Weak.	Moderate. Back-up strategy in down-stream revalorisation.	Weak. <35 clauses; advisory only.

4 Discussion

This paper links four discourse levels to examine why CE ideas in construction of-ten remain aspirational. The same pattern appears across all four: concepts are well developed in research, partially echoed in policy, weakly represented in public dis-course, and only selectively binding in technical standards, consistent with a "translation chain" interpretation where failure occurs at interfaces between communities and institutions (Graham et al., 2006). This complements existing barrier research: while cost, fragmented responsibilities, and limited incentives are well documented, they do not explain why clear concepts still fail to become enforceable requirements. Our results point to weak conversion from concepts into standardised, enforceable language as a key underlying mechanism.

Vertical disconnects: ideas weaken on the way to standards: The clearest result is vertical attenuation: higher-order CE strategies prominent in research and policy weaken sharply in technical standards, where CE-related provisions are often advisory and rarely paired with compliance checks. Design-for-disassembly illustrates this pattern, common in research as an enabling concept for reuse and adaptability, yet difficult to translate into specific, measurable, and enforceable standard clauses. Similarly, material and product passports are widely discussed as traceability tools but depend on data governance and interoperability practices not automatically present in standards systems. When strategies lose specificity and binding force as they move downward, implementation remains uneven even where policy ambition exists.

Horizontal variation: policy pathways depend on institutions, not only income. The policy clustering shows that countries do not converge on a single CE pathway. Different national profiles emphasise different parts of the 10R hierarchy, and many countries prioritise downstream or lower-risk strategies first. This aligns with broader evidence that CE progress depends strongly on institutional, cultural, and governance conditions rather than technology alone (Kirchherr et al., 2018). It also matches construction-specific policy research arguing that CE policy is often fragmented across instruments and stages, with limited integrated frameworks that link strategy to delivery mechanisms. Our contribution is to connect this variation to what becomes codified. A strategy can be present in policy language yet remain weak in standards if enforcement capacity, administrative routines, or market infrastructure are missing. This suggests that policy ambition is not a reliable proxy for implementation readiness. A more useful indicator is whether a country can translate CE priorities into clauses that specify responsibilities, verification, and consequences for non-compliance.

Missing feedback loops: practice signals do not correct upstream agendas. A third result is the weak upward flow of information. Public discourse and survey responses emphasise feasibility, cost burdens, and responsibility gaps. Standards analysis shows limited enforcement language and limited coverage of higher-order strategies. Yet these signals do not clearly reappear as corrective inputs in academic framing or policy priorities. This resonates with critiques that CE can become concept-heavy and politically convenient, while structural constraints and power dynamics remain under-addressed (Corvellec et al., 2022). From a knowledge translation perspective, feed-back is not optional. Iteration is central to moving from evidence to sustained practice (Graham et al., 2006). In a construction context, this means that the standards revision process, procurement feedback, compliance outcomes, and observed implementation failures should be visible upstream and should shape both research agendas and policy design. Our results suggest that these feedback channels are weak or informal, which contributes to repetition of well-known "barriers" without corresponding improvement in codification and enforcement.

Three implications follow. First, advisory language is insufficient for CE outcomes requiring coordinated action: standards need more measurable, verifiable clauses, particularly for higher-order strategies dependent on early design decisions. Second, policy design should match institutional capacity: the risk is not that countries follow different CE sequences, but that policy language is imported without the governance mechanisms to implement it. Third, standards revision should be formally linked to compliance evidence and practical constraints, and shared with researchers and policymakers. Without this, CE remains aspirational rather than corrected by implementation reality. Methodologically, the main contribution is the comparative design: a shared taxonomy across discourse levels combined with text-based evidence of attenuation, variation, and missing feedback. LLM-assisted extraction is valuable for large regulatory corpora, but the goal remains governance insight, identifying what be-comes binding, what is verifiable, and what is left as suggestion.

5 Conclusions

This paper presented a multi-level diagnostic framework examining how CE ideas in construction move from concept to practice, linking academic literature, public discourse, policy documents, and technical standards through a shared 10R taxonomy. Three key findings emerge. First, higher-order CE strategies visible in research and policy are weakly represented in technical standards, often appearing as recommendations rather than mandatory provisions. Second, countries cluster into distinct CE strategy profiles, reflecting differences in institutional capacity and regulatory tradition. Third, feedback loops are weak – feasibility and cost concerns raised in public discourse do not consistently inform research agendas or policy design. The frame-work has practical implications: policymakers should ensure CE priorities translate into specific, verifiable, and enforceable clauses; industry can distinguish binding rules from voluntary guidance; and researchers should study translation mechanisms more directly. Limitations include geographic and temporal variation across levels and a single-country standards analysis. Future work should extend the analysis to additional contexts and test whether translation patterns hold in other regulatory environments. Overall, the framework makes

translation gaps visible, supports targeted interventions, and emphasizes stronger links between research, policy, and practice.

Abstract. This paper investigates end-user expectations regarding building thermal insulation materials through a multi-stakeholder survey of 115 respondents across 12 European countries, complemented by statistical analysis and validation with industry manufacturers. The research methodology comprised a literature review of end-user preferences, conceptual model development, survey design, statistical analysis using the Kruskal-Wallis nonparametric test, and a two-phase manufacturer validation. Survey results demonstrate that end-users maintain a functional approach to insulation material selection, prioritizing specifications that deliver tangible, measurable benefits, with a strong emphasis on health and safety considerations, thermal performance, durability, moisture resistance and energy efficiency and relatively low importance assigned to aesthetics and sustainability credentials. The end-user behavior hierarchy ranks technical factors as the most important, followed by economic, environmental, and, lastly, social considerations, a ranking confirmed independently by industry manufacturers. Critically, a sustainability gap is identified: current preferences for environmental specifications remain substantially below levels implied by EU policy goals, yet higher-knowledge respondents show significantly greater appreciation for sustainability criteria, suggesting that education and regulation will progressively reshape market priorities. The manufacturers' validation identified durability demonstration, moisture resistance, cost competitiveness, and communication as critical development challenges for innovative materials, defining the frontier where material innovation must meet market requirements to enable widespread adoption of sustainable construction solutions.

1 Introduction

The transition towards sustainable built environments requires a deep understanding of end-user expectations regarding construction materials, particularly thermal insulation. Despite the proliferation of innovative insulation solutions, including bio-based, recycled, and high-performance aerogel materials, their market uptake remains constrained by complex socio-technical factors extending beyond technical performance alone [1, 5, 16]. While individual studies have examined specific stakeholder groups or national contexts, no prior work has systematically quantified preference hierarchies across multiple end-user categories and diverse European geographies simultaneously, nor triangulated those preferences against manufacturer market experience.

Existing research has explored barriers and drivers for energy-efficient technologies from various perspectives [3, 4, 11], but systematic quantitative assessments integrating multiple end-user categories across diverse European contexts remain limited. This paper addresses this gap through a comprehensive multi-stakeholder survey conducted within the SNUG European project (https://snugproject.eu/), targeting 115 end-users from 12 European countries, validated through direct engagement with building component manufacturers. The study examines which material specifications end users prioritize, how decision-making varies by expertise level, and the implications for developing and positioning innovative, sustainable insulation solutions.

2 Theoretical Framework

A literature review established the conceptual foundation for the study, synthesizing two streams: technical assessments of insulation material properties [1, 6] and socio-behavioral studies examining barriers and drivers affecting innovative material adoption [2–5, 7–16]. Jelle [1] identified critical insulation properties including thermal conductivity, fire protection, water resistance, and climate-aging durability. Schiavoni et al. [6] conducted a comparative analysis across commercialized materials on thermal performance, acoustic properties, environmental impact, and vapor resistance. On the adoption side, Camarasa et al. [11] found that technical and economic drivers have the greatest potential to promote energy-efficient technologies, while economic barriers remain the primary impediment. Studies on bio-based and circular materials [5, 13, 16] identify inadequate incentives, insufficient knowledge, performance concerns, and supply chain immaturity as significant barriers. Regulatory frameworks consistently emerge as dual-role factors [3, 12, 15], while Tsoka et al. [7] highlighted that investment costs, maintenance issues, and low professional knowledge levels are the main constraints to technology diffusion in Mediterranean contexts.

The conceptual model (Fig. 1) synthesizes these findings by mapping insulation specifications to key driver and barrier categories: technical, economic, environmental, social, and regulatory. This framework guided both survey instrument development and results interpretation.

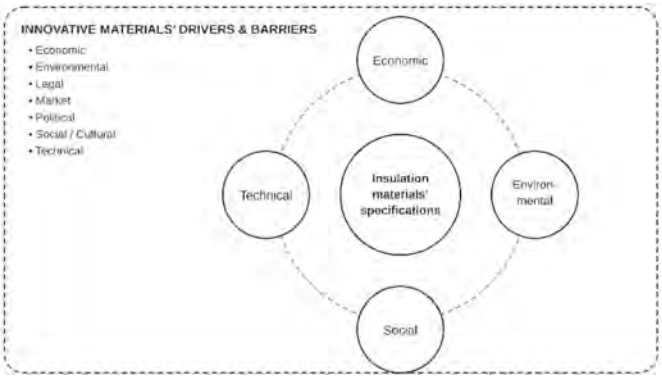

Fig. 1. Literature-based conceptual model that represents insulation material specifications together with market drivers and barriers influencing innovative material adoption.

3 Materials and Methods

3.1 Survey Design and Instrument

An online questionnaire, "Desired properties of buildings' thermal insulation", was developed on the Google Forms platform and distributed in English. Based on the conceptual model, the survey assessed 35 insulation material specifications. Respondents rated each specification on a five-point Likert scale from "not important" to "very important," and additionally selected their top three most important specifications. Background sections collected data on respondent category, country of origin, and self-assessed knowledge level of insulation materials.

3.2 Stakeholder Categories and Sampling

Thirteen end-user categories were defined through a dedicated SNUG project workshop: architects, planners and engineers; building occupants; building owners; building and construction companies; energy consultants; facility managers; certification providers; financing organizations; professional organizations; property managers; public authorities; real estate agents; and associations of building component manufacturers. A total of 115 responses were collected during March 2024 from 12 European countries. Spain (20%), Austria (16%), Greece (13%), and Portugal (12%) had the highest participation. Architects, planners and engineers constituted the largest group (28%), followed by building occupants (15%) and private building owners (11%). Approximately 40% of respondents self-assessed their knowledge as high, 40% as average, and 20% as low. Sampling was coordinated through SNUG project partner networks (minimum ten respondents per country), a convenience approach that over-represents southern and central European professional networks; findings should therefore be interpreted as indicative of practitioner-weighted European preferences rather than a fully representative population sample.

3.3 Statistical Analysis

Statistical analysis was performed using SPSS 20. Descriptive statistics characterized overall importance ratings. Given the ordinal nature of Likert-scale responses, nonparametric Kruskal-Wallis H tests were applied to compare importance ratings across the three knowledge-level groups (low, average, high), with pairwise post hoc tests for comparisons that showed statistically significant differences ($p < 0.05$). Top-3 specification selections and the four-criteria ranking question (technical, economic, environmental, social) were analyzed using frequency distributions.

3.4 Manufacturer Validation

Survey findings were validated through a structured questionnaire distributed to five building component manufacturers participating in the SNUG consortium during September–October 2025, followed by a dedicated online workshop on 8 October 2025 with six participants from four partner organizations. This two-phase validation methodology enabled both individual written reflection and collective discussion of discrepancies between survey findings and market experience.

4 Results

4.1 Overall Specification Importance Rankings

The survey results reveal a clear hierarchy in how end-users prioritize insulation material specifications. Impact on human health led all specifications with 70% of respondents rating it "very important," followed by release of dangerous substances (68%), durability (67%), energy efficiency (67%), thermal conductivity/thermal insulation performance (63%), thermal comfort (60%), resistance to fire (59%), fume emission during fire (57%), and water/vapor resistance (54%). The overall ranking of selection criteria placed technical factors first, followed by economic, environmental, and social considerations.

Conversely, the least important specifications were weight/density (15% very important), aesthetics (17%), bio-based material (18%), and biodegradable material (23%). Notably, cost efficiency/payback period (52% very important) ranked ninth in mean importance values yet emerged as the most frequently selected top-3 specification (11.5% of responses), suggesting that cost operates as a threshold criterion rather than a simple ranking factor in end-user decision-making.

4.2 Knowledge-Level Differences

Kruskal-Wallis H tests revealed statistically significant differences ($p < 0.05$) between knowledge-level groups for six specifications: aesthetics ($p = 0.004$), biodegradable material ($p = 0.026$), recyclability and reusability ($p = 0.000$), supply security ($p = 0.031$), sustainability ($p = 0.028$), and thermal conductivity/thermal insulation performance ($p = 0.031$). Low-knowledge respondents assigned significantly lower importance to biodegradability, recyclability and reusability, supply security, sustainability, and

thermal conductivity than average- or high-knowledge groups. High-knowledge respondents rated aesthetics as significantly less important than the other two groups. Energy efficiency and impact on human health were consistently ranked in the top four across all groups; weight/density and bio-based material remained among the four least important, indicating broad cross-segment consensus on these anchor specifications. From a stakeholder-type perspective, architects, planners and engineers (28%) likely drive the performance-first orientation through code-compliance obligations, while building occupants (15%) reinforce the prominence of health and comfort specifications. The convergence of these groups on the same top-ranked specifications provides robust cross-stakeholder validation of the overall hierarchy.

5 Manufacturer Validation

5.1 Alignment with Market Experience

Manufacturer validation confirmed strong overall alignment between survey findings and market experience. All five participating manufacturers confirmed that the top-ranked specifications (health impact, energy efficiency, durability, thermal conductivity, and fire resistance) accurately reflect customer priorities. Customers typically establish baseline requirements for health, fire safety, and performance before considering economic factors; price and payback become relevant only after these thresholds are met. The criteria hierarchy (technical > economic > environmental > social) was explicitly confirmed by multiple manufacturer partners.

5.2 Contradictions and Discrepancies

Despite overall alignment, manufacturers identified important discrepancies. Cost efficiency carries more weight in actual purchasing decisions than survey rankings suggest, particularly in certain industry sectors. The low ranking of sustainability specifications, especially recyclability and reusability, surprised several manufacturers who observe increasing demand for circular and bio-based solutions in public procurement contexts, revealing a temporal gap between current stated preferences and emerging requirements driven by regulatory pressure and ESG considerations. While lead time appeared unimportant in the survey, manufacturers noted that supply reliability is often decisive in actual projects.

5.3 Development Challenges and Communication Barriers

Manufacturers identified four critical development challenges for innovative insulation materials: demonstrating proven long-term durability (new circular materials lack the field validation of traditional alternatives); achieving moisture resistance comparable to conventional materials; developing cost-competitive production and supply chains; and communicating complex technical benefits, including embodied carbon and durability metrics, to varied audiences. Manufacturers described segmented strategies, from detailed datasheets and LCAs for high-knowledge professionals to comfort, health, and payback messaging for general end-users.

6 Discussion

6.1 Functional Market Orientation

End-users approach insulation selection with a strongly functional orientation, prioritizing measurable performance over aesthetic or abstract sustainability credentials. This aligns with McCoy et al. [2], who identified relative advantage and risk reduction as the primary adoption drivers, and with Camarasa et al. [11], who found that technical and economic drivers have the highest promotion potential across EU markets. The causal mechanism is rooted in risk-aversion and accountability: professional specifiers face regulatory, liability, and warranty obligations that reward proven, certifiable performance, creating institutional incentives that amplify the perceived importance of health, safety, and technical compliance. Sustainability specifications lack equivalent mandatory enforcement mechanisms at the point of specification, relegating them to secondary consideration, suggesting that health-positive framing offers bio-based insulation developers a more effective market-entry strategy than environmental credentials alone.

6.2 The Cost Paradox

The contradiction between cost efficiency ranking ninth in mean importance yet emerging as the top specification in top-3 selections suggests that cost functions as a qualifying threshold rather than a differentiating criterion: materials must be cost-competitive to remain in consideration, after which technical performance and health and safety determine final selection. This two-stage decision architecture is consistent with behavioral economics frameworks where threshold satisficing precedes optimization. As Markström et al. [5] note, inadequate incentives and high costs remain primary barriers for bio-based materials, confirming that cost parity is a critical precondition for market entry.

6.3 Sustainability Gap and Market Evolution

The low importance assigned to sustainability specifications (recyclability: 30%; bio-based: 18%; biodegradable: 23%) contrasts sharply with growing EU regulatory emphasis on circular-economy principles and embodied carbon. Directives such as the EPBD and the Construction Products Regulation are progressively mandating embodied carbon accounting and circular material flows, creating a structural divergence between current preferences and emerging requirements. This gap mirrors that of Gottlieb et al. [16], who documented cultural, market, and institutional barriers hindering bio-based material adoption despite favorable regulatory intent and is sustained by the absence of mandatory sustainability specifications in procurement, limited market education, and the longer payback horizon for environmental benefits. However, higher expertise correlates significantly with greater appreciation for sustainability specifications ($p < 0.05$ for recyclability, biodegradability, and sustainability), indicating that education and tightening regulatory compliance will progressively close the gap. A phased strategy is therefore appropriate: establish performance credibility first, then highlight environmental co-benefits, and ultimately advocate for instruments that elevate sustainability specifications to threshold status.

6.4 Implications for Innovative Construction Solutions

Successful innovative construction solutions must achieve a multi-dimensional value proposition [7, 8]. Environmental credentials alone are insufficient; materials must first deliver competitive technical performance in line with the specifications, as end users prioritize health and safety, thermal performance, durability, and moisture resistance. This reinforces Wang et al. [8], who identified business-related, technical, and policy barriers as the three constraint categories for green building material deployment. The manufacturer validation identifies four critical gaps: cost competitiveness, proven long-term durability, moisture resistance, and supply chain maturity. Bridging the sustainability gap requires coordinated action across three domains: technical (demonstrating performance parity), market (differentiating communication by knowledge level and stakeholder type), and policy (advocating for procurement instruments that elevate sustainable specifications from desirable to mandatory).

7 Conclusions

This study provides a comprehensive evidence base for end-user expectations on thermal insulation materials, integrating a literature review, a multi-stakeholder survey of 115 respondents across 13 categories and 12 European countries, and a two-phase validation exercise with five SNUG project manufacturers. End-users maintain a performance-first approach: health and safety (human health: 70%; dangerous substances: 68%) and core performance specifications (durability: 67%; energy efficiency: 67%; thermal conductivity: 63%) dominate across all stakeholder categories, while aesthetic and bio-based credentials receive substantially lower ratings. The decision-making hierarchy of technical, economic, environmental and social factors was confirmed statistically and through manufacturer validation, with cost efficiency as a threshold precondition. Knowledge-level analysis ($p < 0.05$ for six specifications) shows that higher-knowledge respondents value sustainability, recyclability, biodegradability, and supply security significantly more, revealing that current preferences and EU policy goals are misaligned in a knowledge-mediated way, making education and regulatory mandates effective levers for accelerating the transition. The manufacturer validation identified proven durability, moisture resistance, cost-competitive supply chains, and technical communication as critical challenges, defining the development agenda for sustainable insulation materials.

Acknowledgments. This work was carried out within the Horizon Europe No 101123150 SNUG project. The authors gratefully acknowledge the European Commission for their support and all survey respondents and manufacturers for their contributions.

Earthen Building Culture: Participatory Workshops for the Dissemination and Innovation in Abruzzo (Italy)

Stefania De Gregorio(✉), Luciana Mastrolonardo, and Donatella Radogna

Department of Architecture, University "G.'D'Annunzio" Chieti-Pescara, Pescara, Italy
stefania.degregorio@unich.it

Abstract. Earthen construction represents a sustainable and biodegradable resource, offering significant potential for resilient architectural practices in the context of climate change and environmental degradation. In Abruzzo (Italy), traditional earthen techniques historically supported rural settlements and community-based self-construction. However, the progressive adoption of industrial materials over the last century has led to a profound loss of intangible knowledge associated with this heritage technology. Preserving and reactivating this knowledge is essential for promoting culturally rooted, compatible with environmental protection, low tech and low cost.

This research investigates the results derived from participatory workshops, as tools for reintroducing and disseminating traditional earthen building skills within contemporary communities. Through hands-on laboratories open to citizens and targeted sessions for university students, participants engaged with the properties of local soils, learned traditional *massone* fabrication methods, and explored how variations in mixture composition affect performance. These activities connected the material resource (earth) with its intangible counterpart (collective memory and craftsmanship) highlighting the dual heritage value of earthen construction.

The outcomes demonstrate that participatory knowledge-transmission processes can enhance public awareness of sustainable construction, support local supply-chain resilience, and contribute to the regeneration of community identity. By integrating education, cultural heritage, and material innovation, the study aligns with the goals of resilient and sustainable built environments: reducing environmental impacts, fostering territorial circularity, and strengthening social engagement in the transition toward more adaptive and culturally meaningful construction practices.

Keywords: Sustainable Materials · Local Circular Supply Chain · Participatory Architecture · Traditional Building Culture

1 Introduction

Earthen construction represents one of the most ancient and widespread building techniques globally, experiencing renewed interest within contemporary sustainable architecture discourse [1]. Recent studies demonstrate that earthen materials require up to

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 91–99, 2026.
https://doi.org/10.1007/978-3-032-34930-9_11

90% less energy and CO_2 than fired concrete or brick solutions [2, 3]. Earth as a building material is biodegradable, locally available, requires minimal energy for processing, and can be fully reintroduced in the environment at the end of its lifecycle [4]. Earth construction demonstrates low embodied energy, minimal CO2 emissions during production, complete recyclability, and biodegradability [5]. Earthen walls possess high thermal mass, moderating interior temperature fluctuations and creating comfortable indoor environments limiting the use of mechanical systems [6]. The material's hygroscopic properties enable passive humidity regulation, maintaining optimal moisture levels between 40–60% relative humidity, which contributes to occupant health and well-being [7]. Traditional earthen construction techniques, particularly monolithic systems, demonstrate resilience to seismic events when properly designed [8]. In addition, earthen architecture embodies a cultural heritage, representing community-based construction traditions, collective knowledge systems, and place-based identity [9]. Despite considerable advantages, earthen construction faces technical limitations that have contributed to its progressive disuse, resulted in profound progressive loss of craft knowledge [10]. In fact, earth materials are vulnerable to water erosion and moisture damage [11]. Compressive strength of unstabilised earth typically ranges from 0.5 to 3 MPa, significantly lower than fired brick (10–30 MPa) or concrete (20–50 MPa) [12]. Earth construction lacks comprehensive technical standards in many jurisdictions, creating uncertainties for designers, contractors, and building officials [13]. Given the sustainability of rammed earth constructions, necessary considering the high environmental impact of the construction sector,[1] international research is pushing towards process or product innovation in order to overcome the technical limitations described above. Addition of small quantities (5–15%) of hydraulic lime, natural pozzolans, or biopolymers enhances water resistance and compressive strength while maintaining environmental benefits [16]. Natural fibers from agricultural and industrial byproducts (straw, hemp, sisal, wood chips) significantly improve tensile strength, reduce shrinkage cracking, and enhance earthquake resistance [17]. Emerging technologies including 3D printing with earthen materials, robotic rammed earth compaction, and parametric formwork design enable precision construction with reduced labor requirements and improved quality control [18]. These innovations bridge traditional craft knowledge with contemporary construction logistics. Confirming the importance of this sustainable material, several countries have advanced earthen construction standards, including New Zealand's NZS 4298:2020 (Earth Buildings), Germany's DIN 18945–18947, and emerging Italian regional guidelines [19–22].

1.1 Abruzzo Earthen Architecture (Italy)

Abruzzo's earthen building tradition, documented since the Neolithic period, represents a continuous architectural lineage spanning millennia. The technique reached its apex during the 19th and early 20th centuries, when earthen structures served the agricultural economy [9, 10]. These structures utilized raw earth bricks or the *massone* technique,

[1] The construction sector currently accounts for nearly 34% (year 2023) of global carbon emissions [14], with cement production alone contributing 8% of annual greenhouse gas emissions [15].

distinctive to Abruzzo and Marche regions. The raw earth bricks or *massone* typically utilized 15–35% clay fraction, 20–40% silt, and 30–60% sand and gravel. Cereal straw (wheat, barley, or oat) constituted 3–6% of dry mass, 16–22% of water, providing tensile reinforcement and controlling desiccation cracking. In case of *massone*, the mixture was then hand-formed into loaves, weighing 5–10 kg each, roughly cylindrical with tapered ends, measuring 20–30 cm length and 15 cm diameter. These forms were rolled in additional straw to prevent adhesion during stacking and enhance overall tensile strength of the assembled wall. *Massoni* were stacked in continuous spiral courses 50–70 cm high, forming monolithic perimeter and partition walls simultaneously. Each course required 3–5 days drying before subsequent layer addition, during which builders trimmed and shaped walls to vertical alignment using specialized tools. The resulting walls exhibited characteristic tapering profile, ranging from 80–90 cm thickness at base to 50 cm at eaves [10, 23, 24]. In the Abruzzo region, thanks to the commitment of municipalities and cultural associations (such as the CED Terra in the municipality of Casalincontrada [24]), a process has been underway since 1993 to understand the location and state of maintenance of raw earth buildings, to recover the architectural heritage made of raw earth and to involve the community in its conservation. Systematic documentation conducted during 1985–2021 identified that while in 1930 in Abruzzo (Chieti and Pescara provinces) there were approximately n°7000 buildings made of raw earth, currently n°806 buildings made of raw earth have been registered, of which only n°91 are in a good state of conservation, spread out across the entire territory [24]. Building typologies include single-story agricultural shelters, residential dwellings, and occasional two-story structures incorporating ground-floor stables with upper living quarters. The decline in the number of rammed earth buildings and their state of conservation, due to the widespread use of "universally valid" materials such as concrete and steel, highlights how the cultural reactivation of rammed earth construction knowledge can connect environmental sustainability (it is a low environmental impact and km 0 material widely available), local memory (the memories of elderly people are still linked to the building forms related to this technology) and innovation (to overcome the durability limits of raw earth constructions).

2 Method

The research employed two workshop typologies designed to reach distinct audience segments while maintaining approaches centered on "learn by doing" (see Fig. 1). The first is a participatory workshop "for all" occurred during a public research dissemination event, utilizing an outdoor information and demonstration stand situated in a high-visibility urban location in Pescara (Italy). The stand operated continuously from 9:00–20:00, maximizing accessibility for spontaneous participation. Large-format educational panels communicated the cultural and technical significance of earthen construction in Abruzzo. Content of the panels addressed the environmental benefits of earthen materials; historical development of raw earth brick and *massone* technique; traditional construction processes; contemporary innovation potential; and comparison with conventional fired brick production. Visual documentation included historical photographs, architectural drawings, and lifecycle assessment diagrams illustrating carbon footprint

differentials. A hands-on *massone* and raw earth brick fabrication station enabled visitors to engage directly with material processes. Two expert facilitators staffed the demonstration area: a cultural heritage researcher, and a materials expert specialized in earthen mixture design. Completed specimens remained on display throughout the event, illustrating collective production and material characteristics during drying.

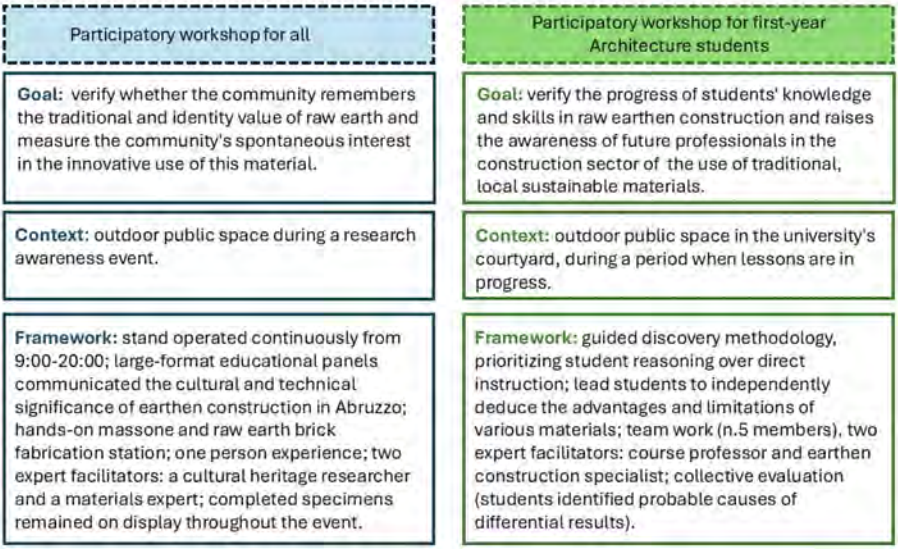

Fig. 1. Goal, context and framework of the 2 participatory workshops.

The second is a participatory workshop for first-year Architecture students at University "G. D'Annunzio" Chieti-Pescara, integrating earthen construction into fundamental building materials curriculum. The session occurred in the university's exterior courtyard, maintaining visibility to campus circulation, creating incidental awareness among broader university community. The workshop employed guided discovery methodology, prioritizing student reasoning over direct instruction. Initial discussion prompted students to articulate prior knowledge regarding construction materials, then introduced earthen techniques through comparative analysis with familiar materials (fired brick, concrete). Facilitated dialogue, coordinated between course professor and earthen construction specialist, led students to independently deduce advantages and limitations of various materials based on material properties, manufacturing processes, and lifecycle considerations. Each group received the basic materials needed for brick production (earth, straw, water), the equipment (mold for shaping, trowel, cauldron) and the recipe to follow. Facilitators demonstrated raw earth brick and *massone* forming in stages, allowing student observation before attempting each step independently. This scaffolded instruction supported skill development while revealing individual interpretation variations in executing teorically identical procedures. Following fabrication completion, the group reconvened for collective evaluation. Raw earth bricks and *massoni* exhibiting various quality outcomes (excellent cohesion and form retention, moderate performance,

significant defects) were analyzed systematically. Students identified probable causes of differential results. This analytical process transformed apparent "failures" into learning opportunities, demonstrating that earthen construction requires attentiveness to material behavior, environmental conditions, and procedural precision. In both cases the land was supplied from a land historically used for the construction of raw earth masonry located in the Municipality of San Martino sulla Marrucina (Chieti) which is approximately 35 km from the Municipality of Pescara, thus enhancing the local building culture. Both workshops employed systematic observation documenting: participant demographics; verbal interactions (questions posed, discussions initiated); technical outcomes (successfully formed raw earth brick or *massoni*, quality assessment); and post-workshop feedback (expressed interest, knowledge retention indicators).

3 Results and Discussion

In the "workshop for all," approximately n°110 visitors stopped by the stand to observe the informational materials and the ongoing activities involving the production of raw earth bricks and *massoni*. Of these, only 23 participants chose to actively make a raw earth brick or a *massone*, dedicating about 30 min to the activity. Participants showed a distinct age distribution: ages 5–10: 5 (21.7%); ages 11–18: 5 (21.7%); ages 18–28: 11 (47.8%); over 65: 2 (8.7%). The 28–65 age group showed a complete absence from hands-on participation: they often accompanied and encouraged their children or grandchildren to take part, while remaining observers themselves. Interviews with visitors and observational analysis revealed two contrasting interpretations of the workshop activity. Children up to 11 years old and the adults accompanying them perceived the manufacturing process as a recreational activity. In contrast, participants aged 18 and over recognized the activity as valuable training for skills development. The 18–28 age group actively inquired about material sourcing, regulatory requirements, and professional opportunities in sustainable construction. Interviews with visitors who did not participate in the practical activity identified several deterrents: concerns about getting dirty in the absence of nearby facilities to wash or support the activity; lack of sufficient time to complete the activity (at least 20 min required); and lack of confidence in their ability to successfully make a brick, with the consequent fear of embarrassment.

The university workshop, on the other hand, involved 55 first-year Architecture students, divided into groups of five, and was integrated into the "Materials" course. It presented raw earth construction as a real and contemporary building option rather than a historical curiosity. The facilitated discussion comparing fired bricks and unfired earth blocks proved particularly effective. Participants produced n°11 raw earth bricks and n°3 *massoni*. Despite the guided process and shared base materials, the results showed varying levels of quality. The subsequent analysis phase evolved into a competition for the best brick and generated moments of comparison and mutual support among participants. Common issues included: insufficient initial mixing, which created pockets of straw or unmixed clay lumps that weakened overall cohesion; an excessively plastic mixture causing slumping and poor shape retention; and insufficient manual pressure during forming. Only three bricks were well mixed, with smooth surfaces and adequate compaction. Students therefore identified that identical theoretical inputs produced variable outputs due

to procedural differences in execution. Post-workshop discussions revealed a strong understanding of the principles of earth construction, its environmental advantages, and its technical challenges. The workshop, held in the university courtyard, also created a ripple effect of indirect exposure among passersby (third parties, faculty from other disciplines, and students), generating curiosity and raising awareness on the topic. Both workshops demonstrated that participatory methodologies effectively transmit foundational earthen construction knowledge, though with demographic and contextual variations. Public settings attracted self-selected, intrinsically motivated participants, with limited demographic diversity. Academic integration ensured broader exposure, developing interest through direct experience. All active participants successfully completed fabrication, demonstrating that basic technical procedures can be transmitted in a time between 30 and 60 min. However, the quality of fabrication requires extended practice, confirming that workshop experiences provide entry-level exposure rather than comprehensive mastery. Post-workshop discussions revealed strong comprehension of earthen construction principles, environmental advantages, and technical challenges. Direct contact with the materials highlighted their technical complexity, the skills required, and their current relevance, helping to dismantle preconceptions that rammed earth constructions are obsolete and short-lived. While a single-session workshop "for everyone" is useful to raise awareness in the community, in the case of workshops with university students it doesn't provide sufficient training for a professional use. For them, multi-session progressive training programs would better. Demographic analysis reveals that age significantly influences engagement patterns, with young adults (18–28 years) demonstrating highest participation quality and receptivity. The notable absence of adults from 28 to 65 years, from hands-on participation suggests that cultural norms and contextual factors mediate workshop accessibility, requiring targeted strategies to engage this demographic group, which can have a high impact in terms of potential applicability of

Fig. 2. Phases of raw earth bricks production during the participatory workshops

the use of raw earth. Future editions should include shorter 10–15 min activities, pre-organized washing/support facilities, and low-threshold introductory tasks that reduce performance anxiety. Participants gained tangible understanding that sustainable construction alternatives exist and proven viable across centuries, challenging assumptions that environmental performance requires technological complexity or economic effort. While the workshops have not yet been systematically tracked in terms of direct transfer to completed building sites or formal policy measures, they should be read within the broader regional process of earthen heritage recognition (Fig. 2).

4 Conclusions

This research demonstrates that participatory workshops constitute effective instruments for reintroducing and innovating traditional earthen building knowledge, while advancing broader sustainability objectives including circular economy principles, local supply chain resilience, and community identity regeneration. Given the wide geographical diffusion of earthen architectural heritage, the workshop format presented here can be replicated in other regions, adapting materials, techniques, and communication strategies to the specific local building culture. Scaling earthen construction knowledge dissemination requires development of trainer programs, and open-access educational resources enabling broader geographic reach. Integration within university study path represents particularly strategic opportunity, ensuring that future construction professionals possess foundational knowledge of earthen techniques.

Synergies for Circularity Networks: Building Open Relationships for Boosting Remanufacturing Loops for High-Value Building Components

Cinzia Maria Luisa Talamo[1], Nazly Atta[1], Giancarlo Paganin[2], and Michele Laurante[1](✉)

[1] Department of Architecture, Built Environment and Construction Engineering (DABC), Politecnico di Milano, Milan, Italy

Abstract. Extending the service life of products and components is key to achieve resource efficiency, waste minimisation, and sustainable consumption. Among the various circular economy strategies, remanufacturing stands out as a high-value recovery approach that enables product life extension and multiple use cycles. Despite that, differently from other industrial fields, in the construction sector the practice of remanufacturing is still underdeveloped. A continuous and consistent reverse flow of building components from renovation sites to remanufacturers is not yet practicable due to some barriers such as low quantities of returned products, difficulties in product traceability and synergistic partnerships among stakeholders. To address these issues, the paper firstly proposes and discusses some innovative circular organisational models characterised by the central role of the Original Equipment Manufacturer (OEM) that, according to different logistic schemes, activates open and collaborative partnerships with multiple end-users to improve the opportunities for the collection of recovered products. Secondly, the paper applies one of the proposed organisational models to the case of an Italian raised flooring manufacturer, intending to verify the suitability of the model to boost synergistic partnerships by engaging multiple end-users involved in office site renovations and to enlarge the source of materials for remanufacturing loops.

Keywords: Remanufacturing · Circularity Networks · Product life extension · Circular Economy · Organisational Models

1 Introduction

Product life extension is receiving increasing attention in policy agendas as a strategic measure to reduce environmental impacts, limit material dependency, and boost economic competitiveness in businesses [1].

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 100–107, 2026.
https://doi.org/10.1007/978-3-032-34930-9_12

Among the circular economy strategies (reuse, recondition, repurpose and recycling) proposed by international standards [2, 3] and European regulations [4, 5], remanufacturing emerges as a high-value recovery approach able to extend the useful service life of products and components [6].

Remanufacturing is a "value-retention process" [6] that restores used parts, or cores, to "like-new" condition, with a warranty equivalent to an original new product [3]. Remanufacturing enables product life extension and multiple use cycles by minimising material inputs and energy demands, and it reduces acquisition and production costs, possibly allowing products to be marketed at lower prices [7]. Traditionally, remanufacturing practices have been successfully implemented in heavy industrial sectors – e.g., automotive, aerospace, and electronics – characterised by capital-intensive products with long service lives and predictable return flows [8]. In these sectors, manufacturers have progressively optimised supply chains to standardise remanufacturing and increase core recovery volumes. On the contrary, for sectors characterised by irregular return flows and fragmented supply chains, the diffusion of remanufacturing chains still remains highly variable [9].

The construction sector, recognised as one of the most environmentally impactful sectors [4], demonstrates significant delays in overcoming linear model of production and consumption [10] and, in particular, in developing systemic remanufacturing strategies. In 2020, the total amount of construction and demolition waste CDW (excluding soils and dredges) generated in the EU-27 stood at 333 million tonnes, making it the largest waste stream in the EU by weight [10]. Despite various possibilities of recovery, currently downcycling and low-grade operations (e.g., backfilling, energy recovery) still remain the most implemented ones [11]. In this scenario, the amount of building products that at the end of their service life are reintegrated into new construction through reuse or remanufacturing practices remains substantially low [12].

One of the barriers to reuse and remanufacturing can be recognised in the organisational structure of construction supply chains. Building product manufacturers usually do not manage the entire life cycle of their products [13]. Once products are sold and installed, manufacturers are rarely involved in their subsequent use, maintenance, or end-of-life management. Product ownership changes over time, information about performance degradation is seldom collected, and reverse logistics are not systematically organised. As a result, high-value building components such as floorings, ceilings, partitions, etc. – commonly used in tertiary buildings – are frequently directed to landfill and/or downcycling despite retaining material and a significant economic value.

Several scholars argue that to overcome these barriers, the development of open and collaborative organisational models and the enlargement of the geographical basin for the collection of recovered products can be valuable strategies [13, 14].

Starting from this premise, the paper reports the results of a research that investigates new synergistic models aiming to boost remanufacturing loops for recovering high-value building components.

The research proposes three organisational models of increasing complexity, ranging from traditional closed-loop configuration to integrated collaborative networks. To develop the models, a range of stakeholders – including architects, general contractors, manufacturer and tenants – operating in tertiary renewal projects were interviewed

through focus groups and roundtable discussions. These sessions were aimed at developing and refining the organisational models, with specific attention to stakeholder responsibilities, recovery streams, financial flows and coordination processes.

For validation purposes, one of the proposed models was applied to the case of an Italian raised flooring manufacturer, intending to verify the suitability of the model to boost synergistic partnerships by engaging multiple end-users involved in office site renovations, and to enlarge the source of materials for remanufacturing loops.

Overall, the paper aims to contribute to the emerging discussion on circular supply chains in the built environment by demonstrating how collaborative organisational models can support the scaling of remanufacturing practices for high-value building components.

2 Consolidated Remanufacturing Model for the Tertiary Sector

Tertiary sector seems to be particularly responsive to the implementation of remanufacturing practices. Tertiary buildings exhibit a higher rate of material turnover across a building life cycle [15]. These spaces undergo frequent changes within their layout due to, for example, aesthetic updates, corporate rebranding, or changes in tenancy. In these cases, the very short use phase (every 8–10 years) typically leads to the disposal of perfectly functional systems – e.g., raised access floors, suspended ceilings, demountable partitions – that are still in excellent condition while still retaining a significant residual performance [15]. Moreover, these systems often present specific characteristics – e.g., modularity, dry assembly, standardisation – that closely align with those supporting remanufacturing in other industrial sectors [16].

Evidence from stakeholder consultations and the analysis of existing practices reveals some forms of closed-loop relationships between the end user and the Original Equipment Manufacturer (OEM). This relationship can be described according to a "one-to-one" remanufacturing model (See Fig. 1a).

The "one-to-one" model reflects the traditional remanufacturing relationship, in which product ownership and responsibility remain within a mutual exchange between the OEM and the client. According to this model, the OEM maintains direct interaction with the building owner, and the recovered products are reused within the same spatial context in which they are located. The model is particularly suitable in the case of continuous ownership, such as in corporate headquarters or long-term leased assets. Agreements such as renting, product-as-service or leasing may stabilise relationships between OEM and client.

Despite its feasibility, the success of the "one-to-one" model largely depends on two conditions. On one side, the amount of recovered products that can justify the interest of the OEM in activating remanufacturing practice, and, on the other, the willingness of the client to accept remanufactured products. However, the one-to-one remains confined to the relationship between the OEM and the client, and, at present, it does not have the capacity to activate product flows, quantitatively significant and consequently to boost proper and scalable business strategies.

3 New Collaborative Remanufacturing Models for the Tertiary Sector

The limitations associated with the "one-to-one" model highlight the need to explore innovative models for supporting a consistent and reverse product flow from building sites to the OEM. In response to this need, two organisational models are proposed to strengthen remanufacturing loops for high-value building components in the tertiary sector, namely:

1. **Many-to-One Model (Synergistic Aggregation)**: In this model, multiple sites return limited volumes of products, which are aggregated and remanufactured by the OEM for redistribution to a single large project (Fig. 1b).
2. **One-to-Many Model (Synergistic Distribution)**: Within this model, a single site provides a sufficiently large volume of recoverable products, which, after remanufacturing, are redistributed across multiple recipient projects for reuse (Fig. 1c).

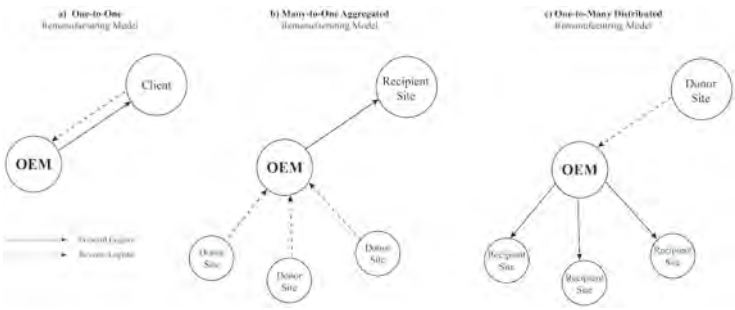

Fig. 1 One-to one (a), Many-to-one (b), One-to-Many (c)

These two models (Fig. 1b and c) derive from the "one-to-one" by progressively expanding the network of actors involved in product recovery and by introducing synergistic mechanisms capable of connecting otherwise independent renovation projects. It is important to notice that the concept of synergy characterising these models does not just refer to the simple collaboration among actors, but relies on the strategic balance of material volumes, incentives to remanufacturing, and interaction across temporally disconnected renovation projects.

3.1 Many-to-One Model: Synergistic Aggregation Configuration

The "many-to-one" model faces the issue of supply-side fragmentation by increasing the volume of recovered products and connecting different project sites.

In this model, multiple sites (donors) return limited quantities of recoverable components, which are aggregated by the OEM for remanufacturing and distributed to a single large recipient project for reuse. Within this structure, the OEM performs a buffering function, both spatially and temporally, by collecting and storing selected heterogeneous

products (both its products and those from other manufacturers) for remanufacturing. Compared to the "one-to-one" model, the OEM assumes more complex tasks, as it has to create and manage relationships with the donors, assess the characteristics and quality of the recoverable products, face the variability across product composition and coordinate reverse logistics among multiple actors.

The viability of this model largely depends on the capability of the OEM to involve many donors and create appropriate logistic chains, and at the same time on the presence of a sufficiently large project available for the supply of remanufactured products. Furthermore, the huge number of interactions between OEM and donor/recipients increases the challenges related to product traceability, characterisation, and assurance of residual performance. Components from different sites may vary in condition, making quality control more difficult, hence requiring careful inspection and assessment before reuse.

3.2 One-to-Many Model: Synergistic Distribution Configuration

Within the one-to-many model, a single donor site provides a large volume of recoverable components, which can be remanufactured and subsequently redistributed across multiple recipient projects. In this sense, the aggregation logic introduced in the Many-to-One model is reversed: a large and concentrated source provides products for reuse/remanufacturing and for small and scattered sites across the territory.

This model represents a strong potential for tertiary renovation projects, where large refurbishments periodically generate substantial recoverable volumes of high-value building components. By redistributing recovered material across multiple sites, the OEM reduce dependency on a single large recipient and diversifies the demand-related risk. Moreover, over time, if the OEM is able to consolidate the relationships and promote exchanges, recipient projects may become donor sites in future renovation cycles, progressively generating an interconnected network of material flows rather than isolated circular loops.

4 Application of One-to-Many Model to a Case Study

The One-to-Many model has been tested on the Nesite company, a leading OEM of raised flooring systems located in Italy.

Nesite supplies raised access flooring panels consisting of calcium sulphate or chipboard cores with an upper layer for resilient or stone finishing, and a lower aluminium layer for backing support.

As part of its business operations, Nesite provides a remanufacturing service dedicated to collecting and remanufacturing discarded Raised Access Floor (RAF) panels from tertiary building sites. In general, remanufacturing activities are focused on their own brand panels.

The possibility of activation of a One-to-Many Model has been studied on the case of a renovation project (the donor site) on a multi-storey office building in Bergamo (Italy), with an area of approximately 2,000 m^2. The intervention concerns the removal of the existing flooring panels, originally supplied by another manufacturer, to allow the installation of a new under Nesite brand. According to the model (Fig. 2), Nesite could

have implemented a take-back incentive scheme, offering new products at a reduced price on the condition that the existing flooring panels are returned. This solution could have reduced disposal costs for the client while securing a sufficient volume of recoverable materials for the OEM.

To assess the possibility of supply of the returned products, a review of the purchase orders received by Nesite from some Clients has been carried out, highlighting the presence of a specific request of another company, seeking remanufactured RAF for four office spaces, ranging between 250 and 400 m^2. This demonstrates the existing conditions for the application of the model that could have been applied according to the following process: (a) identification, (b) floor recovery, (c) remanufacturing, and (d) redistribution to recipient sites.

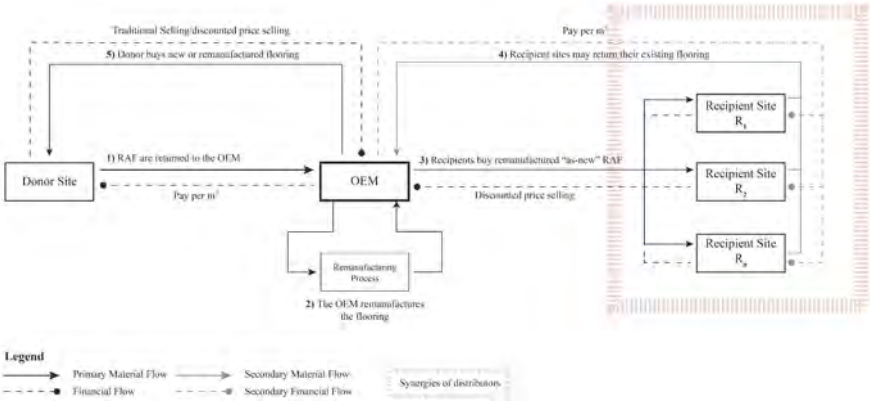

Fig. 2. One-to-many model applied to the Pilot case

To simulate the application of the model, a preliminary technical inspection was conducted to assess the quantity and type of panels suitable for remanufacturing. Results from the preliminary investigation led to the identification of approximately 1800 m^2 of raised flooring panels made of calcium sulphate (34 mm) used for self-laying surfaces, with an aluminium lower surface and four lateral ABS edges glued to the core. Panels located near partitions were considered excluded from the recovery process and sent to recycling. Moreover, because the panels were not originally sourced from Nesite, technical data sheets and the original purchase order were requested by the clients to allow tracing product specifications, identify technical characteristics and analyse the original mechanical performance. Once the material origin and conditions were established, the panels were considered able to be collected and sent to the OEM for remanufacturing. Within this scenario, the absence of any upper surface has been recognised as the best condition for customisation that can be requested by the recipient company. Static performance tests are necessary to ensure the compliance of the regenerated product with "as new" technical performance. In addition, a new identification code should be applied to guarantee traceability throughout the subsequent use cycle.

Overall, the model could enable the reintroduction of a used product into the market for a new cycle of use, hence leading to multiple benefits for the three actors involved.

The receiving client can obtain a regenerated product with high technical performance at a competitive purchase price. The manufacturer can benefit from marketing a flooring product without incurring the high costs of material procurement. Finally, the donor client can gain advantages by receiving a new product while also avoiding significant disposal costs associated with dismantled materials.

5 Discussion and Conclusion

The pilot application with Nesite provides initial evidence of the operational feasibility of the one-to-many model. The results indicate that large office renovation projects can serve as strategic sources of components for remanufacturing, offering a consistent inflow of high value products. The pilot also revealed the key role of OEMs in activating open and collaborative networks of end-users – sources of recovered products' sources – and in coordinating reverse logistic schemes. Particularly, across all proposed models, the following enabling conditions emerge.

- The ability of the OEM to establish multiple partnerships with donor and recipient sites. The OEM should act as a network activator by increasing the supply of recoverable products;
- New roles ("site agents") are required to support OEMs in identifying potential sources of recoverable products, supporting reverse flow coordination and matching supply and demand;
- Clients are more likely to participate when financial incentives and reputational benefits are present;
- Variability in product conditions requires inspection, testing, and grading protocols to ensure performance reliability.

Overcoming the study's limitations, future research should validate the models across multiple cases and integrate quantitative environmental and economic evaluations.

Concluding, the contribution by outlining innovative circular organizational models and related key implementation requirements – including product traceability, systematic technical verification of products, and OEM's ability to coordinate reverse logistics across multiple sites – contributes to promote circular material loops in the construction sector.

Abstract. This presentation presents an integrated approach to pre-demolition auditing aimed at enabling accurate classification of materials, including their quantities and location within the building, to maximize opportunities for reuse before considering recycling. The methodology is based on a cascading questionnaire that guides decision-making across four possible scenarios, consistently prioritizing reuse as the preferred pathway for each element or material. When mixed material streams are unavoidable, the approach incorporates robotic separation technologies capable of sorting the stream into single-material fractions, significantly improving the quality and efficiency of resource recovery. These processes are supported by the Connected Lab, a digital tool developed within the project that enables real-time acquisition of weight data for each material flow and provides remote visualization of the separation process. This eliminates the need for manual sorting or subsequent component testing, streamlining operations while enhancing accuracy and traceability. Overall, the proposed system strengthens circularity in demolition practices by combining structured auditing, automated separation, and digital monitoring to support informed decision-making and promote higher-value material recirculation.

Keywords: pre-demolition audit · material reuse · robotic separation · circular construction · digital monitoring · resource recovery

1 Introduction

Construction and demolition waste (CDW) represents one of the largest waste streams worldwide and poses significant environmental and resource management challenges. In the European Union, CDW accounts for approximately 25–30% of total waste generation, making it a key target for circular economy policies (La Rosa et al., 2018) [1]. Despite this, current CDW management practices still rely largely on conventional demolition processes that generate heterogeneous and contaminated waste streams. As a result, the recovery of high-value materials remains limited, and many materials are downcycled or disposed of instead of being reused (Duan et al., 2019) [2].

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 108–115, 2026.
https://doi.org/10.1007/978-3-032-34930-9_13

To address this issue, the European Union has established ambitious circular economy targets aimed at increasing material recovery and moving towards near-zero CDW generation by 2050. Achieving these objectives requires improved methods for identifying reusable materials before demolition begins, preventing valuable components from entering mixed waste streams (Huang et al., 2018; Adams et al., 2017) [3, 4].

Pre-demolition audits have therefore become an essential tool for enabling more circular demolition practices. These audits aim to identify building materials, estimate their quantities, determine their location within the building and assess their potential for reuse (European Commission, 2024) [5]. However, traditional auditing practices remain fragmented, often involving multiple stakeholders and extensive manual data collection. This reduces efficiency and limits the identification of reusable materials before demolition takes place. Recent research has explored the use of digital technologies to improve this process through automated inventories and data-driven decision-making. One promising approach involves the digitization of legacy building documentation. Artificial intelligence can convert paper-based drawings into CAD models, improving the availability and accuracy of building information (Omer et al., 2024) [6]. These models can then be transformed into three-dimensional representations, while augmented reality (AR) tools allow on-site adjustments to reflect the actual condition of the building. This workflow makes it possible to create more reliable digital inventories that capture material types, quantities and spatial locations, supporting improved demolition planning and waste management (Chi et al.) [7].

At the same time, significant progress has been made in automated waste sorting technologies. Robotic sorting systems equipped with multisensory perception pipelines, including hyperspectral near-infrared (NIR), RGB and depth sensors, can analyze waste streams in real time and classify materials using artificial intelligence algorithms (Pires et al., 2021) [8]. By isolating contaminants such as gypsum, glass or wood, robotic systems can significantly improve the purity of recycled aggregates and increase their suitability for reuse in construction (Ghavami et al., 2020; Huang et al., 2020) [9, 10].

Despite these advances, digital auditing and robotic sorting technologies are typically implemented independently. Digital tools mainly support early demolition planning stages (Omer et al., 2024; Cheng et al., 2022) [6, 11], while robotic sorting systems are generally used later in waste treatment facilities (Pires et al., 2021; Ghavami et al., 2020) [8, 9]. As a result, demolition waste management workflows remain fragmented and lack an integrated framework that links auditing, automated separation and real-time monitoring (Huang et al., 2018; Adams et al., 2017) [4, 10].

2 Methodology

To address this gap, this paper proposes an integrated framework combining digital auditing, robotic sorting and real-time monitoring. The auditing process begins with a digital questionnaire based on the *Pre-Demolition Audits 4.0* workflow. This questionnaire evaluates each building element and categorizes it into reuse, repair, recycling or disposal pathways (Adams et al., 2017; Cheng et al., 2022) [4, 11]. The cascading logic prioritizes reuse over recycling by first evaluating whether a building element can be directly reused in its current condition or with minimal repair interventions. Only when

reuse is not technically, economically or functionally feasible does the evaluation proceed to subsequent cascading questions related to recycling or disposal options. This sequential decision-making approach ensures that higher-value recovery strategies are always considered before lower-value recovery pathways. Legacy building drawings are digitized using AI to generate CAD and BIM-compatible 3D models, which are verified through AR-assisted inspections to produce a digital inventory of materials and associated Eural waste codes (Lu et al., 2005; Gimenez et al., 2016; Cheng et al., 2022; Omer et al., 2024) [6, 11, 14, 15].

Mixed demolition waste streams are subsequently processed using an automated robotic sorting unit equipped with hyperspectral NIR, RGB and depth sensors. A one-dimensional convolutional neural network (1D-CNN) identifies materials such as gypsum, concrete, wood and glass in real time, enabling a pick-and-throw strategy that separates waste into dedicated containers. Previous studies have shown that similar AI-based systems can achieve classification accuracies above 85% while significantly improving the purity of recovered aggregates (Pires et al., 2021; Zhao et al., 2022) [8, 13]. In the current pilot, the reported classification accuracy values were primarily obtained under laboratory-controlled conditions using representative material samples. However, the robotic unit was also tested using real mixed samples directly collected from a construction and demolition waste treatment plant, where the system also demonstrated promising identification and separation performance under more realistic operational conditions. The processing speed of the robotic sorting unit can be adjusted depending on the operational requirements and conveyor belt speed. This flexibility allows the system to adapt to different waste flow conditions and material compositions while maintaining stable classification performance.

Material flows are monitored through a digital platform referred to as the Connected Lab. Industrial scales installed at both the inlet and outlet of the robotic system record the mass of each material fraction and transmit the data via OPC-UA to a web-based dashboard. This dashboard visualizes material flows, key performance indicators and mass balances in real time. In addition, integrated IP cameras provide visual verification of the process, while stored datasets allow post-process analysis and performance evaluation (Zhao et al., 2022; Cheng et al., 2022) [11, 13]. Special attention must be given to environmental conditions during operation, particularly regarding dust generation and fine particles commonly present in demolition waste streams. Since the robotic unit relies on optical sensing technologies such as hyperspectral NIR and RGB cameras, excessive dust accumulation may affect sensor performance and material recognition accuracy. For this reason, protective measures and controlled operating conditions are currently recommended to preserve sensor reliability.

Finally, the data generated during the auditing, sorting and monitoring stages feed into a decision-support module that prioritizes reuse over recycling whenever feasible. By considering factors such as structural safety, economic feasibility and logistical constraints, the system identifies the most appropriate recovery strategy for each material stream and supports circular demolition practices (Duan et al., 2019; Ghisellini et al., 2016) [2, 12].

3 Results

Although several technological advances have been proposed to improve construction and demolition waste (CDW) management, several operational challenges still affect the efficiency of current demolition workflows. These challenges arise from the fragmented nature of the demolition process, where material auditing, waste sorting and monitoring are typically treated as separate stages with limited data exchange between them. Consequently, valuable information generated during pre-demolition audits is rarely connected to downstream waste processing activities, reducing the overall efficiency of resource recovery strategies.

In conventional demolition practices, pre-demolition audits often rely on manual inspections, heterogeneous documentation formats and the subjective interpretation of auditors. This leads to inconsistencies in the identification of reusable components and limits the reliability of material inventories generated during the planning stage. At the same time, waste sorting processes carried out in treatment facilities are frequently constrained by the quality of incoming mixed waste streams, which complicates the separation of materials and reduces the purity of recovered aggregates.

In addition to these technical limitations, many existing systems lack adequate mechanisms for monitoring and tracing material flows throughout the demolition and recycling process. Data regarding material quantities, sorting performance and recovery rates are often collected manually or analyzed retrospectively, which restricts the ability to optimize the process in real time. As a result, the absence of an integrated workflow linking digital auditing, automated sorting and monitoring technologies remains a major barrier to the implementation of circular demolition strategies.

To better illustrate these limitations and the improvements introduced by the proposed framework, Table 1 summarizes the main operational challenges encountered in current CDW management practices and compares them with the solutions implemented in this study. The table highlights how the integration of digital auditing tools, AI-based modelling, robotic sorting technologies and real-time monitoring systems contributes to addressing these issues and improving the overall efficiency, traceability and circularity of demolition operations.

As shown in Table 1, the proposed framework addresses several structural limitations commonly observed in conventional construction and demolition waste (CDW) management workflows. These limitations typically arise from the fragmented nature of demolition processes, where material identification, waste sorting and monitoring are treated as independent stages rather than as parts of a unified system.

The introduction of the digital cascading questionnaire significantly improves the efficiency and reliability of pre-demolition audits. By structuring the evaluation of building elements and standardizing the decision-making criteria used by auditors, the questionnaire reduces the dependence on manual interpretation and improves the consistency of the collected information. This structured approach not only reduces the time required to complete audits but also enables the early identification of reusable components that would otherwise be lost during conventional demolition operations.

In parallel, the AI-driven digitization of legacy building documentation improves the accuracy and completeness of audit inventories. Converting paper-based drawings into CAD and BIM-compatible models enables the automatic extraction of information such

Table 1. Current challenges in CDW management and improvements achieved by the proposed framework.

Challenge in current CDW management	Proposed solution	Improvement achieved
Fragmented and time-consuming pre-demolition audits due to manual inspections, multiple stakeholders and unstructured documentation	Digital cascading questionnaire based on the *Pre-Demolition Audits 4.0* workflow, enabling structured evaluation of building elements and automated categorization into reuse, repair, recycling or disposal pathways	≈20% reduction in audit duration and ≈50% improvement in decision-making accuracy through standardized evaluation criteria
Incomplete or inconsistent building documentation caused by paper drawings or outdated CAD files	AI-driven digitization of legacy drawings converting raster scans into CAD and BIM-compatible 3D models, complemented by AR-assisted on-site verification	Automated generation of material inventories including material types, quantities and Eural waste codes, reducing transcription errors
Limited identification of reusable components in conventional demolition planning	Digital material inventory integrated with structured decision rules prioritizing reuse before recycling	Improved identification of reusable building elements and better alignment with circular economic objectives
Mixed waste streams reducing recycling quality	AI-based robotic sorting system combining hyperspectral NIR, RGB and depth sensors with machine learning classification	Material classification accuracy up to 96.5% and improved separation of contaminants such as gypsum, wood and glass
Low purity of recycled aggregates due to insufficient sorting precision	Robotic pick-and-throw separation of detected materials into dedicated containers	Sorted fractions reaching 84% purity by weight and 97% by object count
Lack of traceability of material flows in demolition waste processing	Connected Lab digital monitoring platform integrating OPC-UA scales and real-time data visualization	Continuous monitoring of material flows, automated mass balance calculation and elimination of manual weighing procedures
Limited integration of data across demolition planning and waste processing stages	Integrated digital framework linking auditing data, robotic sorting outputs and monitoring dashboards	Improved transparency, traceability and decision-support capabilities for circular demolition practices

as material types, quantities and waste codes. Combined with AR-assisted inspections, the resulting digital twin provides a reliable dataset for demolition planning and resource recovery analysis.

At the waste processing stage, robotic sorting technologies improve material separation compared with conventional manual methods. By combining hyperspectral sensing, RGB imaging and depth perception, the system accurately identifies material classes, removes contaminants and increases the purity and reuse potential of recovered aggregates.

Another key contribution is the Connected Lab monitoring platform, which ensures traceability throughout the demolition workflow. Through industrial weighing systems and real-time data visualization, it enables continuous monitoring of material flows and operational performance, improving transparency while reducing the need for manual measurements and laboratory testing.

Finally, the integration of digital auditing, robotic sorting and real-time monitoring supports data-driven decision-making that prioritizes material reuse whenever feasible. Overall, the results demonstrate improvements in efficiency, data quality, material recovery and process transparency, providing a strong foundation for more circular demolition practices.

4 Conclusion

Construction and demolition waste (CDW) remains one of the largest waste streams worldwide and represents a major challenge for achieving circular economy objectives in the construction sector. Traditional demolition workflows are often fragmented, with pre-demolition audits, waste sorting and monitoring processes typically carried out as separate activities. This lack of integration limits the identification of reusable materials, reduces sorting efficiency and weakens the traceability of recovered resources.

This paper presents an integrated framework that combines digital pre-demolition auditing, automated material separation and real-time monitoring to support more circular demolition practices. The proposed approach integrates several technological components within a single workflow, including a cascading digital questionnaire for structured audits, AI-based digitization of legacy building documentation, robotic sorting of mixed waste streams and the Connected Lab digital monitoring platform.

The results indicate that the digital questionnaire improves audit efficiency by reducing the time required for inspections while increasing the consistency of decision-making. AI-based digitization of legacy drawings enables the creation of BIM-compatible digital models that automatically generate detailed material inventories, reducing transcription errors and improving data consistency.

At the waste processing stage, the robotic sorting system demonstrated high classification accuracy and effective separation of mixed CDW streams. By combining hyperspectral sensing, RGB imaging and depth perception, the system identifies contaminants and separates materials into dedicated fractions, improving the purity of recovered aggregates. In addition, the Connected Lab platform enables continuous tracking of material flows and recovery rates, providing transparent and traceable information on sorting performance.

Despite the promising pilot results, challenges remain when dealing with dust, gypsum residues and highly heterogeneous waste streams, which can affect the accuracy of automated classification systems. Future work will focus on improving sensor robustness and AI-based recognition capabilities. Overall, the proposed framework demonstrates that integrating digital auditing, automated sorting and real-time monitoring can significantly improve the efficiency, transparency and circularity of CDW management, supporting more sustainable demolition practices and higher-value resource recovery.

Abstract. The prefabricated composite modular system using lightweight steel frame members connected with double-shell composite walls that play the role of smart façade elements is known and very effective for low-rise buildings. The novelty of this structure is the prefabricated composite twin walled load-bearing walls, which compose a reliable building system based on innovation and sustainable design, giving various advantages to the structural project, reducing costs and safety. In this paper is investigated the structural performance and the respective cost by upgrading this modular prefabricated system from low-rise to medium-rise buildings. Aiming to obtain a clear perspective of the dynamic performance of the upgrading buildings, a known example of a 4-storey building was simulated and estimated using computer software. This analysis includes evaluation of dynamic performance in relation to a similar known reinforced concrete building. Moreover, a similar evaluation in terms of total structural cost was carried out. The verification of the structural performance showed an optimal way to reduce displacements, buckling loads and bending moments for this type of structures. The proposed system can lead to sustainable buildings in terms of total cost and used materials and resources, with advantages to the structural and seismic behaviour, the quality of construction and the speed of erection.

Keywords: Prefabricated Modular Buildings · Composite Steel-Concrete Structures · Façade Elements · Seismic Performance · Sustainable Design

1 Introduction

Over the last thirty years, in many new high-rise buildings worldwide erected by the use steel and composite structural members due to their reliable methods of construction based on prefabrication [1, 2]. Composite of steel and concrete modules can be manufactured in the factory, in many identical copies under a low-cost, high-quality

https://doi.org/10.1007/978-3-032-34930-9_14

and controlled environment [3–5]. This fabrication process and the respective modular erection include optimal techniques for easy transportation [6], integrated and sustainable building systems. In this field, a previously presented and patented modern system [7], based on steel frames infilled with precast load-bearing composite walls have been proved to be particularly effective to erect low-rase buildings. This efficiency is based on one hand on the minimization in cost due to the required steel weight of members and on the other hand on a reliable bearing capacity in serviceability, ultimate and seismic conditions, with easy dismantle and ability to reuse, the most of its components. Moreover, by using prefabricated elements increases the thermal mass of such building types and decreases possibility of overheating, thermal discomfort and cooling energy needs during the warm period of the year [8]. In the presented research [9], an upgrading of this prefabricated system to medium-rise buildings is numerically analyzed and discussed using a typical example of a 4-storey composite building in comparison to a fully concrete one in terms of bearing capacity, cost efficiency and sustainability.

2 Efficiency of Prefabricated Modular Composite Double Shell Wall System

Steel-concrete composite structures are one of the most advanced structural systems in modern engineering [10, 11], as they combine the high strength and ductility of steel with the stiffness and compressive strength of concrete. Their seismic behavior is of particular interest, as the cooperation of the two materials can be exploited to achieve effective seismic energy attenuation, provided that the design is carried out with clear control of the failure mechanisms.

In this study, is used the precast composite of concrete and steel panel (see Fig. 1), performed in the Laboratory of Experimental Strength of Materials and Structures at the Aristotle University of Thessaloniki [12]. This is a structural infilled panel attached to the columns of the steel frame through bolted joints, providing access for easy assembly and service. This system works as a smart control system and can increase the robustness of the steel frame under seismic action [13]. The chosen bolted connections are suitable for easy precast construction, service, and sustainability. The comparison of this type of panels with other load-bearing elements made as sandwich panels with precast concrete shows that the proposed invention offers a better contribution of the envelope to bearing capacity and to dynamic performance of the building.

The increase of this type of construction to higher buildings is a design challenge. First target is the optimal utilization of the bearing capacity offered by the panels to the structural system. Second target is the limitation of the tensile stresses in the concrete shells due to the increased displacements. This research showed that this limitation with elementary only changes in the preconstruction procedure can leads to limited tensile cracks in the concrete for up to 5-storeys buildings.

The combination of precast concrete and structural steel elements in building prefabrication offers structures with enhanced structural and thermal performance. The high interest in mixed construction is motivated by its efficient employment with modular construction techniques enabling faster erection and completion of many different types of buildings compared to conventional constructional methods. The proposed composite

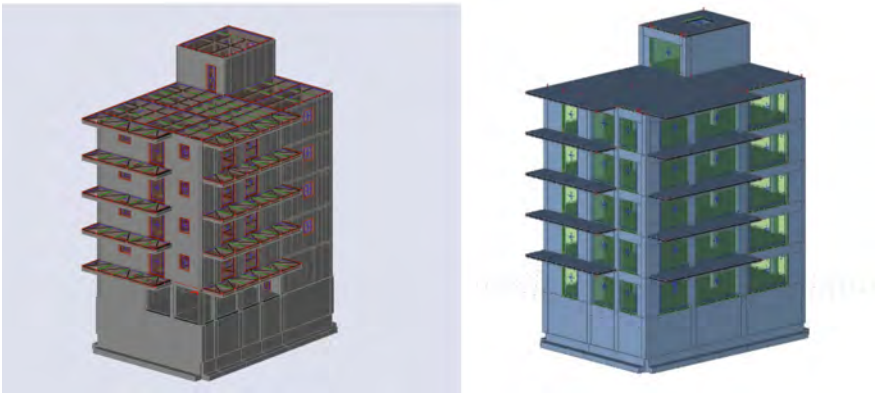
Fig. 1. View of a typical preconstructed module wall in the track (left) and of composite preconstructed building erection (right).

of steel and concrete modules can be easily manufactured in a preconstruction stage of factory-made components under a quality [14] and a low-cost environment, which are transported and assembled on-site using suitable connections to assure structural continuity. The erection and assembly cost on-site could be decrease by the increase of the repeated prefabricated modules. Practically this can happen when the number of floors increases and the prefabrication expands from low-rise to medium-rise buildings. It Is noted that this structural modular system consists of three lateral resisting mechanisms: (i) contribution of the external steel frame; (ii) direct interaction between the steel frame and the compression diagonal strut in the PCSP; (iii) interaction between the steel frame members and the respective upper steel and lower concrete surfaces through friction contact and shear connection by additional shear steel bars and in-situ concrete layer in the lower one [12].

The contribution of the building element to the structural performance of the building leads to lighter steel components of the main steel framework of the building, which in turn decreases the cost of construction, the transportation and assembly on site, as well as the environmental impact through the whole life cycle. The configuration of the proposed element provides structures with increased structural and thermal performance with a minimized wall width. Along with the reduced section of the steel framework's elements the building envelope occupies a lesser percentage of the built area, allowing for more free indoor space for utilization. At the same time, an extra thermal insulation layer embedded between concrete panels, increasing the energy efficiency. Additionally, the concrete shells of the composite walls provide the necessary thermal mass. The high thermal insulation of the building elements in combination with the thermal capacity of the building elements contributes to the minimization of the energy requirements for heating and cooling and therefore leads to the creation of comfortable indoor climatic conditions with the lowest possible energy use becoming to the philosophy of almost zero building energy consumption [15]. Moreover, the used here composite prefabricated models are easily disassembled for fully recycling or reusing.

3 Upgrading Aspects of the Prefabricated Composite Modular System from Low-Rise to Mid-Rise Buildings

A typical workflow of a prefabricated building of such type includes the following steps at the construction site. After a conventional construction of the foundation, anchors are applied in place of the columns to secure the prefabricated composite modules. After this the composite module walls, that were prefabricated from the factory are transferred to the construction site, the columns are secured to anchors through appropriate steel bolts, always in accordance with what has been defined by the design concept.



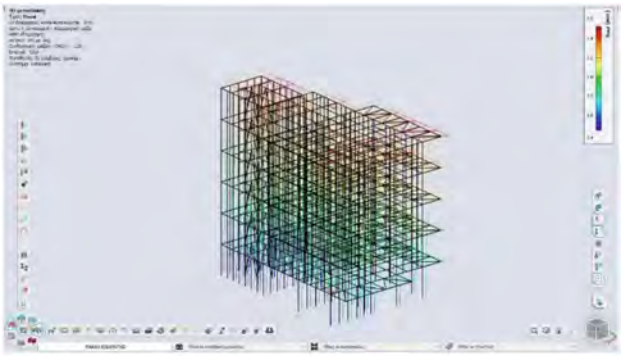


Fig. 2. Simulation models of a composite building (left) and typical concrete building (right).

At this stage and given the general performance of such the system, an investigation is made of the vulnerability to dynamic loads of an upgrading to a representative four-story composite building, in comparison with a corresponding building made of reinforced concrete. The purpose of the work is to evaluate the seismic response and the relative vulnerability of the two structural systems, taking into account modern regulatory requirements and the principles of seismic design. This is followed by the simulation and analysis of the two buildings using the SCIA Engineer software (see Fig. 2), under seismic actions, examining parameters such as the behavior coefficient, soil conditions and seismic zone. Finally, a comparative assessment of the seismic behavior is carried out and critical vulnerability issues are highlighted, regarding the advantages and limitations of this specific composite prefabricated building system compared to conventional reinforced concrete structures.

4 Dynamic Performance and Vulnerability of a Mid-Rise Composite Building with Prefabricated Module Walls

The composite building is a prefabricated structure, which consists of structural members of the previously described system. The load-bearing structure consists of steel frame, on which composite panels and composite slabs are connected. The walls of the load-bearing structure follow the system of prefabricated composite double-shell walls, for

which structural elements an extensive reference has been made previously. These walls are part of the load-bearing system of the building and contribute decisively to the overall stiffness and strength of the structure. The foundation and the basement of the building is constructed entirely of reinforced concrete and consists an independent and sufficiently rigid system for retaining the soil and transferring vertical and horizontal loads to the ground. After a series of numerical tests and checks, the final static model including sizes of structural members emerged, which was used to conduct the analysis.

Eigenmode	Eigenperiod (sec.)	W_x/W_{xtot}	W_y/W_{ytot}	W_z/W_{ztot}	W_{zl_R}/W_{ztot_R}
1st	0,55	0,0155	0,8822	0,0000	0,0036

Fig. 3. First eigenmode (translational in y direction) of the composite building model.

For the seismic analysis, the design spectrum of EN1998 was used, with a design acceleration a = 0.24 g (seismic zone 2), soil category C and behavior factor q = 3. According to the Eurocode 8 classification, the building under consideration falls into category (a), i.e. a moment frame system made of steel or composite elements with connected wall infills made of prefabricated concrete walls.

Initially, the results of the eigenmode analysis for the two respective types of buildings, prefabricated composite and concrete respectively are calculated. More specifically, the values of the eigenfrequencies and the relative eigenmode masses, as well as the main translational and torsional eigenmodes for each building are tabulated. As can be seen, in both cases of buildings the sum of the effective eigenmode masses is ≥90% of the total mass of the building. Furthermore, it is observed that in both analyses the main translational eigenmode in the y direction is the 1st (see Fig. 3), in the x direction the main translational eigenmode is the 2nd and the main torsional eigenmode is the 3rd. The difference arises in the main translational eigenmode in the z direction, where for the composite building it is the 10th, while for the reinforced concrete building it is the 6th. It is worth noting that the percentage of activated mass in the main modes is slightly greater in the case of the reinforced concrete building, while the difference in the main transport mode in the z direction is more noticeable, and this is because the composite building is a lighter structure compared to the reinforced concrete building.

The results of the maximum displacements at each floor for both analyses are presented (see Fig. 4), for the load combinations referred to the main earthquake in x and

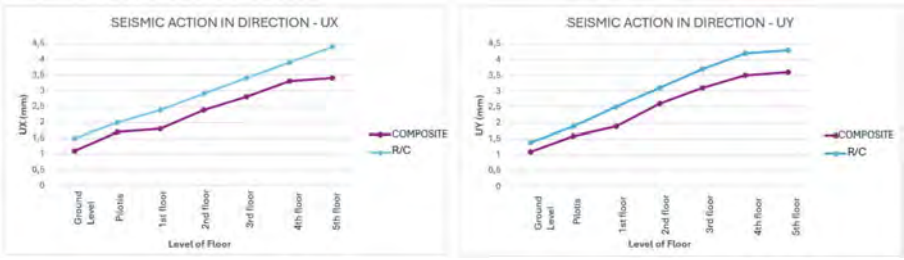

Fig. 4. Seismic displacements in horizontal directions of the building models, composite building results (Cyan), concrete building results (Magenta).

the main earthquake in y, respectively. The reinforced concrete building is a heavier structure compared to the composite building which is a more flexible due to the use of steel frames in the bearing system and that explains the fact that the displacements of the latter are smaller.

In seismic design is very important the degree of sensitiveness of a structure to seismic excitation of a given intensity. This is directly linked to the inherent characteristics of its structural system, such as materials, geometry, typology etc. In this study, the vulnerability of the compared systems investigated through the correlation of structural response quantities, such as displacements, bearing capacity ratios, under the imposed seismic actions for different soil conditions, behaviour factor q and seismic accelerations in respect to the Greek seismic zones. From this comparative examination of the bearing capacity diagrams between the two systems it follows that, for the same seismic assumptions, the reinforced concrete building generally presents higher rates exhaustion of bearing capacity compared to the composite prefabricated building. This behavior is mainly attributed to the differentiated capacity of absorbing and dissipating seismic energy in the two structural systems. In the case of the reinforced concrete building, the limited ductility and the lower energy damping at the structural level leads to increased demands on the individual structural elements, which is reflected in the higher rates of exhaustion (Fig. 5).

On the contrary, in the composite prefabricated building, the collaboration of steel and concrete contributes to more effective absorption of seismic energy and a more uniform distribution of demands, limiting both the tension of the structural members.

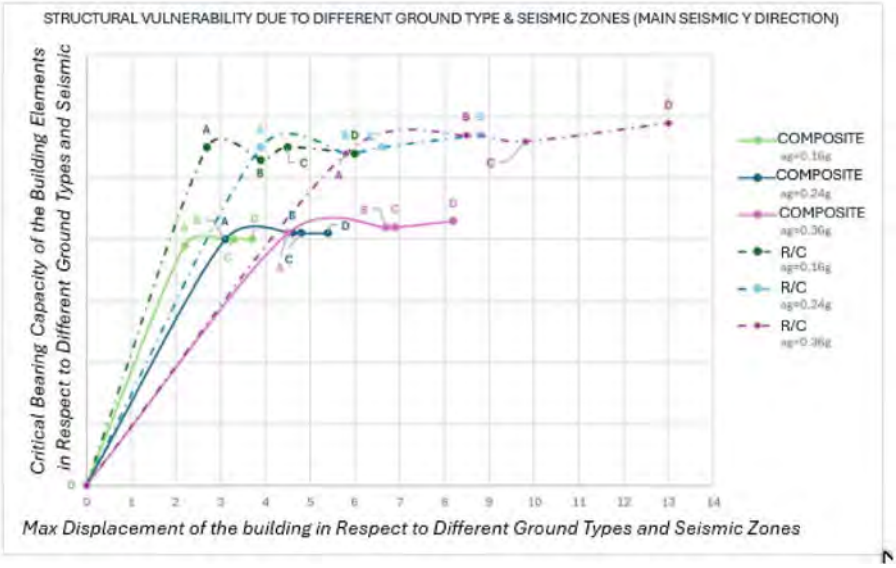

Fig. 5. Bearing capacity ratios of critical structural members for the composite building (continued lines) and concrete building (divided lines) for different response quantities.

5 Conclusions

- The composite prefabricated building exhibits similar stiffness to the corresponding reinforced concrete building, which is usually a design challenge. Moreover, exhibits better torsional behaviour, which is attributed to the targeted and balanced arrangement of the prefabricated double-shell walls.
- Significantly reduced vertical displacements that are observed in the composite medium-rise building, which is attributed to its lower total mass. So, taking into account an equivalent distribution of the composite wall modules to the main directions of the building with considerable stiffness with significant seismic energy absorption with obvious benefits in the safety of the building.
- Under the same seismic assumptions, the prefabricated composite building exhibits lower rates of exhaustion in the bearing capacity of members.
- The configuration of the proposed element provides structures with increased structural and thermal performance with a minimized wall width. Along with the reduced section of the steel framework's elements the building envelope occupies a lesser percentage of the built area, allowing for more free indoor space for utilization.
- The use of this highly effective prefabricated system could be a green and sustainable design choice, especially for medium-rise building cases on high-risk seismic zones.

Abstract. The circular economy approach, which is based on the principles of keeping products and materials in the economic system for as long as possible, reducing waste, and regenerating natural systems, has become a strategic model in many fields, especially in the construction industry, over the last decade. Accordingly, interest in the circular economy has been rapidly growing on various themes. This study aims to examine the temporal and thematic evolution of this growth in the circular economy literature at material, building, and city scales. Within this context, scale-specific queries were identified, and articles related to three scales were systematically analyzed to map temporal changes. Journal articles in English in the Scopus database were included. Publication pools were created with queries representing each scale, and text-corpus was prepared by combining the title-abstract-keyword fields in the bibliographic records. Then, Structural Topic Modeling (STM) was applied in the RStudio environment to extract six thematic clusters specific to the scales. The topic trends were interpreted using FREX, and temporal changes between the periods 2015–2019 and post-2020 were compared. The findings indicate that circularity crystallizes differently across scales. While the focus on performance and material substitution strengthens at material and building scales, discussions on adoption barriers, procurement, and indicator-based assessment become more visible at the city scale. This dual-focused analysis aims to create a dynamic discussion, positioning, and research agenda for future work by emphasizing not only current trends and key themes but also less explored research fields.

Keywords: Circular Economy · Construction Industry · Topic Modeling · Digital Technologies · Circular Design

1 Introduction

The worsening negative impacts of climate change have brought sustainability discussions to the forefront of various agendas. Over the last decade, sustainability practices have evolved to the circular economy (CE) paradigm, which aims to keep materials and

L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 125–133, 2026.
https://doi.org/10.1007/978-3-032-34930-9_15

products in the system as long as possible, design out waste, and regenerate natural systems [1, 2]. With the emergence of the CE, the interest in the circular construction industry has gained momentum to tackle the negative impacts of the construction industry, which accounts for 35% of total waste generation [3] and 50% of raw material consumption [4]. So, CE has been addressed from different perspectives in the construction industry, including reclaimed materials, circular transition, assessment tools for circular building design, and stock-and-flow analysis [5]. CE has also been discussed from the perspective of the supply chain and innovative business models [6]. Beyond these, the impact of digital technologies in accelerating the circular construction industry [7] has been part of the circularity agenda, as information flows across life cycle stages is essential for robustly transforming the industry. All these developments could be achieved through a scale-based approach that considers the micro, meso, and macro scales for a circular built environment [8], addressing not only materials and products, but also components, buildings, cities, regions, industries, and systems. Therefore, CE has gained a different reputation as the construction industry differs from other industries due to its own characteristics. As a result, various themes have evolved within this paradigm, with trends and themes reforming over the last decade.

This study employed a quantitative approach combining bibliometric data collection and text mining to examine the thematic structure and temporal evolution of the CE literature in the built environment and construction industry. The literature review was conducted using the Scopus database. The research design was structured around three scales: material scale, building scale, and city scale [9, 10]. Material scale represented the material circularity, including secondary and reclaimed, recycled materials; building scale represented the design for circularity, including DfD, modularity, adaptability, and building lifecycle extension strategies; and city scale represented the urban circularity, including supply chains, governance, urban mining, and metrics. This approach quantitatively reveals thematic divergence across scales and temporal trends by consistently covering a large number of publications set.

2 Method

This study aimed to analyze the evolution of fundamental themes associated with the CE in the construction industry over the years. The analytical framework was structured at the material, building, and city scales to both simplify the literature conceptually and highlight different research clusters along the material-building-city axis. To this end, the themes were analyzed within three scale perspective, and specific queries were defined for each scale. Firstly, the core filter covering CE and the built environment was combined with scale-specific keyword blocks (Fig. 1) to generate a separate publication pool for each scale, which was then labeled as a scale variable in the analysis.

Data collection was performed through the Scopus database in "*Article Title, Abstract, Keywords*". Only peer-reviewed journal articles published in English were included in the study. Conference proceedings, book chapters, editorials, and others, rather than articles, were excluded. The records were exported in a .csv file, including citation information and abstract and keywords, without a time limit.

For text-based analysis, a document-level text corpus was created by combining the title, abstract, and keyword fields of each record in .csv files. Standard preprocessing

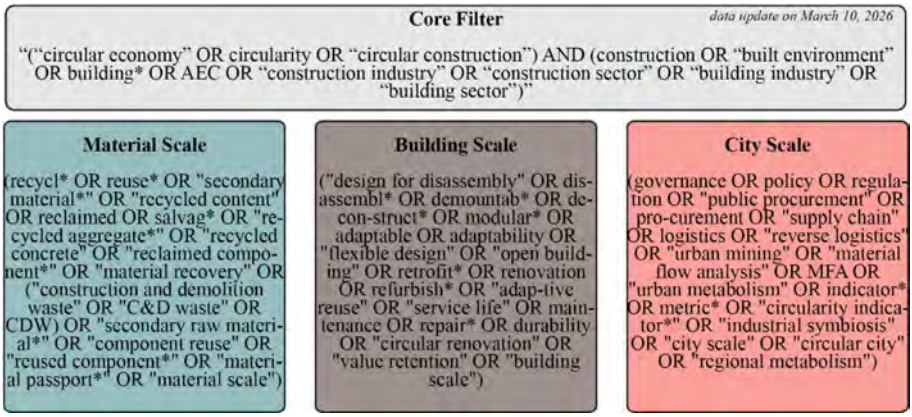

Fig. 1. Boolean queries defined for each scale

steps were applied to the corpus, such as lowercase transcription, removal of punctuation, number, and stopwords, and checking for overly general terms irrelevant to the analysis target. Very low-frequency terms were eliminated according to a specific threshold, simplifying the vocabulary and thus reducing the model's sensitivity to noise.

To reveal the thematic structure and quantitatively track its change over time, analyses were conducted in RStudio using the Structural Topic Model (STM) approach. STM allows modeling the impact of contextual variables on topic prevalence while simultaneously estimating the topic distribution of documents [11, 12]. In this study, the basic contextual variables were defined as year and period classification to compare the temporal changes in CE themes across scales. STM was applied to publication pools created according to the scales, and the number of topics ($K = 6$) was determined considering the theoretical framework and interpretability criteria. The number of topics was kept constant across three scales to maintain inter-scale comparability. A rapid diagnostic assessment ($K = 5–7$) indicated improving model fit with increasing K, while semantic coherence generally decreased. Considering this balance, six topics ($K = 6$) were chosen as an intermediate solution that optimizes both model fit and interpretability. Model outputs were interpreted for each topic using distinctive keywords.

3 Results

Results were evaluated at two levels. First, the trend topics (Table 1) upon FREX terms in each scale were extracted. Second, the annual average topic prevalence was calculated and visualized to track changes over time, and period averages were compared between 2015–2019 and post-2020 (Fig. 2), using 2020 as an analytical breakpoint due to accelerating interest in the CE, rising publication volume in the CE literature, and growing visibility of implementation and measurement tools.

3.1 Trend Topics

Table 1 summarizes the six topics (K = 6) identified for each scale using FREX terms. The six topics obtained at the material scale revealed two dominant lines of research in the CE literature: (i) waste management and (ii) performance-impact assessment of secondary materials. The first line was represented by a cluster highlighting disposal practices such as landfilling and incineration, and particularly plastic-focused streams, including municipal solid waste and construction-demolition waste (CDW) (M1). The second line generated a distinct material-performance focus, involving engineering studies on the mechanical performance of reclaimed aggregates and concrete mixes, including compressive strength, RCA, mortar, and alternative binders, as well as geopolymers (M2). In addition, the environmental impact focus clustered around life cycle assessment (LCA), embodied carbon, and emissions demonstrated that material circularity is considered alongside climate impacts (M4). Functional and multifunctional circular materials constituted a separate research axis in M5. A cluster of topics focusing on batteries and flows, shaped within the context of stock-flow approaches, networks, and machine learning, along a data-driven, systems-analyst-oriented line, stood out. This cluster suggested that the query designed at the material scale also touches upon system-scale analytics (M3). Finally, a cluster of topics in M6 emphasizing cultural heritage, adaptive reuse, stakeholder barriers, and digitalization revealed that adoption, actors, and implementation barriers play a significant role even at the material scale.

At the building scale, the literature pointed to an intertwined understanding of design strategies, assessment, and material innovation. The design-for-circularity approach was strongly differentiated in the context of project and decision-making, particularly with respect to BIM-based tools, adaptability, and design for disassembly (B2). However, demountable structural systems, especially timber load-bearing elements, generated a second set of "design-structural systems" through connection details and reusability (B4). At the building scale, the focus of assessment clustered around LCA, embodied carbon, and emissions (B5) confirmed that environmental performance measurement is a core component at this scale. Yet, the emergence of material-based studies such as recycled aggregates and composite aggregate solutions, such as glass, plastic-reinforced blocks, etc., as a separate topic (B1) and the transformation of material innovations such as binder systems, mortars, fly, ash, geopolymers into a strong cluster (B6) demonstrated that building scale studies largely intersect with material scale in practice. Furthermore, the topic (B3), shaped by themes such as supply chain, policy, social dimension, and cultural heritage and housing, shows that building circularity is discussed not only in the context of technical design but also in governance and implementation.

The topics obtained at the city scale show a distribution closer to the systemic nature of the CE. The waste management axis was highlighted through plastic flows and disposal-recovery processes related to batteries and e-waste (C1). At the city scale, supply chains and actors, along with concepts such as resilience and adaptability, generated a set of issues suggesting that circularity is addressed as a coordination and network management (C2) problem. The climate impacts of material and infrastructure stocks formed an assessment line related to inputs such as concrete-asphalt-cement in the context of GHG and carbon (C3). Adoption barriers and incentive mechanisms stood out as a separate governance focus, especially with procurement practices and awareness

Table 1. Trend topics and sub-topics across scales

Topics	Sub-topics
M1	solid, plastic, municipal, CDW, waste, disposal, demolition, incineration, landfill, plastics
M2	compressive, strength, MPA, RCA, aggregate, flexural, cementitious, geopolymer, powder, mortar
M3	learning, stocks, stock, flows, batteries, flow, China, battery, network, machine
M4	cycle, LCA, life, greenhouse, assessment, warming, timber, embodied, emissions, carbon
M5	insulation, adsorption, wastewater, acoustic, sediments, thermal, wool, biomass, leaching, polyurethane
M6	heritage, adaptive, cultural, barriers, digital, projects, business, stakeholders, interviews, stakeholder
B1	aggregates, recycled, aggregate, concrete, glass, concretes, fine, RCA, plastic, blocks
B2	projects, information, decision, project, adaptability, tool, disassembly, BIM, decision-making, framework
B3	business, supply, chain, housing, heritage, public, policy, innovation, cultural, social
B4	demountable, shear, timber, connections, machine, wood, reusability, beams, learning, structural
B5	cycle, life, LCA, greenhouse, emissions, embodied, gas, stock, assessment, carbon
B6	ash, fly, mortars, conductivity, geopolymer, microstructural, mortar, portland, biochar, binders
C1	plastic, plastics, disposal, solid, treatment, landfill, batteries, recycling, electric, waste
C2	supply, chains, chain, heritage, business, actors, cultural, innovation, resilience, adaptive
C3	wood, emissions, GHG, concrete, asphalt, compressive, thermal, greenhouse, cement, carbon
C4	barriers, adoption, awareness, survey, procurement, factors, design-methodology-approach, drivers, professionals, incentives
C5	design, assessment, cycle, LCA, life, indicators, indicator, architectural, decision, criteria
C6	ecology, spatial, China, stocks, urban, stock, cities, regional, symbiosis, ecological

and survey themes (C4). In parallel, indicator sets, decision criteria, and assessment frameworks constituted a distinct topic field in terms of measuring circularity at the city scale and integrating it into policy and planning (C5). Finally, the topics in C6, which emphasize urban stocks, spatial analysis, regional perspective, and industrial symbiosis or ecology, demonstrated that the "urban metabolism and urban stock" approach and the industrial ecology form a strong thematic stream at the city scale.

3.2 Temporal Changes

The most significant change at the material scale in Fig. 2 is the increasing emphasis on engineering- and performance-oriented studies in the post-2020 period. Specifically, M2 shows a significant increase from 2015–2019 to post-2020; the annual trend graph suggests this increase becomes even more pronounced after 2023. Conversely, M1 and M3 show a decrease in the inter-period comparison; this indicates that the "disposal and waste management" and "stock-flow analytics" axes, which were more dominant in the earlier period, have relatively faded into the background in the post-2020 literature. M4 and M5 follow a more stable trend. Although small increases are seen in the bar graph, annual trends generally show limited fluctuation. M6 has a high share in both periods but has declined somewhat in the post-2020 period; the annual trend indicates a structure that rises around 2016–2018 and then plateaus. The overall picture shows that, at the material scale, the literature after 2020 is increasingly focused on the axis of "secondary material performance and applicability".

The intertemporal divergence at the building scale in Fig. 2 reveals two distinct trends. Between 2020 and 2026, B6 and B1 show significant increases, while B5 and B3 show relatively small decreases. This suggests that the post-2020 literature in the building scale corpus has grown through material substitution and binder and mixture innovation, as much as, or even more than, design and evaluation in some sub-sets. B2 has a visible share in both periods and shows a more limited decrease in the bar graph; the annual trend graph also indicates that this topic has remained relatively stable. B4 shows an annual trend that starts at a very high value in 2015 and rapidly declines, stabilizing at a lower level. Such early-year jumps are often associated with a low number of publications in that year, but can still be interpreted as indicating a sharper focus on "demountable structural systems" in the early years, followed by a greater diversification and dispersion of the literature in subsequent years.

The most prominent feature of the post-2020 period at the city scale is the strengthening of governance and policy tools for adoption. In the bar graph in Fig. 2, C4 shows a very significant increase compared to 2015–2019; the annual trend also supports this result, particularly an increase after 2017 and a higher plateau in the 2020s. In addition, C5 and C3 show limited but consistent increases in the post-2020 period, suggesting that circularity at the city scale is progressing alongside the discussion of "measurability and integration into decision-making processes". On the other hand, C6 and C1 have declined significantly in the post-2020 period; annual trends show that C6, in particular, started high in 2015 and then fell rapidly. C2 remains one of the most dominant clusters with a high share in both periods; however, its relative share has decreased somewhat in the post-2020 period. In general, the city scale in the post-2020 period is shaped as

much, or even more, by adoption barriers, procurement, and governance mechanisms than by "technical management of flows."

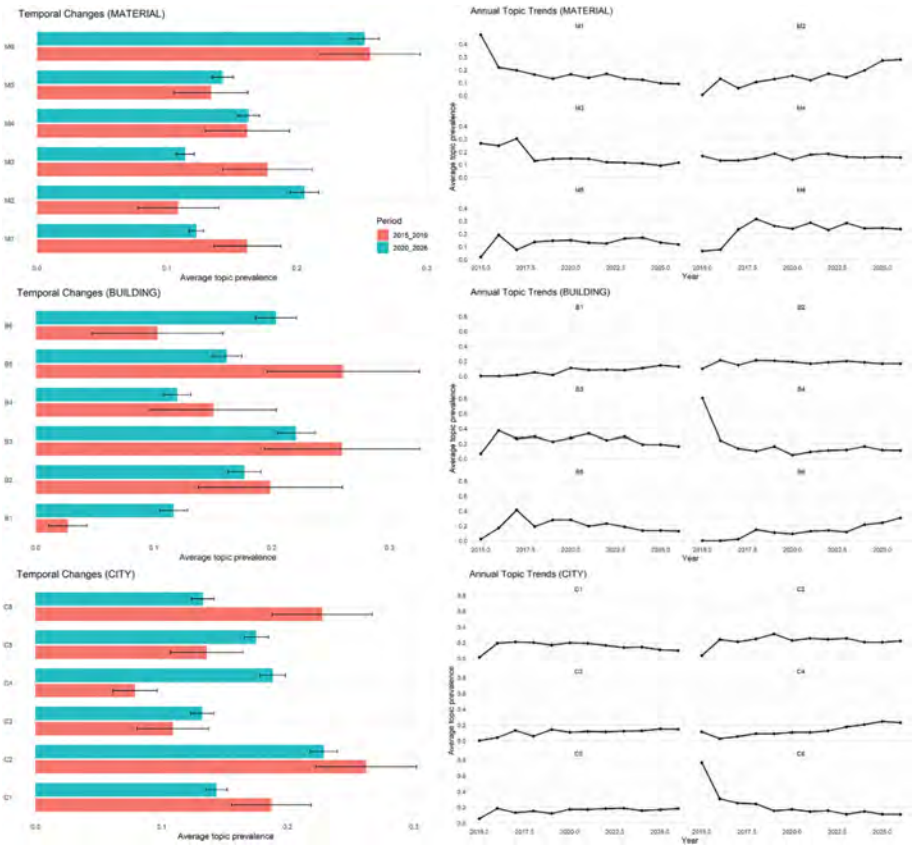

Fig. 2. Temporal comparison and annual changes of topic trends at each scale

4 Conclusion

This study examines CE-construction and built environment literature at the material, building, and city scales, demonstrating how thematic emphasis shifted between the periods 2015–2019 and post-2020. The STM findings indicate that, at each scale, circularity is organized into clusters, including performance and material substitution, environmental impact assessment, reuse through design, and adoption and governance. A temporal comparison reveals that, in the post-2020 period, secondary material performance and binder and mixture innovations have strengthened at the material and building scales, while discussions of adoption barriers, procurement, and indicator-based measurement have become more visible at the city scale.

Because scales are analytical framing, the scale-specific query sets may yield overlapping publication pools. The text field, consisting of title-abstract-keywords, was analyzed in RStudio using STM (K = 6), topics were interpreted using FREX terms, and annual and periodical changes were tracked and indicated. The scope of this study is limited to journal articles indexed in Scopus to ensure interdisciplinary coverage and consistency. Inclusion of additional databases, such as Web of Science, is a future step that could increase the comprehensiveness of the findings. Moreover, the low number of publications in early years may create fluctuations in annual averages, and the analysis relies on bibliographic text fields rather than full text. Nevertheless, the presented scale-based STM framework provides a starting point that systematically allows further refinement of query sets and deeper insights through integrated cross-scale modeling in future studies.

Abstract. Through a case study analysis, this paper reflects on the challenges and opportunities of adopting materials passports and building passport for a repurposed building. The case study is a redevelopment of a vacant retail and car park building into a Multi-Use Community Hub (MUCH) in King's Lynn, Norfolk, UK. This building tests the process and practice of adoption materials passports and building passport to support future reuse and maintenance. This approach allows lifecycle data of construction materials, promote transparency and ease responsive reuse. Materials Passports were created for the existing structure, additional structural elements and facade and linked. This paper presents the challenges and opportunities of adopting digital passports in a real-life project, maps the relationship with current and future building regulations and defines three recommendations for future practice: **1) Passporting strategy:** embed requirement at conceptual design stage, bringing whole design team onboard, **2) Passporting scope:** write requirements into tender/specification documentation, with standardised reporting frameworks, **3) Passporting stewardship:** plan where the data will be held, and how it will be passed to and between building owners. We further recommend the development of a national database to centrally hold all passporting information in one secure location.

1 Introduction

The global construction industry and built environment are responsible for at least 37% of annual global carbon emissions. The focus on waste reduction, material reuse and extension of buildings' life cycles are the most valuable approaches, with renovation generating 50–75% fewer emissions than new construction [1]. Repurposing existing buildings and making the most of their materials is critical to reduce embodied carbon. In the European Union, the Ecodesign for Sustainable Products Regulation (ESPR) [2] is part of a package of measures that are central to achieve the Circular Economy Action Plan 2020 (CEAP) [3] and foster the transition to a circular, sustainable, competitive economy. The ESPR introduces design requirements to improve durability, reparability, and recyclability across all lifecycle stages. It also establishes the Digital Product Passport (DPP), a key data tool that reports environmental information—mirrored in the Construction Products Regulation (CPR) for the construction sector, which relies on Environmental Product Declarations (EPDs), which are standardised, verified documents detailing a product's environmental impact over its lifecycle. DPPs are a digital identity card for products, components, and materials, which will store relevant information to support products' sustainability, promote their circularity and strengthen legal compliance [4].

However, these regulatory frameworks and tools for construction materials and products are mainly focusing on new products. The focus on embodied carbon is a fundamental step towards meeting the Net Zero targets defined by the UK government. Since 80% of buildings that will exist in 2050 have been already built [5], it is imperative that we make the most of the materials already in existence. The reuse of construction materials is the most energy-efficient circular solution and enables the preservation of material value for longer [6]. At the building scale, the EU proposes the creation of digital building logbooks (DBLs), a comprehensive repository of information that can be used for effective management and decision-making throughout a building's lifecycle [7] it provides information on aspects such as design, construction, quality, and environmental and performance criteria. currently shifting from fragmented, regional guidelines to unified European frameworks. The EU formally tasked the European Committee for Standardization (CEN) with developing two comprehensive standards, a DBL implementation framework and a core data template, which are scheduled for adoption by October 2028. Similarly, in the UK, building owners are entitled to provide a building logbook for new or refurbished buildings. In this case study, we tested the process and practice of Materials Passports (MP) adoption and creation of a Building Passport (BP) for a repurposed and extended building to support future reuse and maintenance.

2 A Case Study Approach: Context and Methodology

This paper is based on a case study qualitative methodology that uses focus group discussions (FGD) and document analysis (DA) research techniques to produce rich and detailed findings. The case study focusing on the redevelopment of a vacant retail and car park building into a Multi-Use Community Hub (MUCH) in King's Lynn, Norfolk, UK. The data collection was led by Ana Rute Costa (AC) and supported by Danielle Densley Tingley (DT), academics which previous research informed the project delivery. We

delivered two FGD with the key stakeholders involved in this project. All the participants on these FGD are co-authors of the paper and have a relevant role in the project delivery: Chris Akinrodoye, Design Manager; David Bentley, Project Manager; Jeannine De Sousa, Client Representative of NCC; Thomas Hesslenberg, Structural Engineer; Chidinma Nwaigwe, Sustainability Manager; Charlie Vella, Sustainability Technician. Document analysis covered: Kings Lynn MUCH Sustainability Strategy, presentations delivered by Elliott Wood with MP Scope, progress delivery, final MP and BP Database and project drawings.

3 Adoption of Materials and Building Passports for a Repurposed Building

3.1 Adoption of Materials Passports and Initial Consideration

As part of a wider aspiration to embed circular economy principles in the project, the client (NCC) defined a sustainability strategy to target BREEAM Excellence, embed robust environmental, social and economic (ESE) framework, achieve LETI 2030 'A' rating and create the first NCC MP and BP database following the policy framework developed [8, 9]. Currently, MPs are not mandatory and the individual case studies are led by individual champions across the Architecture, Engineering and Construction (AEC) industry. Participants agreed that the public sector lacks a unified policy, regulatory framework, or central repository for MP data and the MP adoption relies on isolated initiatives and project-specific resources. In this case study, the MP scope was defined by the client (NCC) and the Engineering team (Elliott Wood). Due to a limited budget and programme constrains, the MP scope comprised the **creation of MP for existing structure and substructure, new structural products and the new façade system.** Elliott Wood has defined the MP templates with the following parameters:

1. **GUID** – Global Unique Identifier produced by Revit to locate that specific element;
2. **PUID** – Project Unique Identifier used to help simplify the location of the element;
3. **Location – Zone** – Only if applicable (e.g., Lobby 1);
4. **Type** – Name of the element (e.g., 150 mm thick RC slab);
5. **Level** – Building level where the element is located (e.g., Level 00);
6. **Description** – Description of the element (e.g., Reinforced Concrete Ground Beam);
7. **Materials** – Material composition (e.g., Reinforced Concrete);
8. **Volume (m^3)** – Total volume of the element;
9. **Area (m^2)** – Total area of the element;
10. **Grade** – Material grade (e.g., RC32/40);
11. **Length (mm)** – Element length;
12. **Width (mm)** – Element width;
13. **Height (mm)** – Element height;
14. **Air Gap (mm)** – Air cavity size if applicable;
15. **Insulation Thickness (mm)** – Thickness of insulation layer;
16. **RICS Building Element** – Classification (e.g., 1.1.1 Standard Foundations);
17. **Manufacturer** – Name of the manufacturer + **Certification Number.**
18. **Warranty Info** – Warranty period (e.g., 10 years);

19. **Design Codes / Standards** – Applicable design codes (e.g., BS 8110);
20. **Test Data** – Test information (e.g., Schmidt Hammer Test – 15 Nm);
21. **Coating** – Surface coating specification (e.g., skid-resistant coating);
22. **Data Source** – Link or reference to the source of the data;
23. **Installation Date** – Date installed (e.g., 01.01.2030);
24. **Lifespan** – Expected service life (e.g., 60 years);
25. **Weight (kg/m or kg/m^2)** – Element weight per unit length or area (e.g., 45 kg/m^2);
26. **Maintenance** – Maintenance requirements (e.g., inspect every 10 years);
27. **H&S** – Health and safety considerations during construction and lifespan;
28. **Condition (if existing/reused)** – Condition notes (e.g., small cracking to face).
29. **Connections** – Connection information if applicable (e.g., steel plate bolted);
30. **Fire Resistance** – Fire rating (e.g., 90 min);
31. **Colour** – Element colour (e.g., grey);
32. **Changes After Install** – Any post-installation modifications (e.g., opening cut in slab);
33. **Proposed EoL Strategy** – End-of-life strategy (e.g., demolished and used as aggregate);
34. **Disassembly Instructions** – Method for removal (e.g., pneumatic breaker);
35. **Salvageable Mass (%)** – Percentage of material recoverable (e.g., 40%);
36. **H&S Considerations** – Safety considerations during demolition process.

A simple data template was developed in Microsoft Excel to record key information relating to the building elements assessed within this study. The template consists of four worksheets: **existing structure, proposed structure, existing façade, and proposed façade**. Each worksheet contains a consistent set of parameters intended to capture essential information about individual building products, including identification, location, material composition, geometric properties, and basic lifecycle attributes.

3.2 Data Collection Process

For the existing structural elements, the MP data collected was informed by site surveys, point cloud data and intrusive surveys (Concrete Testing). This enabled the documentation and characterization of the existing primary and secondary structure to be reused. For the new construction elements, the data was managed by Mace Construction and sourced by subcontractors via a shared template developed by Elliot Wood. This intended to be a simple tool, however, due to 1) lack of familiarity of MP framework, 2) absence of Environmental Product Declarations (EPDs) and 3) subcontractor tendency to overshare all data rather than carefully select the required data, the data collection process resulted in substantial data being discarded and cleansing effort by the design and sustainability teams. Building Information Modelling (BIM) protocols were not adopted for this project and were only employed for clash detection among the design teams. As a result, data had to be extracted manually using Revit's scheduling features, meaning that the MP database relied heavily on spreadsheets and manual inputs.

3.3 Main Challenges of Adopting MP and BP for a Repurposed Building

Despite the guidance provided by the sustainability strategy, the communication and early coordination of MP was one of the main challenges identified by the stakeholders since they were not aware of individual and collective expectations of MP delivery. In this case study, a single MP database was created alongside the project delivery without intermediate deadlines or data handover and therefore the process did not seem linear, straightforward or efficient. Concurrently, the lack of industry maturity in this field caused challenges, the subcontractors had limited understanding of MPs and circularity and perceived MP's creation as an additional administrative burden. Since the construction sector does not have a standardized data infrastructure for MP, the reliance on Excel spreadsheets and manual coordination made MP adoption more challenging. Furthermore, with no clear guidance or nationally agreed approach on long-term storage, ownership, or accessibility of MP/BP data, there is a risk that the data produced could be lost and not used to inform future CE practices.

3.4 Lessons Learned and Recommendations for Future Adoption

Following MP strategy guidance [8], and aligned with this project delivery, the participants believe that MP scope should be defined at the beginning of a project, RIBA Stage 1–2. However, this should then be embedded in subsequent tender documentation, with defined deliverables for subcontractors supported by clear data collection templates. The data collected within the MP and BP can be optimized and integrated into other required documentation, e.g. O&M manuals, Golden thread requirements, Whole-life carbon assessment and BREEAM documentation. The long-term intention is that the MP database can inform circularity initiatives and future regulations, e.g. future deconstruction, material traceability and reuse, carbon taxation compliance, and quantification of a property portfolio. Overall, the stakeholders involved in this case study believe that MP adoption can potentially drive competition among subcontractors, where those ready to provide MP data can gain advantage.

3.5 Building Passport Delivery

The BP was completed based on the template provided by Sheffield University [9]. The BP is composed by the following sections: 1) Building Overview; 2) Building Record; 3) Building Design, 4) Building Energy Performance; 5) Appendix. The MP are nested within the BP created, as recommended by Costa & Hoolahan [8].

At this stage, BP is substantially complete, with only some outstanding test data relating to EPC ratings. All elements were relatively straightforward to populate, as the BP primarily provides an overview for the user, indicating where detailed information can be found. Much of the data it contains is already documented elsewhere, so compiling the BP was largely a collation process. The main challenge lies in ensuring that the information remains up to date as the project evolves, which is a common consideration in any passporting approach. The MP informed BP by supplying detailed material-level data, ensuring that the BP accurately reflects the building's composition and specifications.

3.6 Reflections on passporting's Value and Case Study Limitations

This project helped to recognize the passporting's value and its integration with wider building data requirements. However, there is still a lack of long-term passporting MP data stewardship. Without a clear strategy and regional/national centralized database, data risks being lost, unused, fragmented or unusable over time. All the participants in this study agree that the lack of national leadership on passporting within the UK poses a challenge, and that this would be essential for widespread updating of passporting approaches.

This case study focused on the creation of MP for existing structure and substructure, new structural products and the new façade system, allowing us to test MP for existing and new materials. Recording MP data for existing products is useful to define the conservation state and surveys made. This data can also be used to inform savings on embodied carbon. The MP data for new products can be potentially informed by the coming DPP. The MP database produced represent a small portion of materials used in the building. Capturing wider building layers, particularly those with more frequent replacement rates, e.g. services, could present different opportunities for building maintenance, and shorter-term reuse. This case study demonstrates that while MPs have a strong potential to support CE metrics, their implementation in real-world projects is constrained by current industry practices, fragmented guidance, lack of regulations or institutional support. This project highlights the importance of early planning, digital integrations, and policy leadership. MP are valuable CE tools but require systemic change to deliver full value.

4 Discussion & Recommendations

4.1 Collective Understanding of the Role of Materials Passports and Building Passports for a Repurposed Building

In this case there was a single MP database along all RIBA Stages of work. However, the MP policy paper [8] suggests the creation of 1) Basic MP database for the existing materials at RIBA stage 2, 2) Proposed MP database during the design phase between RIBA Stage 2–4, and 3) Completed MP database once the construction has finished (RIBA Stage 5–6). Unfolding the MP database according to the nature of MP (for existing or new materials) and aligning it with the design and construction phases would facilitate allocation of responsibilities and stakeholders involved in the data collection process. Furthermore, in this case study it was perceived that there was a lack of collective understanding of the role and value of materials passports for a repurposed building. Despite the client leadership and the commitment of the construction and engineering team, there is a need to upskill the wider AEC industry. The MP data can be used to inform diverse circular metrics and other regulation requirements [10], however, these links are not clear or straightforward. Our findings align with those of Jones, Farghaly and Toth [11] who argue that regulatory bodies must harmonise information requirements and data specifications across policy instruments to improve efficiency and reduce compliance costs. Achieving this will require coordinated action from policymakers, financial institutions, and industry leaders to develop a transparent, efficient, and futureproof data ecosystem for the built environment.

4.2 Materials Passports and Building Passports Alignment with Current and Future Regulations

The principle of a MP [12] is similar to a DPP, and it follows the characteristics of a passport for circular economy identified by Capelleveen et al., [13]. The CPR provides harmonised rules for the marketing of construction products in the EU and defines a common technical language to assess the performance of construction products. The revised CPR, launched in January 2026 [14], adds requirements for recyclability, disassembly, durability, repairability, and recycled content for new products. This is a great step for future circularity in the built environment, however, the current CPR and DPP regulations consider products as independent entities. According to MP frameworks published earlier [8, 15, 16] a level approach is recommended where products are nested with wider hierarchy levels/types. As pointed out previously, by centralising DPPs of a building in a single database would facilitate CE metrics and inform future maintenance and disassembly processes. The Digital Building Logbooks (DBLs) are centralized, secure, online repositories that store relevant data about a building throughout its entire lifecycle, are a key enabler of seamless data exchange across the real estate market [11]. Several data sources on buildings already exist at different levels in Europe, and their interoperability is crucial for a proper data population of the future DBLs [17]. Future research is needed to understand the alignment of DPP, CPR and DBLs and potential integrate MP of existing materials/products/elements/systems. Due to increased demand of data transparency in the built environment and proliferation of unaligned reporting standards and regulations, there is an urgent need for a nationally agreed base data structure for passporting to allow interoperability of building and product information between passporting platforms. Furthermore, a central digital database to store and link to all passporting information would ensure that there is one location to source information in the future, reducing the risk of data being lost during building handovers and sales.

Different approaches are needed for passporting for new construction versus existing buildings. For new construction, passporting could be mandated as part of an expansion of 'the golden thread' [18] UK building safety act, where building design and construction information for higher-risk buildings must be held, and kept up to date to ensure building safety throughout its lifecycle. In contrast, existing buildings often lack any information about their design and the materials within them. Material stock modelling approaches can be used to provide rough estimates about potential materials available for salvage. Although pre-redevelopment or demolition audits will capture more detailed and accurate assessments at the individual building level. When carried out, ideally these audits, and additional information, e.g. structural surveys could be held in a centralised platform to detail what is known about the building. These can then be developed into existing MP databases and inform renovation and repurpose design strategies.

4.3 Recommendations and Closing Remarks

This case study highlights the importance of delivering **1) Passporting strategy:** embed requirement at conceptual design stage, bringing whole design team onboard, **2) Passporting scope:** write requirements into tender/specification documentation, with standardised reporting frameworks, **3) Passporting stewardship:** plan where the data will be

held, and how it will be passed to and between building owners. We further recommend the development of a national database to centrally hold all passporting information in one secure location. Meanwhile, initiatives like MUCH project show that AEC industry can rapidly upskill and adopt MP and BP to centralise data collected throughout the design and construction and inform wider CE metrics and building requirements.

Transforming Decommissioned Wind Turbine Blades into a Scalable Airport Parking Infrastructure System

Ahmed K. Ali(✉)

Texas A&M University, College Station, TX 77845, USA
ahali@tamu.edu

Abstract. The rapid expansion of renewable energy technologies has introduced new environmental challenges associated with end-of-life components of infrastructure. Wind turbine blades (WTBs), typically composed of fiberglass-reinforced composite materials, are difficult to recycle due to their heterogeneous structure, large dimensions, and the technical challenges associated with separating constituent materials. As a result, most decommissioned blades are currently disposed of in landfills. With lifespans ranging from 20 to 35 years, cumulative global WTB waste is projected to reach approximately 43 million tons by 2050, highlighting the need for scalable waste management solutions. This study proposes a design-driven repurposing strategy that transforms decommissioned WTBs into structural shading elements for large parking infrastructures. Blade sections are reused with minimal processing and arranged to enhance airflow and passive cooling in extensive paved environments. A case study application for airport parking facilities integrates repurposed blades with photovoltaic panels and geothermal wells to generate electricity and power site lighting. By converting end-of-life blades into functional infrastructure components, the proposed system extends material lifecycles, mitigates urban heat-island effects, and generates renewable energy. The concept establishes a form of industrial symbiosis between the wind energy sector and airport infrastructure systems, demonstrating a practical pathway for implementing circular economy principles in renewable energy waste management.

Keywords: Wind Turbine Blade · Creative reuse · Infrastructure · Industrial Symbiosis · Circular Economy · Airport Parking

1 Introduction

The global transition toward renewable energy is accelerating amid rising energy demand, population growth, and the urgent need to reduce greenhouse gas emissions. Wind and solar energy have become central components of this transition, enabling countries to diversify their energy portfolios while reducing reliance on fossil fuels. In the United States, renewable sources now account for more than 22% of electricity generation, with wind and solar accounting for a significant share of that output (U.S. Energy Information Administration, n.d.; Navarkar et al., 2020).

Despite their environmental benefits, renewable energy systems generate significant end-of-life (EoL) waste streams. Wind turbine blades (WTBs) are constructed primarily from fiberglass-reinforced polymer composites designed to withstand extreme environmental conditions. While these materials provide durability and structural strength, they also make recycling difficult due to their layered composition and chemical bonding. As a result, most decommissioned blades are currently disposed of in landfills. Global projections indicate that cumulative WTB waste could reach approximately 43 million tons by 2050 (WindEurope, C., & EuCIA, 2020; Liu & Barlow, 2017). Similarly, solar photovoltaic panels (SPs), which typically have lifespans of around 30 years, are expected to generate 60–78 million tons of waste during the same period (International Renewable Energy Agency, 2016; Vekony, 2021). Current recycling and reuse practices remain limited, leaving large quantities of materials underutilized. Addressing these challenges requires moving beyond purely technical recycling approaches toward design-driven strategies that reimagine waste materials as valuable resources. Within the circular economy framework, repurposing infrastructure components offers opportunities to extend material lifecycles while reducing environmental impacts. This study proposes a scalable infrastructure concept that repurposes decommissioned wind turbine blades as modular shading structures for large parking areas. When integrated with photovoltaic panels and geothermal systems, the design provides shading, passive cooling, and renewable energy generation. By linking renewable energy waste streams with transportation infrastructure, the approach establishes a form of industrial symbiosis that supports sustainable urban development.

1.1 Circular Economy and Renewable Energy Waste

The circular economy (CE) framework promotes strategies that extend product lifecycles and minimize waste generation. While traditional sustainability models emphasized the "reduce, reuse, recycle" hierarchy, recent CE frameworks have expanded this concept into a broader set of strategies often referred to as the 12R framework, including refuse, rethink, redesign, repair, refurbish, remanufacture, repurpose, recycle, and recover (Cramer, 2017). Among these strategies, reuse and repurposing are particularly valuable because they preserve the embodied energy and structural integrity of materials while minimizing additional processing. Several research initiatives have explored potential second-life applications for wind turbine blades. The Re-Wind project has investigated repurposing blades as structural elements for pedestrian bridges, demonstrating the feasibility of using their aerodynamic form and composite strength in civil infrastructure. Similarly, Netherlands-based Superse Studios has incorporated decommissioned blades into urban furniture and playground installations with minimal modification. Other initiatives, such as the ECOBULK project, have explored the reuse of composite materials across construction and manufacturing sectors. While these efforts demonstrate promising design approaches, most remain at demonstration scale and address only a small portion of the projected waste stream. The lack of large-scale applications capable of absorbing significant quantities of decommissioned blades highlights the need for infrastructure-based reuse strategies.

In contrast to wind turbine blades, research on repurposing solar panels remains limited. Most current approaches focus on recycling rather than reuse, often excluding panels that exhibit degradation or physical damage. As renewable energy deployment continues to grow, identifying scalable reuse strategies for both WTBs and SPs will become increasingly important. Infrastructure systems that require large structural elements represent promising opportunities for repurposing these materials. Parking structures provide expansive surfaces that can be shaded to reduce thermal loads while integrating renewable energy generation.

2 Methodology

This research employs a design-based methodology that integrates architectural design exploration with engineering feasibility analysis. The research process consists of four primary stages. First, a literature review was conducted to examine circular economy strategies and existing repurposing initiatives for wind turbine blades and composite materials. This review identified key design opportunities and limitations associated with current reuse practices. Second, a material assessment was performed to evaluate the structural properties, dimensions, and potential reuse configurations of typical decommissioned wind turbine blades. The analysis considered blade geometry, weight, and structural characteristics relevant to infrastructure applications. Third, a conceptual infrastructure system was developed to explore how blade segments could be integrated into modular shading structures. The design prioritized minimal processing to preserve structural integrity and reduce energy consumption associated with material modification. Finally, a case study evaluation was conducted using a large parking facility at George Bush Intercontinental Airport (IAH) in Houston, Texas. The case study examined the spatial requirements, material quantities, and potential renewable energy generation associated with implementing the proposed system in a real-world context. This methodology enables evaluation of the system's scalability, environmental benefits, and feasibility for large infrastructure applications.

3 Results

3.1 Literature Review

Current WTB waste management approaches primarily focus on recycling and landfilling. However, recycling technologies for composites are still in early stages of development and are rarely economically viable on a large scale (WindEurope, C., & EuCIA, 2020). The renewable energy sector is fully committed to producing 100% recyclable turbines by 2040 (Recyclable Blade, n.d.). Through ongoing efforts and innovations, they are actively working towards increasing the recyclability of wind components. However, until recycling technology is available, decommissioned stock will continue being sent to landfills. These challenges highlight the need for alternative strategies that are both environmentally responsible and economically and socially feasible. Repurposing as a CE strategy offers a promising alternative. Unlike recycling, repurposing does

not require breaking material into its raw components, reducing cost and energy consumption. Recent design-based efforts have explored how decommissioned WTBs can be used in infrastructure applications, ranging from playgrounds to pedestrian bridges (Mavrokefalidis, 2021; Superuse Studios, n.d., Web-4). However, most of these projects remain at the single-attempt and demonstration-scale intervention stage.

Large, paved surfaces, such as parking lots and transportation infrastructure, significantly contribute to urban heat island effects. These surfaces absorb and retain solar radiation, raising local temperatures and increasing cooling demand. The city of Houston, Texas, is characterized by a highly car-dependent urban structure. Parking infrastructure occupies a substantial portion of impervious land area, particularly near transportation hubs. The city experiences approximately 90 fully sunny days and 114 partially sunny days per year, exposing vehicles and pavement surfaces to prolonged solar radiation. As one of the largest transportation hubs in the United States, George Bush Intercontinental Airport (IAH) accommodates hundreds of thousands of travelers daily and requires extensive parking infrastructure. Vehicles parked in uncovered lots are vulnerable to heat-related damage, including deterioration of interior materials and reduced functionality of safety systems. These conditions create an opportunity to introduce shading systems that simultaneously reduce surface temperatures, improve user comfort, and generate renewable energy (Fig. 1).

Fig. 1. A typical decommissioned WTB landfill, Source: the web.

3.2 Material Assessment of WTBs

The proposed carport design provides a scalable, feasible, and innovative partial solution to the massive waste problem posed by decommissioned WTBs and SPs. The main issue to consider when searching for a scalable solution is the ability to deliver solutions that meet the region's local needs and are close to the area where the waste is generated. The main factor in ensuring scalability is maintaining a balance between the amount of waste generated in that region and its level of use; additionally, the solution can be repeatable. Its modular nature and dual functionality, providing shade and generating renewable energy, highlight its potential to address specific regional challenges, such as urban

heat islands and energy demands in car-centric cities such as Houston. Additionally, the design can use new solar panels rather than decommissioned ones. Thus, the idea can also contribute to the installation of charging infrastructure for electric vehicles. Carport design demonstrates a design that requires minimal blade cutting, reducing energy use and environmental hazards associated with blade segmentation. This approach aligns with ongoing efforts to optimize processing methods.

The proposed infrastructure system repurposes wind turbine blade sections as structural shading elements installed above parking rows. Blade segments are mounted on steel frames and arranged to create modular carport structures that provide shade while maintaining natural airflow beneath the canopy. The aerodynamic curvature of the blades promotes passive ventilation, reducing heat accumulation within the parking area. The design requires minimal cutting or modification, preserving the structural integrity of the composite materials while minimizing energy consumption during processing. Solar photovoltaic panels are integrated into the upper surfaces of the structure to generate renewable electricity. The panels supply energy for LED lighting, security systems, and auxiliary infrastructure loads. In future implementations, the system could also support electric vehicle charging infrastructure.

3.3 Conceptual Infrastructure System Development

The design was developed for an existing parking lot at George Bush Intercontinental Airport, a surface parking facility covering approximately 83,654 m^2 and accommodating approximately 2,951 vehicles. The proposed system consists of modular units arranged in two rows of parking spaces facing each other. Each module shades approximately 26 vehicles and incorporates blade segments mounted on steel columns. The design requires 681 wind turbine blades, each approximately 37 m in length and weighing around 2.5 tons, and 1,552 photovoltaic panels, each measuring 1×2 m. Repurposing these materials diverts approximately 1,702.5 tons of composite waste from landfills while creating shaded infrastructure for the parking facility.

Fig. 2. Before and after rendering for Parking lot 2 on Will Clayton at IAH. Source: Author

3.4 Case Study Evaluation

This innovative carport concept is designed to be implemented in pre-existing or newly built parking lots, benefiting both vehicles and passing pedestrians. The inspiration for this design came from the pattern of decommissioned blades that end up in landfills. The authors developed a design based on the use of whole decommissioned blades. Parking Spot 2, which covers approximately 83,654 m^2 and is located on Will Clayton at IAH, was chosen as a potential application site. The primary material used for the design is steel, with various types of hardware supporting the turbine blades and solar panels. 681 decommissioned blades (37 m long) and 1552 decommissioned solar panels (1 × 2 m) were used to design this open parking lot with a total capacity of 2951 cars (Fig. 2). A two-row module, where vehicles can park facing each other between two axles (column-to-column), can shade 26 cars. A 37-m wind turbine blade weighs approximately 2.5 tons, based on average values reported for medium-length composite blades (Liu & Barlow, 2017; WindEurope, C., & EuCIA, 2020). Accordingly, the design diverts an estimated 1,702.5 tons of composite waste from landfills, which are otherwise difficult and energy-intensive materials to recycle. The integrated photovoltaic panels generate approximately 55.7 kWh per month per panel, providing renewable electricity for site lighting and operational systems. Over five years, the system is projected to produce approximately 5,187,120 kWh of electricity. Based on U.S. Environmental Protection Agency emission factors, this level of electricity generation could offset approximately 1,936.75 tons of carbon dioxide emissions. The WTB supporting structure will integrate geothermal wells to power charging stations. In addition to energy production, the shading structures reduce pavement temperatures and mitigate urban heat-island effects by reducing solar radiation absorption across large, paved surfaces.

4 Discussion

The increasing volume of renewable energy infrastructure reaching the end of its life presents a growing environmental challenge. Repurposing strategies that extend the life-cycle of these materials offer an important complement to recycling technologies. This research demonstrates how decommissioned WTBs can be integrated into urban infrastructure systems with minimal processing. By combining material reuse with renewable energy generation, the proposed design addresses multiple environmental challenges simultaneously. Unlike many existing repurposing initiatives, which remain limited to small-scale demonstrations, the proposed system emphasizes scalability and repeatability. Its modular design allows implementation across large parking facilities, making it suitable for airports, stadiums, logistics centers, and commercial developments. The concept also illustrates how industrial symbiosis can be achieved by linking waste streams from the renewable energy sector with infrastructure needs in the transportation sector. Such partnerships could reduce landfill waste while providing cost-effective construction materials. However, several challenges must be addressed before large-scale implementation becomes feasible. Transportation logistics for large blade segments remain complex, and efficient strategies for blade segmentation and transport will be necessary. Structural performance and long-term durability must also be evaluated through detailed engineering analysis and life-cycle assessment. Despite these challenges, the

concept demonstrates the potential of design-driven repurposing strategies to transform renewable energy waste into valuable infrastructure components (Fig. 3).

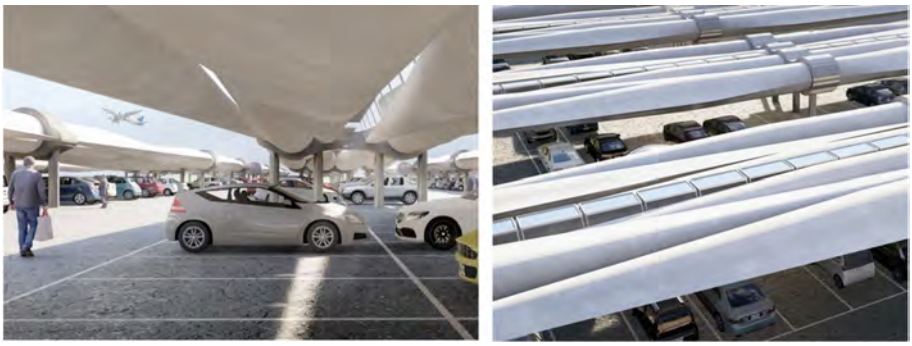

Fig. 3. Renders of the proposed carport made from decommissioned WTBs. Source: Author

5 Conclusion

This research presents a scalable infrastructure concept that repurposes decommissioned wind turbine blades and solar panels as modular carport systems for large airport parking facilities. By transforming renewable energy waste into functional infrastructure, the proposed design demonstrates how circular-economy principles can be applied in the built environment. The case study application at George Bush Intercontinental Airport illustrates the environmental and operational benefits of the system, including reduced landfill waste, renewable energy generation, and mitigation of urban heat island effects. The modular design allows adaptation to different parking configurations and blade sizes, supporting scalability across diverse urban contexts. Although the proposed system represents only a partial solution to the growing challenge of renewable energy waste, it provides a practical framework for integrating material reuse with sustainable infrastructure design. Future research will focus on structural optimization, life-cycle assessment, and logistical strategies for large-scale implementation. Through collaboration among designers, engineers, and policymakers, repurposing strategies such as the one proposed here can help transform renewable energy waste streams into valuable resources for sustainable urban development.

Department of Civil Engineering, Institute of Metal Structures, Aristotle University of Thessaloniki, Thessaloniki, Greece
thnik@civil.auth.gr

Abstract. The aim of the present study is to investigate the operational and seismic behaviour of an innovative, modular, two-story prefabricated residential modular building made of structural aluminium. More specifically, it concerns an approach in optimal designing of a sustainable and energy-efficient aluminium building system, with regards to their structural performance, easy assembly and disassembly, low cost and preconstruction. The structure as a whole was simulated and estimated using Dlubal RFEM software package and the critical assembly joints of beam-to-column and the column base respectively was simulated using IDEA StatiCa and ANSYS software packages in accordance to Eurocodes framework. The load-bearing system, made of aluminium alloy columns, beams and joints and orthotropic aluminium deck slabs. Lateral stiffness against horizontal loads is ensured by a combination of Moment Resisting Frames MRF and cable X-bracings made of stainless-steel. The critical assembly joints of the prefabricated parts were designed with the aim of avoiding impractical on-site welding and enabling disassembly/reuse. Solutions are proposed for demountable bolted connections using specially formed galvanized steel parts. The verification of individual joint components was carried out using finite element analysis software packages. The structural performance shows an optimal design including the effectiveness of the proposed connection system for the safe transfer of loads. The proposed system can lead to lightweight buildings that are structurally sound, economically competitive, and environmentally sustainable, making them suitable for broad future application in construction.

Keywords: Structural Aluminium · Prefabricated Modular Building · Critical assembly joints · Sustainable Optimal Design · Lightweight structures · disassembly

1 Introduction

Aluminium is a material that is still rare in its use as a load-bearing structural element material [1], The density of aluminium is approximately 1/3 that of steel: aluminium, therefore this is its most attractive feature for wider use in structural and complex architectural applications. Although the production of primary aluminium requires a large

https://doi.org/10.1007/978-3-032-34930-9_18

amount of electricity, but the energy reinvested during its reconstruction requires only 3–5% of the energy consumed in primary production, so aluminium can be considered as an energy bank [2]. Modular prefabrication is a subject of research and development worldwide [3, 4], as its technology now allows the construction of increasingly complex buildings [5–7].

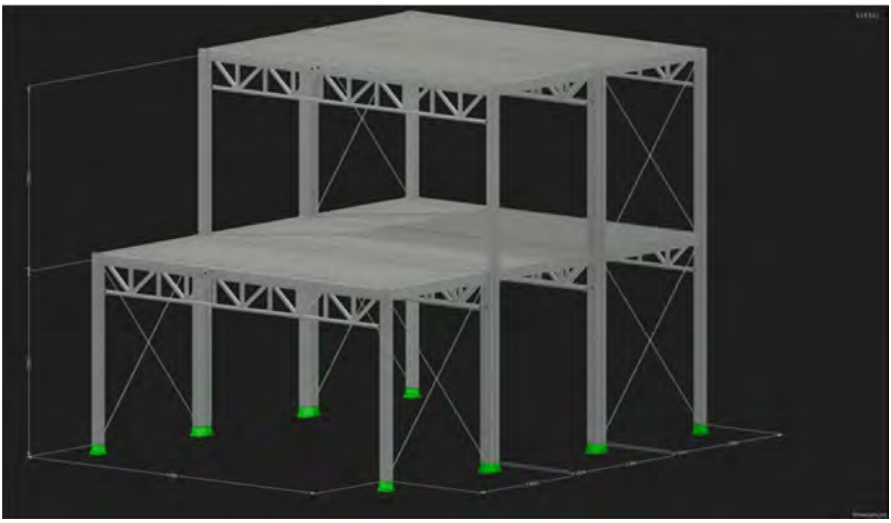

Fig. 1. 3D sketch of the load bearing system of the prefabricated modular building.

The basic concept here is to create an innovative and smart aluminium modular designed building system (see Fig. 1), which promotes fast controlled factory-made modules that are transported and bolted assembled on-site. For the purposes of this research work, an example of a two-story house consists of three prefabricated modules on the ground floor and two modules respectively on the 1st floor [8].

The most difficult part of a modular prefabricated systems is the assembly of joints [9], whether here it concerns the intra-modular connections of the modules that favor speed and sustainability, become detachable and can be carried on the construction site without on-site welding and therefore subsequent HAZ. The proposed special joints formed using an additional bolted (with galvanized bolts) connecting piece on-site, which should be designed in such a way as to remain the joint intact during the operational life, under different characteristic design limit states of the structure.

2 Resilience Design Aspects of the Modular Building System

In order to achieve a sustainable and resilient structural system, during the design of a single module, was chosen rigid beam-column connections, forming Moment Resisting Frames MRF in the longitudinal direction and a combination of moment resisting frame reinforcing by vertical X Cable Lateral Bracings in the transverse direction. The external

shape of the column cross section with multiple grooves allows the optimal integration of T-head bolts together with suitable distributed holes (see Fig. 2(left)). Regarding the boundary conditions, around axis y-y columns, made by complex hollow section by extruding aluminium through a suitable shaped machine the support is considered to be fixed, while around axis z-z is considered to be hinged.

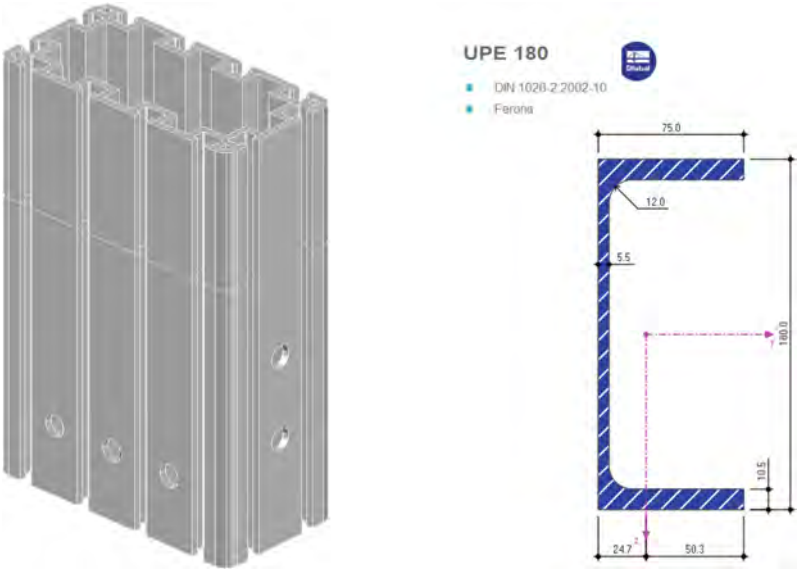

Fig. 2. 3D Sketch of the typical column cross section (left) and typical beam cross section (right).

For the Top chord of the trussed aluminium beams (truss lattice girder), it was formed by an open U-profile cross-section (see Fig. 2(right)), which would allow the recessed application of the 15 cm high orthotropic aluminium slab inside. Placing an elastomeric sheet between the two aluminium surfaces, the inner surfaces of the beam flanges and the orthotropic plate, can effectively reduce slab vibrations. Moreover, the rest of a smart lattice girder (see Fig. 3), formed by SHS truss member sections. The design of the aluminium deck floor is designed to avoid vibrations [10], by exploiting the technologies of extrusion and friction welding. With the aim to avoid corrosion phenomena and to decrease the total structural weight and the need for maintenance, stainless steel X wire ropes that forms light unilateral diagonal prestressed bracing members (working only in tension), are added to the final structural system.

3 Sustainable and Circular Design Assessments

Since aluminium was first utilized in civil engineering projects, many aluminium alloy structures have been in use and are approaching a large volume of incoming wastes. Recycling these wastes to forming new structures significantly reduces energy consumption and carbon emissions, while the basic properties of the material generally remain

unchanged during recycling. Comparing aluminium with steel, it turns out in one hand that it's an expensive material as its production cost is at least 50% more expensive than that of steel.

Fig. 3. 3D Sketch of the Modular aluminium prefabricated building.

The structural elements of the proposed modular construction (see Fig. 3) are choused, in order to be realized a manufacturing and easy assembly building system with small impact to the total material weight. By this, the amount of circular and recycled elements is maximized and the use of reinforced concrete is limited only to the foundation. Moreover, the non-bearing elements of the building include wood laminate floor covering, suspended gypsum ceilings, light gypsum internal partition walls, perimeter external double shell aluminium claddings with thermally insulating rockwool boards inside. On the other hand, taking into account the lower total weight of the structures, as well as their resistance to corrosion in particularly adverse environments, ultimately under a modular design project, this load-bearing aluminium structure can be created at a similar cost or even lower than that of a steel structure [11].

4 Design of Critical Joints by Numerical Nonlinear Analysis

Two special joint pieces are designed using additional hollow elements of S275 galvanized steel. To avoid plasticizing phenomena of internal members of the special steel connection pieces, during critical design loads, it was simulated in IDEA StatiCa software as independent members (see Fig. 4). The dimensions of these pieces were additionally defined with the aim of passing internally the aluminium columns and beams as configured in the system.

The special piece intended for the column base joints consists of a 15 mm thick base plate to which the 10 mm thick rectangular piece is welded centrally, from the inside

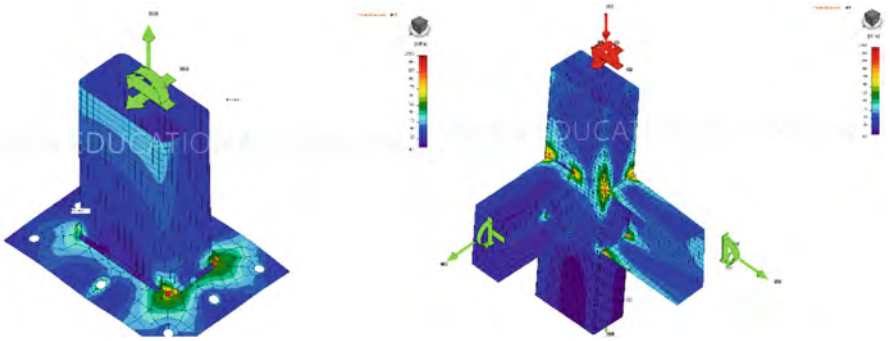

Fig. 4. Critical von-Mises stress distribution of special internal joint pieces of base (left) and column-to-beam (right).

of which the aluminium column is "digested" to be connected to it via longitudinal M16/8.8 bolts (through-bolts). The connection of the base plate to the foundation will be made using hook-end steel anchor bolts. Similarly, the special piece intended for the 3D column-to-beam joints consists of the same shape 10 mm thick rectangular piece welded to connected plate pieces.

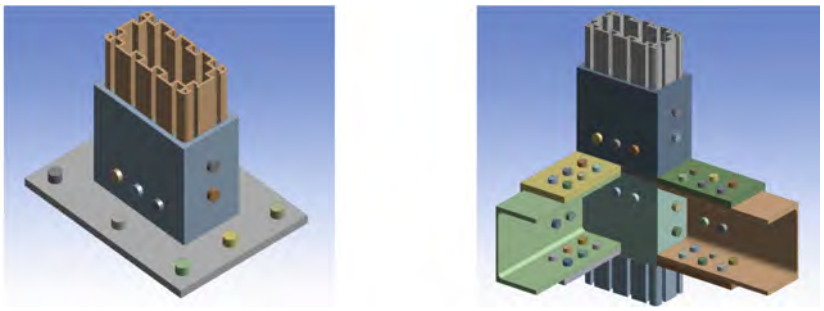

Fig. 5. Discretized model of a typical base joint model (left) and a typical column-to-beam joint model (right).

Additionally, two special joints of a) a typical base joint and b) a typical column-to-beam joint, was simulated in details separately in ANSYS software (see Fig. 5). All contacts were chosen to be simulated as nonlinear frictional contacts, with a coefficient of effective friction $\mu = 0.2$ between metal surfaces.

For all contacts, symmetric behaviour is also activated, which prevents the interpenetrating of the mesh joints of the two surfaces in contact [12]. The consider contacts between bodies surfaces where was consider the bodies involved are in contact from the beginning, was also activated the adjust to touch option, in order to facilitate the computer analysis and to avoid penetration and large gap problems. This was not was taken only in the case of contacts at the base joint, because this is not realistic and additionally, the step and the amount of sharp contact between column section and steel piece is of

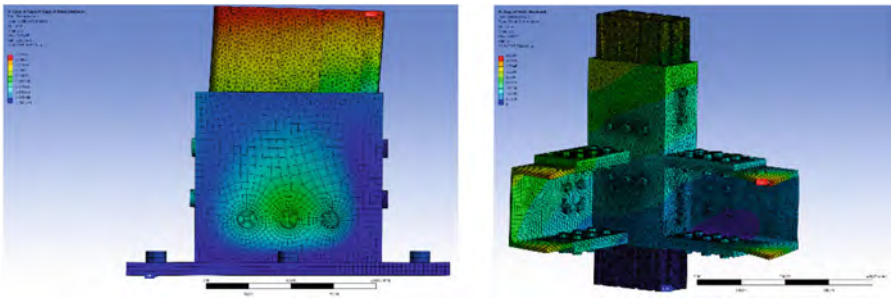

Fig. 6. Critical von-Mises stress distribution on base complex joint (left) and on column-to-beam complex joint (right).

high interest. For the lower side of the base plate, the non-linear compression-only support option was defined, which only restrains the vertical compressive-negative stresses, together with restraints at the base of the anchors that simulate their restraint due to their encasement in the concrete box. All stress and displacement results indicate adequate bearing capacity and safety (see Fig. 6). The critical points on this time-cost analysis were the marginally sufficient of some specific longitudinal bolt holes, because they are extremely forced by the receiving moments from the joint to the column.

5 Numerical Analysis of the Assembled Modular Structure

The fully assembled modular structure was simulated using Dlubal RFEM software taking into account all the critical details that come from the detailed analysis with specific simulations at the joints. Due to the assembly method the internal columns become with double cross-sections by placing special connecting pieces (in three positions) along their height. In this way, the buckling resistance of these columns is significantly increased, by making a typical bundle column member with parallel elastic sections in contact [13]. Moreover, the vertical displacements of the light composite floors (see Fig. 7(left)), $u_{max} = 3.32$ mm $< L/360 = 6{,}94$ mm and the critical horizontal displacements (see Fig. 7(right)), $v_{max} = 9{,}74$ mm $< H/150 = 20$ mm, at SLS, satisfies the strictest design limits for sensitive structures with composite floor systems like this.

Regarding seismic response of the building using Dlubal RFEM software, the assessment was derived from a linear analysis using eigenvalue analysis (see Fig. 8) and elastic spectra according EN1998–1. Moreover the evaluation of the of the hysterical behaviour of the structure was derived by the same software from a nonlinear Pushover analysis.

A Stress-Strain analysis was also performed for all aluminium members, linear and area ones (at ULS and Seismic Design States), with a limit check to maintain equivalent von-Mises stresses below the conventional yield limit of 0.2% (stress-strain analysis Add-On).

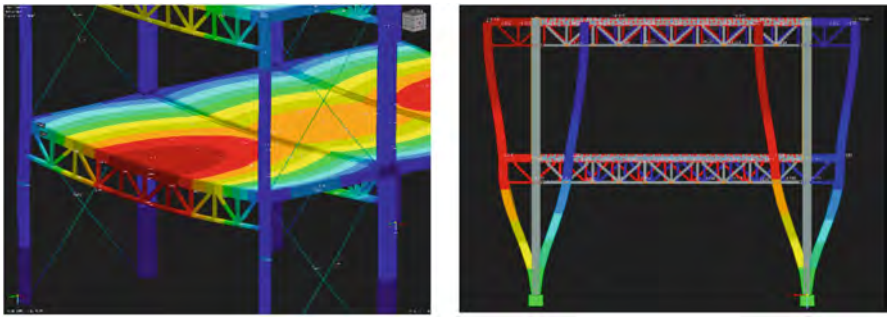

Fig. 7. Vertical(left) and horizontal (right) critical floor displacements at SLS.

Fig. 8. Total perc. of participating masses of the structure per degree of freedom.

6 Conclusion

The main conclusions of this research analysis were:

- High load-bearing capacity of aluminum hollow and open cross-sections by a smart combining of the appropriate structural members and the useful and optimal form of the connection joints.
- The performance and operation of the orthotropic slab was optimal. Indeed, this aluminium plate, exhibited excellent stress and strain behavior, confirming its suitability for structural building applications.
- The proposal of galvanized steel pieces at the bases of columns and at column-to-beam joints demonstrated reliable load reception and redistribution, while simplifying construction and assembly, without significant yielding areas and plasticization in the numerical simulations.
- This research deserves to be continued with the integration of laboratory experimental tests to confirm the optimal numerical results.

It follows that in the context of achieving a circular economy, the state deserves to help and finance the competitiveness of prefabrication and research into structural aluminum applications in Greece. It is clear that the proposed system can lead to lightweight buildings that are circularity sound, economically competitive, and environmentally sustainable.

Advancing Concrete Circularity: From Deconstruction to Cascading Valorisation Coupling Reuse and Recycling Approaches

Emilie Du Mortier(✉) and Emilie Gobbo

Louvain Research Institute for Landscape, Architecture and Built Environment (LAB), Université catholique de Louvain, B-1348 Louvain-La-Neuve, Belgium
emilie.dumortier@uclouvain.be

Abstract. Concrete is one of the construction materials with the highest environmental impact, mainly due to CO_2 emissions associated with cement production. Recycling through selective demolition remains the most common recovery method. Still, it mostly leads to downcycling: it reduces the need for virgin aggregates without significantly reducing cement demand, the primary source of environmental harm. In this context, reusing concrete elements reclaimed through careful deconstruction represents a high-value strategy that can substantially mitigate the impact of new concrete production while aligning with the waste hierarchy. However, despite growing interest, research remains fragmented and only partially documents recovery and reuse processes. This study conducts a structured analysis of the literature to examine how research addresses the concrete reuse process, focusing on categorizing scientific studies according to their coverage of the different reuse process stages and providing an overview of implemented case studies documented in scientific research. The mapping reveals three key gaps in scientific research: limited investigation of reclamation practices, a lack of large-scale implementation studies, and the strong yet understudied influence of donor building characteristics on both reclaimed element typologies and their potential valorisation. To address these challenges, future research should develop a more detailed analysis of the literature to precisely identify how the reclamation phase is currently addressed in studies. This refined examination will also help identify gaps in the current research landscape, providing clearer insight into how the reclamation phase is conceptualised and identifying areas requiring further investigation.

Keywords: Concrete · Reuse · Recycling · Deconstruction · Circular economy · Reclamation

1 Introduction

Concrete manufacturing accounts for 8 to 9% of global anthropogenic CO2 emissions and 2 to 3% of energy consumption [1]. In Europe, concrete accounts for approximately 30% of waste flows in the construction sector, including 5 million tons annually in Belgium alone. It is projected that annual cement production could increase by an additional

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 160–167, 2026.
https://doi.org/10.1007/978-3-032-34930-9_19

50% by 2050, underscoring the urgent need to develop solutions to integrate concrete into a circular economy [2].

The most widely adopted solution is the recycling of concrete aggregates, which reduces the need for raw material extraction. However, producing concrete with recycled aggregates still requires cement clinker–the most CO_2-intensive material due to its calcination process (65%) and fuel combustion (35%). This often leads to downcycling, particularly in application such as road construction or backfill.

Furthermore, conventional recycling does not fully align with the waste hierarchy set out in the EU Waste Framework Directive. In this context, the reuse of concrete elements reclaimed through careful deconstruction represents a high-value strategy that can substantially mitigate the environmental impact of new concrete production while aligning with the priority levels of the waste hierarchy.

Unlike crushing, reuse involves integrating existing concrete elements into new construction while preserving their formal integrity as well as their technical and architectural qualities, thereby extending their lifespan [3]. Research shows that reusing concrete elements can considerably reduce carbon emissions and energy consumption during the product phase– by up to 93% and 98%, respectively– compared to new production or recycling [4].

While concrete recovery is increasingly recognized as a sustainable practice, reuse implementation remains fragmented across isolated case studies and technical reports [5]. This fragmentation reveals a critical research gap: the absence of a structured overview of which phases of the concrete reuse process are addressed in scientific literature. To address this gap, this study combines a systematic literature review with an analysis of pilot projects. It provides a holistic view of the concrete reuse value chain, from potential reuse evaluation to the reclamation of concrete elements and then their reintegration in new projects.

2 Scope

This study examines research focusing exclusively on the reuse of concrete elements from buildings not originally designed for dismantling or deconstruction–including both precast and cast-in-place concrete. The scope excludes research on non-concrete structural elements, elements from buildings designed for disassembly, and applications primarily intended for recycling.

3 Methodology

3.1 Systematic Literature Review

A systematic literature search was conducted across Scopus (for its rigorous indexing and reproducibility) and Google Scholar (for its broad coverage, including grey literature), following PRISMA guidelines, as shown in Fig. 1. This dual-database approach initially identified 598 records, of which 105 studies were retained after applying predefined eligibility criteria, as illustrated in Fig. 1.

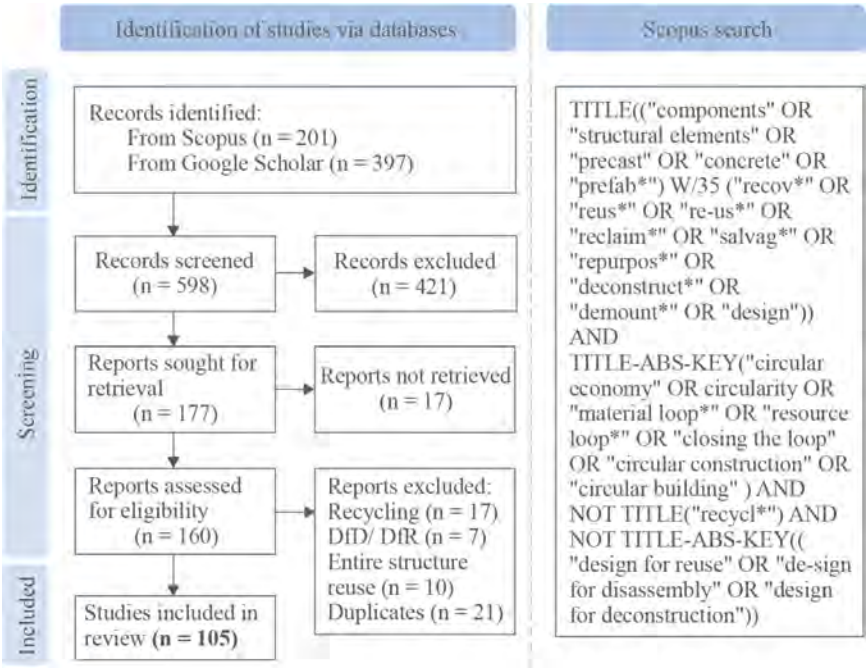

Fig. 1. PRISMA screening for Literature review

3.2 Classification of Literature Review

The literature review was systematically categorized according to the key stages of the concrete element reuse process, as defined by Huuhka et al. [4] and illustrated in Fig. 2:

1- Pre-Deconstruction Audit – Feasibility studies assessing remaining service life, structural capacity, and technical criteria.
2- Deconstruction Planning – Research developing inventory-based structural and practical deconstruction plans, ensuring safe and efficient dismantling.
3- Deconstruction/Dismantling – Studies proposing tools, frameworks, or methodologies to optimize technical operations (e.g., sawing, lifting).
4- Transport to Interim Storage – Research addressing logistical optimization of materials flows, including transport and storage strategies.
5- Quality Assurance & Refurbishment – Studies emphasizing the documentation and certification of reused components, ensuring compliance verification, and adaptation when necessary.
6- Design of a New Building – Research developing innovative approaches for integrating reclaimed concrete elements into new construction projects, focusing on design strategies and mounting solutions.
7- Construction of the New Building – Research documenting implemented case studies or prototypes that demonstrate practical applications of concrete element reuse

In addition to these process stages, the review identified four cross-cutting dimensions that influence the entire reuse value chain: Managing information digitally (e.g., BIM, QR code for tracing), structuring conditions (e.g., enablers & barriers, political/legal frameworks), dynamic mechanisms (e.g., stakeholder interactions, knowledge exchange), and measurable outcomes (e.g., environmental, economic, and social impacts, as well as value creation across the chain).

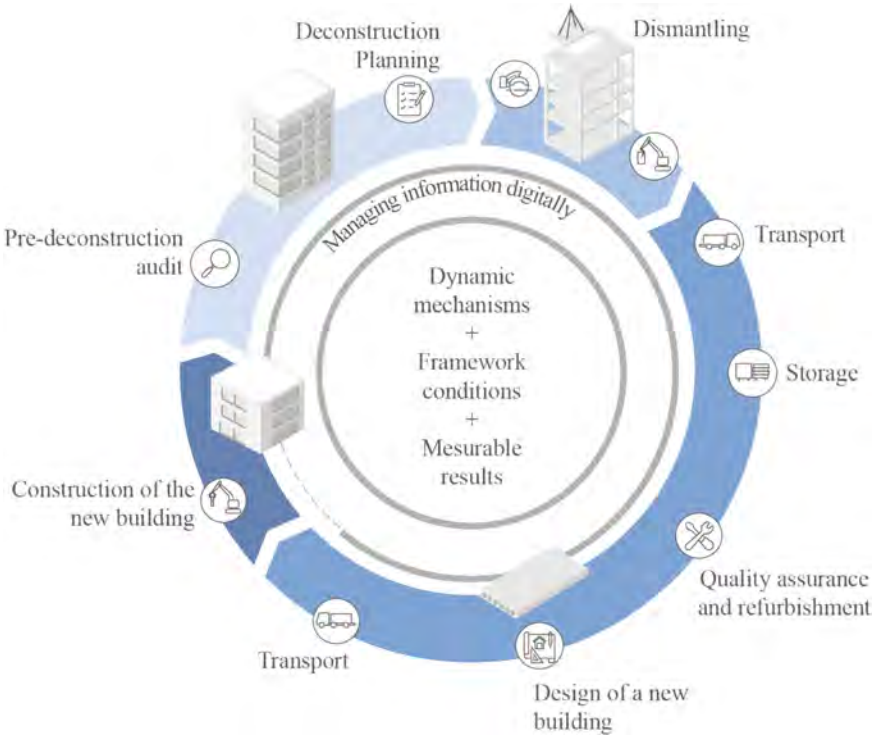

Fig. 2. The process of concrete element reuse

3.3 Analysis of Implemented Projects

The implemented projects were categorized using three key criteria. The first criterion characterizes the nature and context of reuse, including donor building characteristics–particularly the mode of concrete placement (cast-in-place or precast), which significantly influences the reclamation process. It also classifies the typologies of reclaimed elements, as in [6] (3D assemblies, elements including panels and linear elements, blocks, rubbles, and irregular debris), and according to the case study analysis. Valorisation levels (equivalent reuse, downcycling reuse, and upcycling reuse) are defined using the definitions proposed by Küpfer et al. [5].

The majority of projects analysed originate from two key sources: "Atlas for Reused Concrete" by Küpfer et al. [7], and the original collection of 77 PRECS (Piecewise

Reuse of Extracted Concrete in new Structures) projects documented by Küpfer et al. [5], which were implemented between 1967 and 2022 across Europe and the U.S.A.

4 Structured Mapping of Implemented Projects and Scientific Studies

4.1 Delimitation of Reclamation and Integration Processes

The mapping, as shown in Table 1, reveals a significant disparity in research coverage: Design is addressed in 33 studies, compared to 6 studies on dismantling only. While some studies only mentioned the reclamation process as a preliminary step without analyzing it or providing methodological, experimental, or conceptual contributions to this stage, the integration dimension remains the primary aim of most studies [8–12].

Several studies [9, 10] describe initial design phases, propose configurations incorporating reused concrete elements, and evaluate their technical feasibility– though primarily within the context of prototype development research rather than large-scale implementation.

Table 1. Distribution of concrete reuse studies by process stage

Stages of the concrete element reuse process	Example of an Article	Scopus total	Google Scholar total	Total both databases
Pre-deconstruction audit	X	21	12	33
Deconstruction Planning		2	2	4
Dismantling		4	2	6
Transport to interim storage		1	0	1
Quality assurance & Refurbishment	X	9	10	19
Design for a new building	X	20	13	33
Construction of the building	X	11	5	16
Managing information digitally	X	10	7	17
Dynamic mechanisms		6	2	8
Framework conditions		2	9	11
Mesurables results	X	27	11	38

4.2 Nature and Conditions of Reuse Concrete Elements

In most studies, donor building characteristics and reclaimed element typologies emerge as two interdependent dimensions, both closely tied to the specific context of each case study. For instance, research on prefabricated concrete structures —which represent the majority of documented cases—typically distinguishes between two primary reclaimed element types: linear elements (such as columns, beams) and panels (including walls, facade panels, hollow-core slabs). As illustrated in Table 2, these two typologies are predominantly associated with cases of equivalent reuse.

In contrast, buildings constructed using cast-in-place concrete —less commonly and primarily analysed in prototype-based reimplementation studies—typically yield smaller element typologies, such as blocks or rubble, though they may also generate 3D assemblies in certain cases. The smallest elements are most frequently documented in downcycling reuse applications, including flooring or street furniture [13], or in hybrid configurations combined with other structural materials—particularly metal—as demonstrated by several prototypes developed in Switzerland [9]. On the other hand, 3D assemblies offer the most effective reuse, preserving structural and architectural integrity for significant upcycling potential—even compared to new equivalents [14, 15].

Table 2. Element-Specific reuse outcomes in pilot projects

Donor	Placement mode			Type of elements (per project)		Receiver		Valorisation		
	PC	CIP	Both			Protot.	Case Studies	↘	=	↗
64	35	8	3	A	2	2	1			2
				E	51	8	47		48	2

				I	1	0	1	1		
64						**16**	**57**	**11**	**49**	**6**

PC: precast concrete, CIP: cast-in-place, A: 3D assemblies, E: Elements, B: Blocks, R: Rubbles, I: Irregular debris, ↘ Downcycling reuse, Equivalent reuse, ↗ Upcycling reuse.

5 Discussion

The structured mapping of studies and projects reveals two main limitations in current research on concrete reuse.

1. Insufficient scientific research on reclamation practice

   Reclamation represents a complex and decisive process that remains largely under-theorised. Scientific articles typically only treat them as preliminary steps.

This asymmetry reveals a structural gap in literature: the absence of a comprehensive scientific framework for analyzing, comparing, and standardizing reclamation practices.

2. Limited large-scale implementation

   The predominance of small-scale prototypes —particularly for elements reclaimed from cast-in-place buildings—constrains the assessment of concrete reuse at scale. As [16] has already pointed out, without large-scale implementation, the sector cannot assess the feasibility, economic viability, or logistical challenges of widespread adoption.

The analysis of implemented projects reveals the significant yet understudied influence of donor building characteristics on concrete reuse outcomes. Current research typically examines element typologies (such as 3D assemblies, elements, blocks, rubble) as isolated technical examples rather than components within a systematic valorisation hierarchy. However, the valorisation potential depends on complex interactions between donor building characteristics, reclamation methods, and element typologies – relationships that are rarely investigated in combination.

6 Conclusion

This study identifies three critical research gaps that currently hinder concrete circularity: (1) insufficient scientific investigation of reclamation practice, (2) limited large-scale implementation studies, and (3) the absence of a tailored valorisation hierarchy for concrete reuse.

To address these challenges, a more detailed analysis of the literature is needed to precisely determine how the reclamation phase is currently addressed in existing studies. This refined examination would help expose gaps in the current research landscape, providing clearer insight into how the reclamation phase is conceptualised and pinpointing specific areas requiring further investigation.

These limitations raise fundamental questions about the barriers embedded in current deconstruction practices that hinder wider adoption of concrete reuse. Rather than requiring a radical transformation of existing practices, this transition could be achieved through more controlled, incremental implementation approaches.

Acknowledgments. This research is funded by the CIT Blaton Chair for more sustainable construction in Belgium.

Abstract. Although Circular Economy has emerged as a key paradigm for sustainable transitions in the built environment, its integration into sustainability assessment protocols remains fragmented and methodologically incomplete. Existing frameworks are largely shaped by operational performance, prioritising environmental efficiency over resource circularity. Consequently, current protocols insufficiently address structural retention, temporal adaptability, design- for-transformation, and material cycling – dimensions central to circularity in adaptive reuse. This paper reframes sustainability assessment by conceptualising circularity as a multiscalar, temporal, and systemic property of building lifecycles rather than a set of isolated material or design attributes. Drawing on circular economy theory, systems thinking and lifecycle perspectives, the study develops (i) a conceptual model positioning adaptive reuse as a regenerative process integrating material, functional, and temporal circularity, (ii) a critique of existing assessment protocols revealing implicit linearity assumptions and gaps related to long-term adaptability, embodied resource value, and future climatic conditions, and (iii) a framework embedding circularity into sustainability assessment through relational indicators capturing synergies between material retention, whole-life energy reduction, and climate-responsive adaptation and mitigation. By conceptualising circularity as a relational and dynamic construct, the study advances a lifecycle-based perspective capable of recognising the systemic value of adaptive reuse and supporting more coherent integration of circularity into sustainability assessment practice.

1 Introduction

1.1 Background: Circular Economy and the Built Environment

Circular Economy (CE) has progressively consolidated its role as a guiding paradigm for sustainability transitions within the built environment, reframing resource management from linear throughput models toward systemic value retention and regenerative material cycles [1]. Within the architecture, engineering and construction (AEC) sector – responsible for a substantial share of global material consumption, waste generation, and greenhouse gas emissions – the operationalisation of circularity has become a strategic priority for both research and policy [2].

Historically, sustainability efforts in the building sector have focused predominantly on operational energy efficiency. While this focus has delivered measurable environmental improvements, growing attention is now directed toward embodied impacts, lifecycle extension, and the long-term adaptive capacity of buildings [3]. With- in this expanded perspective, adaptive reuse of existing assets is widely recognised as one of the most effective circular strategies, enabling the preservation of embodied carbon, the extension of service life, and the reduction of demolition-related externalities [4]. Despite this recognition, the integration of circular economy principles into mainstream sustainability assessment protocols remains uneven and methodologically fragmented [5].

1.2 Problem Statement: The Circularity Gap in Sustainability Protocols

Prevailing sustainability assessment frameworks in the AEC sector continue to exhibit a strong bias toward operational-performance metrics [6]. Although these systems have significantly advanced performance benchmarking, they tend to marginalise several dimensions that are theoretically central to circularity, including structural retention, temporal adaptability, design-for-transformation, and long-term material cycling [7].

This condition produces what can be defined as a circularity gap: a structural misalignment between the systemic ambitions of circular economy theory and the predominantly linear, snapshot-based logic embedded in current sustainability protocols.

1.3 Research Aim and Questions

This research aims to critically evaluate the extent to which widely adopted sustainability assessment protocols operationalise circular economy principles relevant to adaptive reuse and to develop a relational framework capable of strengthening this integration. The investigation addresses three research questions:

RQ1. To what extent do current sustainability assessment protocols explicitly integrate circular economy principles relevant to adaptive reuse?
RQ2. How are structural retention, adaptability, design-for-transformation, and material cycling represented within existing assessment criteria and scoring systems?
RQ3. What systemic gaps emerge from the comparative analysis, and how can relational lifecycle indicators contribute to bridging these gaps?

2 Theoretical Foundations

This section outlines the theoretical foundations underpinning the study by examining key conceptual perspectives on circular economy, adaptive reuse, and systems-based lifecycle thinking in the built environment. Together, these perspectives establish the conceptual framework through which circularity is interpreted as a systemic and temporally dynamic property of building performance.

Circular Economy beyond Material Recycling. Contemporary discourse on the circular economy in the built environment is increasingly shifting its focus from waste management to strategies that preserve embodied value, slow resource flows and extend asset lifespans. Within buildings, maintaining structural components and enabling long-term functional adaptability are considered to be the most circular approaches. This perspective challenges reductionist metrics that treat circularity as an isolated material attribute, instead calling for lifecycle-oriented evaluation frame-works that can capture interdependencies across temporal and spatial scales.

Adaptive Reuse as a Circular Strategy. Adaptive reuse operationalises circularity by coordinating processes such as material retention, functional repurposing and temporal reactivation. By extending the service life of existing assets and avoiding preventable demolition, reuse strategies generate cumulative environmental benefits that build up over time. This dynamic value creation reveals the limitations of static assessment approaches and emphasises the requirement for models that can represent deferred impacts and cross-lifecycle synergies.

Systems Thinking and Lifecycle Ontology. From a systems perspective, buildings are dynamic socio-technical complexes characterised by non-linearity, path dependency and evolving performance conditions. Therefore, circularity cannot be reduced to a single metric but must be interpreted as an emergent property arising from the interactions between the material, functional and temporal subsystems. This perspective necessitates relational and temporally explicit assessment frameworks that can capture the adaptive behaviour of the built environment over time.

3 Methodology

Research Design and Analytical Strategy. The study employs a theory-building, cross-protocol comparative methodology to evaluate how contemporary sustainability assessment systems implement circular economy principles relevant to building adaptive reuse. Rather than benchmarking individual buildings, the study examines certification protocols as socio-technical artefacts that embed normative assumptions about lifecycle temporality, material value and transformation capacity. This meta-evaluative approach enables the identification of structural blind spots within assessment architectures and supports the formulation of a relational circularity framework. The methodological workflow consists of five sequential steps: (1) global protocol mapping; (2) indicator-level analytical screening; (3) semi-quantitative circularity sensitivity assessment; (4) conceptual modelling of circular adaptive reuse; and (5) formulation of relational circularity constructs.

Global Protocol Mapping. A purposive sampling strategy identified internationally influential sustainability protocols according to four criteria: (i) global diffusion and market penetration; (ii) availability of updated technical documentation; (iii) applicability at building scale; and (iv) recognised policy or certification relevance. The resulting sample includes LEED v5, BREEAM UK Refurbishment and Fit-out (RFO) 2.0 (SD216), DGNB, WELL v2, Living Building Challenge, EU Level(s), Green Star (Australia), CASBEE (Japan), BEAM Plus (Hong Kong), GRIHA (India), China GBES, Estidama Pearl Rating System, Green Mark (Singapore) and ITACA (Italy). This selection ensures geographical representativeness and methodological diversity.

Indicator-Level Analytical Screening. A structured document analysis was conducted to systematically review the technical manuals, credit catalogues and scoring structures of each protocol. The screening was guided by four analytical dimensions derived from circular economy theory and adaptive reuse literature: (i) structural retention, referring to the valuation of preserving existing structural components and embodied carbon; (ii) design for adaptability, concerning transformability, reversibility, and spatial flexibility; (iii) material cycling dynamics, including reuse, disassembly, recycled content, and material traceability; and (iv) whole-life integration, addressing lifecycle assessment, whole-life carbon (WLC) accounting, and long-term impact reasoning. For each dimension, the analysis assessed not only the presence of relevant criteria, but also their operational depth, distinguishing between narrative recognition and effective integration within certification scoring logic.

Semi-Quantitative Circularity Sensitivity Assessment. To enable structured cross-protocol comparison, a semi-quantitative ordinal scoring system was devised, ranging from 0 to 3, with intermediate increments of 0.5. The scoring system does not evaluate building performance; rather, it assesses the architectural readiness of each protocol to recognise and reward circular adaptive reuse strategies within its internal logic. Scores were assigned through cumulative consideration of three evaluative aspects: (i) the explicitness of circular or adaptive reuse requirements, (ii) the degree of methodological operationalisation and measurability, and (iii) the relative weight attributed to such criteria within the overall rating structure. The four analytical dimensions were scored independently. Table 1 shows the scoring system adopted.

Table 1. Interpretation of the 0–3 Scale.

Score	Degree of Integration	Operational Meaning
0	Absent	No reference to circular/adaptive reuse principles
0.5–1.0	Marginal	Narrative reference with minimal scoring relevance
1.5	Emerging	Recognised in measurable form but limited weight or scope
2.0	Moderate	Quantified criteria with tangible scoring impact
2.5	Advanced	Systematic integration with lifecycle reasoning
3.0	Structural	Circular logic embedded in core assessment architecture

The "Overall Gap Level" was derived from the average of the four analytical dimensions and interpreted through qualitative thresholds. It was determined that protocols with average scores below approximately 1.0 were to be classified as exhibiting a very high circularity gap. Values between roughly 1.1 and 1.5 were to be classified as indicating a high gap; between 1.6 and 2.0, a medium gap; between 2.1 and 2.5, a medium–low gap; and above 2.6, a low gap. This hybrid quantitative-qualitative approach has been demonstrated to enhance transparency and reproducibility, while preserving interpretative flexibility appropriate to theory-building research (Table 2).

Conceptual Modelling of Circular Adaptive Reuse. Building on the comparative assessment, a systems-based conceptual model was developed to reinterpret adaptive reuse as a dynamic circular process unfolding across the building lifecycle. Circular performance is framed as an emergent property arising from the interaction between *material circularity*, understood as the retention and preservation of embodied resource stocks; *functional circularity*, defined as the capacity for spatial and programmatic transformation; and *temporal circularity*, referring to lifecycle extension and resilience under uncertain future conditions. By integrating feedback loops, path dependency, and deferred environmental benefits, the model overcomes the limitations of static, attribute-based certification approaches, establishing a theoretical bridge between protocol gap analysis and assessment reformulation.

Formulation of Relational Circularity Constructs. The final methodological phase addresses a key limitation identified in existing protocols: the prevalence of single-variable indicators that fail to capture systemic interactions. Conversely, this study proposes relational circularity constructs as higher-order evaluative categories that can represent interdependencies across lifecycle variables. In this context, circular value emerges from the coordinated behaviour of material stocks, energy performance, and adaptive capacity over time.

Three relational constructs are conceptually advanced: (i) the interaction between structural retention and whole-life energy performance, highlighting how embodied carbon preservation influences long-term operational impacts; (ii) the nexus between adaptability and climate response capacity, reflecting the role of flexibility in managing environmental uncertainty; and (iii) the relationship between lifecycle extension and avoided future impacts, capturing the cumulative benefits of deferring demolition and reconstruction. These constructs are intentionally formulated as conceptual categories rather than prescriptive metrics, providing a scalable foundation for embedding adaptive reuse within next-generation sustainability assessment systems.

Table 2. Comparison of Sustainability Protocols and CE Integration for Adaptive Reuse

Protocol	KPI/Score Category	Structural Material	Retention Cycling	Adaptability	Whole-Life Cycling	Overall Gap Level
DGNB	Lifecycle value, dismantling, LCA	3.0	2.5	2.0	3.0	Low

(*continued*)

Table 2. (*continued*)

Protocol	KPI/Score Category	Structural Material	Retention Cycling	Adaptability	Whole-Life Cycling	Overall Gap Level
EU Level(s)	WLC, adaptability	3.0	2.0	2.0	3.0	Low
LEED v5 WLC	Building reuse, EPDs	2.0	1.5	2.0	2.0	Medium
BREEAM	Refurbishment pathway	2.0	1.0	2.0	1.5	Medium

Living Building	Net-positive, materials	2.5	2.0	2.0	2.5	Medium-Low
Challenge						

4 Results

Comparative Circularity Performance. The cross-protocol analysis reveals marked heterogeneity in the integration of circular economy principles relevant to adaptive reuse. DGNB and the European Level(s) framework demonstrate the highest structural alignment, primarily due to systematic lifecycle modelling, explicit treatment of whole-life carbon and measurable consideration of adaptability and disassembly. Living Building Challenge shows strong philosophical consistency with regenerative principles, although its lifecycle quantification remains less structurally embedded than in DGNB. LEED v5 evidences significant progress compared with previous iterations through expanded whole-life carbon accounting and material transparency provisions;

nevertheless, operational energy continues to exert dominant influence within its rating architecture. BREEAM Refurbishment and Fit-Out, Green Star and CASBEE exhibit moderate levels of integration, addressing material efficiency while only partially operationalising adaptability and structural retention. BEAM Plus, GRIHA, China GBES, Estidama, Green Mark and ITACA demonstrate fragmented incorporation, where circular provisions remain peripheral. WELL v2 displays minimal alignment with circular adaptive reuse due to its health-centred evaluative focus.

Structural Blind Spots and Systemic Implications. Four recurrent structural blind spots emerge across the analysed frameworks. Firstly, operational energy metrics continue to dominate weightings in ratings, which constrains the relative importance of preserving embodied carbon. Despite representing the most effective strategy for maintaining embodied value, structural retention rarely receives proportional scoring relevance. Furthermore, design for adaptability is poorly operationalised and is often expressed in qualitative rather than quantifiable terms, limiting its influence on certification outcomes. Lastly, material indicators prioritise recycled content or waste diversion over the long-term deceleration of resource flows through lifecycle extension.

Collectively, these blind spots reinforce a predominantly linear evaluative paradigm that treats buildings as static artefacts rather than dynamic systems that evolve over time. The findings therefore support the idea of reframing circularity as a relational and temporally dependent property. Adaptive reuse does not emerge as just one circular strategy among many, but as the most significant circular intervention in the built environment, capable of preserving structural, material, and cultural capital simultaneously. However, current protocols insufficiently reward this systemic value.

Toward a Dynamic and Reform-Oriented Interpretation of Circularity. The relational constructs developed in Sect. 3 demonstrate that circular performance can only be coherently assessed when material retention, functional adaptability and temporal extension are treated as interdependent dimensions within lifecycle-sensitive evaluation frameworks. By shifting from attribute-based to interaction-oriented assessment logic, the proposed approach provides methodological guidance for recalibrating certification weightings, strengthening adaptability criteria, and supporting practitioners in evaluating adaptive reuse as a primary circular strategy. In performing this task, the study offers more than a mere comparative analysis of existing protocols; it provides a conceptual framework for their progressive evolution towards dynamic, lifecycle-integrated sustainability assessment.

5 Discussion and Scientific Advancement

The comparative analysis reveals that most sustainability assessment protocols remain structurally anchored in efficiency-driven paradigms, where operational energy continues to dominate rating architectures. Although circular economy language is increasingly present, embodied carbon preservation, structural retention and long-term adaptability are rarely embedded as core evaluative dimensions. Consequently, circularity is often reduced to material attributes, such as recycled content, rather than being interpreted as a systemic, lifecycle-dependent property.

Adaptive reuse emerges among the most effective circular strategies in the built environment because it preserves embodied resources, avoids demolition impacts, and maintains spatial capital over time. However, its systemic value is insufficiently rewarded within existing certification structures. The principal advancement of this research lies in reframing circularity assessment from an attribute-based model towards a relational and dynamic logic. The semi-quantitative sensitivity matrix enhances methodological transparency in cross-protocol comparisons, while relational constructs demonstrate how circular value arises from the interaction between structural retention, whole-life energy performance and adaptive capacity. This provides a theoretical and operational basis for recalibrating future sustainability protocols.

6 Conclusions and Future Research

The study confirms the persistence of a structural circularity gap across widely adopted sustainability frameworks. While some systems demonstrate emerging lifecycle integration, adaptive reuse remains peripheral in most assessment architectures. By conceptualising circularity as a relational lifecycle property, this research contributes a methodological scaffold for embedding adaptive reuse within next-generation certification schemes. Future research should prioritise empirical validation through applied adaptive reuse case studies, integration with digital whole-life carbon modelling tools, and extension of the framework to district-scale assessment, where circularity interacts with broader urban metabolism dynamics.

Abstract. The construction sector has a major environmental impact due to high resource consumption, energy use, and carbon emissions. Concrete, in particular, is a major contributor to GHG emissions. Increasing recycling and reuse or sourcing local materials can considerably optimizing its individual use and significantly reduce concrete's environmental footprint and improve construction sustainability. This paper presents the benefits of reusing building materials in a circular approach by reducing dependence on virgin resources and strengthening circular supply chains for reused concrete elements and recycled concrete. It will analyze national regulation and standard and their impact on reuse potential and new concrete mixes.

In this study, new methods of using recycled aggregates in concrete production are compared according to relevant standards. Benefits of reusing building materials in a circular manner are evaluated. Applied methodologies include systematic literature reviews, case studies, and life cycle assessments as developed by the COST Action CA21103 CircularB. Key results include the potential of new models for reuse of concrete, the identification of key barriers and opportunities, and the recommendations for a variety of stakeholders. The study is highly relevant as it addresses concrete's significant environmental impact and offers pathways toward greater sustainability and economic resilience.

Keywords: Circular Economy · Recycled Concrete · Construction and Demolition Waste · Secondary Materials · Standards and Regulation

1 Introduction

The construction sector is responsible for approximately 6 billion tons of CO_2 emissions [1]. Concrete is the most widely used construction material worldwide because of its durability, availability, and relatively low cost. Global concrete consumption exceeds 30 billion tons annually, making it the most consumed human-made material on Earth.

Cement production, a key component of concrete manufacturing, is highly energy-intensive and produces large quantities of carbon dioxide emissions. These emissions

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 177–183, 2026.
https://doi.org/10.1007/978-3-032-34930-9_21

result from both fuel combustion and the chemical decomposition of limestone during the calcination process. Additionally, the extraction of natural aggregates such as sand and gravel cause landscape alteration, ecosystem disruption, and resource depletion.

Simultaneously, construction and demolition waste (CDW) represent a growing environmental challenge. CDW accounts for approximately 36% of total waste produced on Earth [2]. However, CDW also represents a valuable secondary resource that can be recovered and reused in new construction activities.

Within this context, recycled concrete aggregates and also the reuse of structural elements represent important strategies for reducing the global warming potential of concrete construction. Recycled concrete aggregates (RCA), obtained by crushing and processing concrete, have been widely investigated as a substitute for natural aggregates in new concrete production. However, not all parameters have been investigated. Under what conditions can the use of recycled concrete fines lead to an additional reduction of the GWP (Global Warming Potential)?

The objective of this study is to investigate circular approaches to concrete use in the construction sector by analyzing environmental benefits, technical challenges, and regulatory constraints associated with recycled concrete applications and concrete fines.

The study applies three main research approaches as methodology: A systematic literature review, case studies of crushed concrete fines, and Life Cycle Assessment (LCA), including a comparison of virgin versus recycled materials.

2 Literature Review

2.1 Environmental Impact of Concrete Production

Concrete production has significant environmental implications due to its large-scale material and energy requirements. Cement production alone accounts for approximately 7–8% [3] of global carbon dioxide emissions and for approximately 0.8 tons of CO_2 emissions per ton of cement produced.

2.2 Circular Economy in the Construction Sector

In the context of concrete, circular approaches include the reuse of structural elements, the recycling of demolition waste into new aggregates, and the development of closed-loop supply chains. Research indicates that adopting circular construction strategies can significantly reduce dependence on virgin raw materials while improving waste management and reducing environmental burdens.

Furthermore, circular construction encourages innovative approaches such as material passports, digital tracking of building components, and design for disassembly. These strategies enable future reuse of structural elements and facilitate the recovery of valuable materials at the end of a building's life cycle.

2.3 Reuse and Recycling of Concrete Materials

Several studies have investigated the mechanical performance of recycled aggregate concrete (RAC). While RAC may exhibit slightly lower compressive strength and higher

water absorption compared with conventional concrete, appropriate mix design and processing techniques can significantly improve performance. Advancements in recycling technologies have improved the quality of recycled aggregates, enabling their use in structural applications under certain conditions.

2.4 Existing Research Gaps

The literature review has stated three main areas of lack of knowledge

- Lack of circular supply chains
- Limited regulatory support
- Lack of detailed data of strength and durability on the use of recycled concrete fines lead

3 Regulatory Framework and Standards

Despite the environmental benefits of recycled concrete, several barriers hinder its widespread adoption in construction practice. One of the primary challenges is the lack of harmonized standards and regulatory frameworks governing the use of recycled aggregates in structural concrete. There are relevant initiatives on the European Committee for Standardization (CEN) as well as on national standardization boards to cover the topic.

Technical concerns regarding durability, variability in recycled aggregate quality, and long-term structural performance have also limited the acceptance of RAC in many regions. Differences in national standards and testing procedures further complicate the implementation of recycled concrete technologies. For example, the Swiss standard SIA 2030: 2021 (Concrete with recycled aggregates) [5] refers to the use of recycled concrete fines in Table 1.

Table 1. The potential use of recycling concrete according to Swiss standard SIA 20230:2021.

Recycled concrete class	Concrete type according to SN EN 206:2013 + A2:2021, Table NA.5 and NA.8								Pile concrete P1,P2,P3,P4
	0	A	B	C	D	E	F	G	
RC-C25	permissible				1)	inadmissible			permissible
RC-C50	permissible				1)	inadmissible			1)
RC-M10	permissible				1)	inadmissible			1)
RC-M40	permissible				1)	inadmissible			1)

Another detailed regulation for concrete fines, use of cement and durability is presented in the standard SIST EN 197-6:2023 01-Oktober-2023 (Cement-Part 6: Cement with recycled building materials) [6].

Therefore, recent research suggests that improvements in quality control, recycling technologies, and performance-based standards could significantly increase the reuse

potential of concrete materials. Future research and policy development are therefore crucial for enabling large-scale adoption of circular concrete systems.

4 Case Studies on Crushed Concrete Fines

Experimental research on crushed concrete fines indicating a strong relation between the granularity and geometry of the recycled aggregate from waste concrete and the water absorption rate.

In this study, granulometry, dry density and water absorption of one type of NA and four types of RA were examined and compared (Fig. 1).

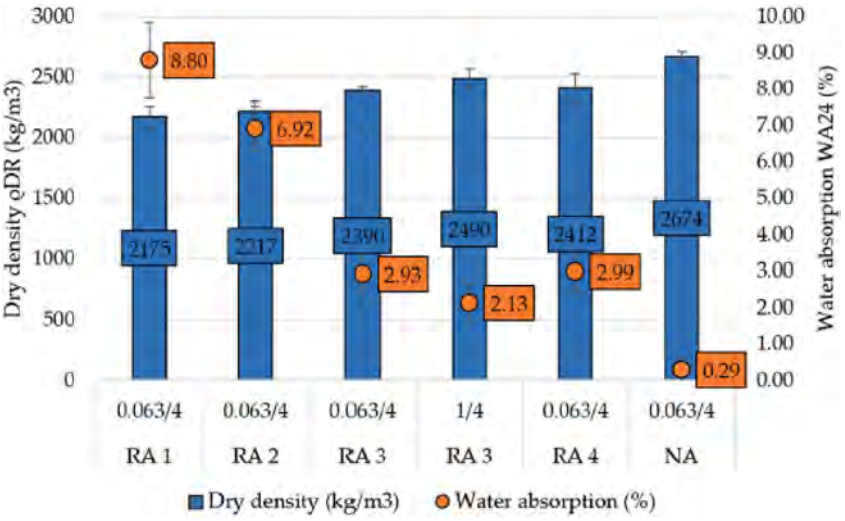

Fig. 1. Oven dry density and water absorption rate of aggregate according to CSN EN 10907–6.

All tested properties of RA differed from NA, especially the water absorption capacity, which was more than ten times higher and ranged from 2.1 to 8.8% for fine fraction of RA, where the highest water absorption was measured for RA 1 originated from waste concrete from recycling center [7].

The water absorption rate together with results in strength and durability related tests are the indicators of the cement demand for the concrete mixture when using recycled aggregates. Recent studies also focus on the geometry and on the dimension of the fines as another important indicator for the demand of cement proportion in the mix of recycled concrete.

5 Life Cycle Assessment (LCA)

5.1 Comparative LCA Results from Literature

Life Cycle Assessment (LCA) was applied to evaluate the environmental performance of different concrete production scenarios [8]. The system boundary for this study includes raw material extraction, aggregate processing, concrete production, and transportation stages.

Two scenarios were evaluated in the study: conventional concrete using natural aggregates and concrete containing recycled aggregates. In this study, two water-cement ratios (WCR) and four recycled concrete aggregate replacement rates (RCARR) were tested on two natural aggregate concrete (NAC) and six recycled aggregate concrete (RAC) samples.

A meta-analysis of recycled aggregate concrete mixes shows that environmental impacts vary depending on replacement ratio, transportation distance, and additional cement requirements [9].

These values correspond with results reported across multiple LCA investigations of recycled concrete materials. This is shown (Table 2) in comparative LCA results from literature:

Table 2. Environmental comparison of concrete production scenarios.

Concrete type	CO_2 emissions (kg CO_2/m^3)
Conventional concrete	300–350
30% recycled aggregate concrete	250–300
50% recycled aggregate concrete	220–270
Reused structural elements	<100

An evaluation of recycled concrete mixes according to further confirm that recycled aggregate concrete generally achieves **lower environmental impacts while maintaining acceptable mechanical performance**, particularly when optimized mix proportions are used and other parameters, such as optimal transport conditions are considered.

This analysis also indicates that **transportation distance and cement content are the two most influential variables** affecting the environmental performance of recycled aggregate concrete systems.

5.2 Methodologies Developed in COST Action CA21103 CircularB

In the framework of the Cost Action CA 21103 CircularB, a comprehensive method to assess the impact of transport parameters and its impact on the Global Warming Potential (GWP) for different concrete mixes using natural aggregates or recycled aggregates was developed [10]. For example, a 5% contribution of recycled concrete aggregate leads to a reduction of 4.56% CO_2 eq in the presented LCA study.

The findings indicate a relevant environmental advantage of using recycled concrete, however, it is highly context-dependent on a case-sensitive situation. Transportation distances play an important role, with the potential to turn environmental gains into losses if not considered properly.

6 Discussion

Replacing natural aggregates with recycled materials reduces resource extraction and waste generation. However, several barriers remain, including material quality variability, regulatory restrictions, and limited recycling infrastructure. Policy support, technological innovation, and improved supply chain coordination will be essential for scaling circular construction practices. Furthermore, market acceptance will be strongly influenced by quality control issues and availability of the recycled materials. Parameters such as transport distance will be a decisive factor for an overall positive impact on the GWP. This will pose a challenge to local material sourcing and circular supply chains.

7 Recommendations

For different stakeholders:

Policy Makers: Policy makers should update standards for recycled aggregates to ensure their safe and effective use in construction, and introduce incentives that encourage the adoption of circular construction practices.

Construction Industry: The construction industry should develop reuse networks that facilitate the recovery and redistribution of construction materials, and invest in advanced recycling technologies to improve the efficiency and quality of recycled construction materials.

Research: Researchers should focus on improving material testing methods to better evaluate the performance of recycled materials, and develop optimized concrete mix designs that maximize the use of recycled aggregates while maintaining structural performance in relation to strength and durability.

8 Conclusion

This study demonstrates that circular approaches to concrete use offer significant opportunities for reducing environmental impacts in the construction sector [9]. The incorporation of recycled concrete aggregates can reduce carbon emissions, energy consumption, and raw material extraction.

The optimal use of the mix of the recycled concrete and the parameters for the transports involved are important factors. Despite these advantages, regulatory barriers, technical challenges, and economic factors continue to limit widespread adoption. Future research should focus on improving recycling technologies, developing performance-based standards, and strengthening circular supply chains for construction materials.

Abstract. The transition toward a circular built environment requires that prefabricated structural systems be conceived not only for first-life performance but also for safe and reliable second-life applications. This state-of-the-art review examines the seismic performance of prefabricated structures in the context of circular economy principles, focusing on the feasibility of reusing structural systems and components in seismic regions. The paper synthesizes experimental and numerical investigations on the behaviour of prefabricated and modular systems under earthquake loading, with particular emphasis on connection performance, damage accumulation, and residual capacity after prior service or seismic events. Studies on design for deconstruction, demountable connections, and reusable precast elements are critically analysed to clarify how circularity strategies interact with seismic performance requirements. Special attention is given to assessment and verification methodologies capable of demonstrating that reused structural elements meet target performance levels and safety margins. On this basis, the review explores whether, and under which conditions, a second life of prefabricated structures can be enabled without compromising life safety and resilience. The paper concludes by identifying key knowledge gaps, codification challenges, and research needs, and by discussing the main criteria needed to integrate seismic performance considerations into circular design and reuse decision-making for prefabricated structures.

1 Introduction

Circular economy (CE) represents a transition from the conventional linear model toward a regenerative system based on closed loops of reuse, remanufacturing, and recycling. Within the construction sector, this transition implies that buildings and their components

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 184–191, 2026.
https://doi.org/10.1007/978-3-032-34930-9_22

should be conceived so that materials remain in use at their highest possible value across multiple life cycles [1]. In practical terms, this involves extending the service life of materials through strategies such as recycling and, more effectively, direct reuse.

Applying CE principles to buildings therefore requires anticipating multiple service lives already at the design stage. In seismic regions, however, this objective introduces additional complexity, as structures must simultaneously satisfy stringent earthquake performance requirements while remaining compatible with future disassembly and reuse. Prefabricated structural systems must therefore achieve robust seismic performance during their first service life, while also incorporating design strategies that allow structural components to be safely recovered, inspected, and reconfigured. Integrating these objectives is essential for enabling structural reuse without compromising life safety and resilience and constitutes a key step toward the realization of a truly circular built environment.

Structural reuse is motivated by economic, environmental and social factors. Demolition wastes enormous embodied energy and materials, while reuse greatly cuts carbon emissions [2, 3]. Prefabricated buildings are well-suited for reuse because their components (panels, modules, frames) can be standardized and easily deconstructed [3]. In seismic regions, reuse can also improve resilience: for example, after the fire that destroyed a school in British Columbia, 75% of the original steel frame was salvaged and reused in the rebuild, dramatically reducing new material needs [3]. The remaining challenge is ensuring safety: reused buildings must still meet seismic performance targets. Therefore, integrating CE principles with seismic design is needed so that a second life can be enabled without compromising life safety and performance [4].

2 Circular Economy and Structural Reuse in the Built Environment

CE in construction aims to establish closed material loops with systems that minimize waste through recycling, reuse, and reprocessing of materials [1, 2]. A central principle of CE is the extension of material service life (e.g. steel is infinitely recyclable and its direct reuse significantly reduces resource consumption [2]). A distinction should therefore be made between extended life, where a structure continues to perform its original function through maintenance or upgrading, and second life, which implies designed recoverability, i.e., the capacity to disassemble, assess, and redeploy assets safely in a new structural configuration or location.

For prefabricated construction, second-life opportunities may arise at different scales. At the largest scale, entire buildings or modular units may be relocated and reused. Structurally, this pathway preserves not only materials but also the spatial and functional system, including the original load-path logic. In seismic regions, however, relocation may alter the seismic hazard, site conditions, and performance objectives, meaning that "second life" requires not only reinstallation but also re-verification under a different hazard and regulatory context. At intermediate scale, panels or volumetric modules may be recovered and integrated into new systems. This approach aligns with the concept of "buildings as material banks" and digital inventories that treat buildings as repositories of recoverable components [1]. Structurally, this reuse scale introduces interface challenges, as seismic performance often depends on inter-module connections, diaphragm

continuity, and the cumulative damage experienced by boundary elements under cyclic drift demands. At the smallest scale, individual beams, columns, slabs, or wall elements may be salvaged and reassigned to other structural applications. In seismic regions, however, reuse must account for prior cyclic demands, including low-cycle fatigue, cracking, yielding history, and anchorage distress, and may require sacrificing certain components to preserve the reusability of primary members. Each level of reuse involves different technical and regulatory challenges, particularly with respect to load transfer, compatibility, documentation, and verification of residual performance.

Seismic contexts pose additional uncertainty and performance demands for structural reuse. Earthquakes produce variable dynamic loads, so a reused structure must remain resilient under unpredictable seismic demands. This requires clear understanding of residual capacity after first life or any prior event. Any permanent deformations in reused members undermine this capacity. Umaraj et al. (2025) underscore that for safety, reused elements "should have no permanent deformation or change in geometry… and [offer] the same safety and reliability as an unused" component [4]. In other words, a reused building must effectively behave like new one from the standpoint of seismic codes. In practice this means damage-free disassembly, or else reconditioning of elements to restore strength. It also means adopting appropriate safety factors.

Despite the advantages of reuse, significant barriers remain. Implementing reuse requires new engineering assessment methods, reliable documentation of structural performance, and market confidence in reused components [3]. Uncertainty in seismic demand and in the history of reused components also mandates conservative design and rigorous assessment for any second-life use.

The working hypothesis is that prefabricated systems can be conceived from the outset to achieve dual performance: safe first-life operation and reliable second-life reuse. Integrating circularity strategies during the design phase enables prefabricated buildings to be prepared for future disassembly using modular dimensions and demountable connections [3, 5]. Experimental studies have shown, for example, that steel structures equipped with interlocking, demountable column bases can retain their load-bearing capacity across multiple reuse cycles [3, 5]. The long-term feasibility of this approach depends on design choices such as standardized spans to facilitate the interchangeability of reused modules and clear documentation of component properties through material passports [1]. The goal is to achieve resilience in first life and then require only minimal adjustments for second life. In practice, this might mean designing components to higher initial standards or providing post-dismantling refurbishment steps.

3 Prefabricated Structures in Seismic Regions: Systems and Failure Mechanisms

Prefabricated buildings used in seismic regions may generally be classified into four broad typologies: precast reinforced concrete (RC) frame systems, precast wall-panel systems, modular volumetric systems, and hybrid systems combining prefabricated and cast-in-situ components [6]. Structural assemblies may consist of linear elements (columns and beams), planar elements (slabs and walls), or spatial volumetric modules. Classification is generally based on the type of vertical load-resisting system and the mechanism used to ensure lateral stability.

Precast RC frame systems, composed of prefabricated beams and columns with moment-resisting or semi-rigid beam-column connections, are widely used, particularly in parking structures and commercial buildings. Precast wall-panel systems are extensively used in residential construction [6]. Hybrid prefabricated systems, combining precast gravity frames with cast-in-situ cores or shear walls, are commonly used to enhance global stiffness, ductility, and seismic reliability. In industrial construction, precast portal frame systems with cantilevered columns and simply supported beams are prevalent in Mediterranean countries, although past earthquakes have highlighted vulnerabilities associated with connection detailing and loss of support. Finally, modular volumetric systems, composed of three-dimensional prefabricated units connected at floor and wall interfaces, are increasingly used where seismic performance depends on the collective interaction of modules and the integrity of inter-module connections and diaphragms.

Across all types, seismic performance is predominantly governed by connection behaviour rather than by the strength of individual members. Field observations following major earthquakes and analytical investigations of precast industrial buildings show that column bases, beam-column joints, diaphragm interfaces, anchorage regions, and seating supports frequently control collapse mechanisms and damage propagation [7]. Typical failure modes include joint shear failure, brittle anchorage rupture, loss of seating support, insufficient tie forces, diaphragm discontinuities, and inadequate confinement.

Experience from past earthquakes, as well as findings from experimental and numerical studies, has shown that prefabricated structures often exhibit damage concentrations at connections rather than in primary load-bearing members. Common deficiencies include inadequate diaphragm continuity or slab-to-beam anchorage [7], loss of seating and insufficient mechanical continuity between hollow-core units and supporting beams [8], inadequate detailing, insufficient confinement, and weak lateral load-resisting systems [9], diaphragm cracking and seating vulnerabilities due to beam elongation and displacement incompatibility [10], failures of friction-based beam-column and roof connections [11].

From a circular-economy perspective, second-life suitability depends on whether seismic damage is (i) localized, (ii) inspectable, and (iii) repairable without compromising global stability. Systems designed with ductile, capacity-protected connectors or replaceable dissipative zones exhibit greater reuse potential than systems relying on brittle anchorage or minimal seating length. Residual drift and connection deformation capacity therefore emerge as decisive performance indicators not only for life-safety verification but also for reuse feasibility.

Overall, prefabricated systems are not inherently less suitable for seismic regions; rather, their reuse compatibility depends on connection philosophy, redundancy, diaphragm integrity, and the concentration pattern of damage.

4 Assessment and Verification Methodologies for Reused Structural Elements

The safe reuse of prefabricated structural elements in seismic regions requires a rigorous assessment framework capable of addressing both conventional existing-structure concerns and reuse-specific uncertainties. Existing standards and guidelines, including

ISO 13822, EN 1998–3, and ASCE/SEI 41–23, provide a valuable basis for evaluating the seismic performance of existing buildings. However, these documents do not explicitly address the certification and qualification of reused prefabricated components or the implications of prior service history for second-life structural use. Studies on structural reuse therefore emphasize the need to complement existing-building assessment procedures with reuse-specific inspection and documentation protocols [12].

A reuse-oriented assessment process generally involves four interrelated stages. The first stage is inspection and documentation, which includes identification of the structural system, review of available drawings and records, visual condition assessment, and examination of joints and support regions. The second stage is testing and material characterization, carried out where uncertainty exists regarding geometry, reinforcement, mechanical properties, durability, or damage state. The third stage is structural analysis, in which the system is evaluated under the relevant load combinations and seismic actions, with explicit consideration of connection behaviour, diaphragm action, degradation, and possible prior damage. The fourth stage is decision-making, through which components or assemblies are classified for direct reuse, reuse after repair or strengthening, repurposing for lower-demand applications, or recycling. When entire prefabricated buildings are considered for reuse or relocation, assessment must also include system-level verification of diaphragm continuity, load transfer between structural sub-systems, and robustness against progressive collapse.

Experimental investigations on prefabricated and hybrid systems show that seismic response is often governed by the behaviour of connections rather than primary structural members. Damage tends to be localized in beam-column joints, diaphragm connectors, or slab seating regions, while the main elements remain largely undamaged. Experimental tests on precast wall systems with energy-dissipating devices have demonstrated stable cyclic behaviour and limited residual drift, suggesting that structural damage can be concentrated in replaceable components [13]. This capacity-protected design philosophy is particularly relevant for circular-economy strategies, as prefabricated elements may retain sufficient residual capacity for reuse if damage remains confined to replaceable components. Consequently, demountable and replaceable connection systems have been proposed to enhance both seismic resilience and reuse potential of prefabricated structures.

Despite recent progress, important methodological gaps remain. There is currently no standardized damage-state classification for prefabricated connections in the context of reuse certification, and most seismic assessment procedures focus on single-event performance rather than cumulative loading histories. In addition, existing standards provide limited guidance for proof-testing salvaged connectors or diaphragm interfaces, which often control the seismic performance of prefabricated systems. Developing standardized inspection procedures, degradation models for multi-event seismic exposure, and certification protocols for reusable components will therefore be essential for enabling safe structural reuse in seismic regions.

5 Case Study: Finish Prefabricated Structures and Second-Life Potential

A practical illustration of the challenges and opportunities of second-life use is provided by a residential complex in Joensuu, Finland, investigated within the Interreg Aurora project EU-MAT. The complex consists of three residential buildings constructed in 1985 using load-bearing prefabricated concrete (PC) wall elements and semi-precast floor systems. Each structure has a transversal system of load-bearing prefabricated wall elements and reinforced semi-precast floor system (beam-and-block floor) on three levels. The case was examined in the context of planned demolition, with the objective of evaluating whether selected structural elements could be directly reused or alternatively recycled as concrete aggregate.

The assessment process began with the collection of available documentation, followed by visual inspection and in-situ verification of geometry and condition. Particular attention was paid to cracking, moisture exposure, deterioration of seams and joints, and signs of freeze-thaw damage. Additional investigations included non-destructive testing and extraction of material samples in order to determine concrete strength, density, and durability-related properties. Screening for contaminants was also necessary, since the presence of hazardous substances may restrict both reuse and recycling options.

The case study revealed several barriers that are representative of current practice. Direct reuse of PC elements requires selective dismantling to avoid damage during demolition, but such procedures are more time-consuming and costly than conventional demolition methods. In addition, the absence of standardized re-certification procedures for reclaimed structural elements creates uncertainty and often necessitates extensive testing before reuse can be considered. Under present regulatory and market conditions, recycling into recycled concrete aggregate is therefore more readily achievable than direct structural reuse. Namely, in Finland and Scandinavian countries only concrete hollow-core slabs can be re-certified relatively easily, without significant cost increase. Re-certifying prefabricated wall elements is only possible after performing extensive tests that would prove their load-bearing ability and serviceability.

The Joensuu case demonstrates that second-life use of PC elements is not solely a technical issue, but also one of process integration, documentation, and early planning. The EU-MAT case study and other circular construction projects taking place across Finland such as ReCreate [14] may provide significant insight into the possibilities, as well as the challenges that may arise during such activities.

6 Conclusions

Enabling structural reuse in seismic regions requires formalizing the interaction between circularity and seismic performance criteria. Prefabricated systems offer important advantages for circular construction because of their modularity, repeatability, and potential for disassembly. However, these characteristics alone do not ensure reuse potential. In seismically active regions, second-life applications must be supported by robust evidence that reused elements and systems can satisfy target performance requirements without compromising life safety (including damage limitation, replaceable energy-dissipating elements, and verification of residual capacity).

Three conditions emerge as particularly important. First, the structural system must be sufficiently documented and inspectable, so that its geometry, material properties, detailing, and service history can be established with confidence. Second, damage must be either absent or limited to forms that are detectable, localized, and compatible with repair or controlled reuse. Third, the reused configuration must be verified through appropriate assessment methods that consider not only member resistance, but also connection behaviour, diaphragm action, robustness, and cumulative damage effects.

Advancing circularity in seismic design requires research on performance validation and new code provisions. As prefabricated buildings become more common, creating clear verification workflows and embedding them in standards will be crucial for safe reuse in seismic regions.

Abstract. The transition toward a circular economy in the construction sector promotes the reuse of materials, the development of bio-based composites, and the recycling of industrial waste streams. While these strategies significantly reduce resource consumption and environmental impacts, they also introduce new challenges related to fire safety, material performance, and regulatory compliance. Circular construction increasingly incorporates combustible bio-based materials, recycled polymers, and waste-derived composites, which may alter fire behavior and increase fire loads in buildings. This paper reviews recent developments in circular construction materials, including bio-based composites, recycled tire rubber concrete, wood-based insulation foam, and agricultural waste reinforced polymers. Furthermore, the study discusses the role of bio-based flame retardants, and the emerging regulatory challenges related to hazardous substances and waste reuse. The findings highlight the need for integrated design approaches that combine sustainability, fire safety engineering, and risk management frameworks. Achieving safe circular construction requires collaboration between researchers, industry, and policymakers to ensure that environmental benefits do not compromise building safety.

Keywords: Fire Safety · Combustible Materials · Circular Materials · Recycled Materials · Bio-based Composites · Sustainable Construction

1 Introduction

The construction sector is a major consumer of raw materials and a significant contributor to environmental degradation, accounting for substantial energy use, greenhouse gas emissions, and waste generation across the building lifecycle [1]. In response, circular economy (CE) principles have emerged as a key strategy to improve resource efficiency and reduce environmental impacts in the built environment.

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 192–200, 2026.
https://doi.org/10.1007/978-3-032-34930-9_23

CE approaches aim to replace the linear "take–make–dispose" model with systems that prioritize reuse, recycling, and extended material lifespans [2]. In construction, this includes design for disassembly, modularity, adaptability, and the use of renewable and recycled materials, reducing construction and demolition waste while improving sustainability performance, [3]. Circular construction increasingly incorporates recycled and waste-derived materials, such as recycled aggregates, rubberized concrete, bio-based composites, and polymer-based products [4]. While these reduce reliance on virgin resources, they often exhibit different mechanical, thermal, and durability characteristics compared to conventional materials.

A key challenge is fire safety. Many bio-based and polymer-based materials are combustible or behave differently under fire exposure, potentially increasing fire loads, flame spread, and smoke production. Reused materials may also lack reliable fire performance data or fail to meet current regulatory requirements. Circular construction systems must therefore ensure adequate structural integrity and fire resistance, including designs intended for disassembly and reuse. Addressing these challenges requires integrating material science, structural engineering and fire safety engineering. Achieving safe and sustainable circular construction depends on balancing environmental benefits with fire performance and structural reliability.

This paper examines the relationship between circular construction materials and fire safety, reviewing recent material developments, evaluating fire and structural performance, and discussing associated regulatory challenges.

2 Circular Materials

The transition toward a circular economy in the construction sector has led to an increased adoption of recycled, reused, and bio-based materials. While these approaches improve resource efficiency and reduce environmental impacts, they also introduce new challenges related to fire safety. In particular, the thermal behaviour, combustibility, and structural performance of circular materials under fire exposure may differ significantly from those of conventional construction materials.

Based on a review of existing literature defining the material characteristics and the thermal response of various circular materials [2–21], a classification framework for circular materials is proposed, focusing on their origin and circularity characteristics. Materials are categorized into four main groups: reused (RU), recycled (RC), renewable (RN), and those providing additional environmental benefits (ECO) (Table 1). This classification is essential for subsequent fire analysis, as it enables systematic evaluation of the fire performance and behaviour of different circular material groups.

Table 1. Classification of circular construction materials.

Material	Reused (RU), Recycled (RC), Renewable (RN) and Additional Environmental (ECO) Benefits
Metals	(RU/RC): steel; aluminum

(*continued*)

Table 1. (*continued*)

Stone and fired clay	(RU): stone; fired clay bricks; (RC): ceramic materials
Timber, bamboo, bio-based materials and composites	(RU/RC/RN/ECO): timber; bamboo; engineered timber/bamboo; cork (RC/RN/ECO): natural fiber-reinforced composites; wood fiber; hemp; flax; kenaf; jute; sisal; coir; bamboo fiber; cellulose; mycelium-based materials (RU/RN/ECO) straw
Concrete, cementitious and lime-based materials	(RU): concrete/mortar; (RC): concrete/mortar with recycled aggregates including mineral-based, glass-based, ceramic-based, polymer-based and bio-based aggregates; (RC/ECO): low-carbon concrete/mortar; (RU/RC/ECO): lime-based concrete/mortar; (RC/ECO): geopolymer concrete/mortar
Glass	(RU/RC): glass; foamed glass
Polymers and polymer fiber-reinforced composites	(RC/RU): plastic structural profiles/lumber; thermoplastic structural composites; reprocessable fibre-reinforced composites; (RU/RC): PET; polyester; some rubber products etc.
Earthen materials	(RU/RN/ECO): rammed earth; adobe; cob; compressed earth blocks
Animal-based materials	(RU/RC/RN/ECO): sheep wool

3 Fire Performance Classification of Materials and Elements

In addition to material origin and circularity, fire performance is a critical parameter in building design and regulation. Fire classification systems distinguish between reaction to fire, describing a material's contribution to fire development (ignitability, flame spread, heat release, and smoke production), and fire resistance, referring to the ability of a building element to maintain structural and functional performance under fire exposure. According to EN 13501-1 [22], construction materials are classified into Euroclasses A1–F based on reaction-to-fire performance:

- A1–A2: non-combustible or limited combustibility
- B–C: combustible with limited contribution
- D–F: highly combustible

Additional classifications address smoke production (s1–s3) and flaming droplets or particles (d0–d2), providing a standardized framework for evaluating and comparing fire behavior.

Fire resistance is defined over a specified period under standard fire exposure or over the full duration of a parametric fire EN 1991-1-2 [23]. It is expressed through:

- R (load-bearing capacity): ability to maintain mechanical resistance
- E (integrity): ability to prevent passage of flames and hot gases
- I (insulation): ability to limit temperature rise on the unexposed side

These criteria are often combined (e.g., REI 60), indicating that an element satisfies load-bearing, integrity, and insulation requirements for 60 min under standard fire exposure, or throughout the fire duration in parametric design.

4 Fire Behavior of Circular Materials

The fire behavior of circular materials depends on composition, prior use, processing history, and system integration. Unlike conventional materials, reused and recycled products may vary in ignitability, heat release, smoke production, and structural performance, requiring assessment at both material and system levels.

In the following sections, the most representative material groups are examined based on a review of the existing literature. Table 2 summarizes the fire behaviour and corresponding fire safety strategies for key circular material groups, classified according to the Euroclass system.

Table 2. Fire safety considerations for circular construction materials

Euroclass	Material Type	Typical Materials	Fire Behavior	Fire Safety Strategy
A1–A2	Mineral-based materials	RCA; recycled brick/masonry; glass (cullet, foam glass); fly ash; GGBS; silica fume; geopolymer concrete; mineral composites	Non-combustible; negligible heat release; no smoke; high thermal stability	Structural optimization; spalling control; mineral binders/additives
B–C	Wood-based composites	Treated timber; engineered wood (e.g., CLT) *(untreated typically D)*	Combustible; forms protective char layer	Fire-retardant coatings; protective linings
B–C	Natural fiber composites (treated)	Hemp; flax; cellulose; cork; bio-based insulation	Pyrolysis; potential char formation	Bio-based flame-retardant systems
D–F	Polymer insulation	EPS; polymer foams; synthetic insulation	Melting/dripping; promotes fire spread	Flame-retardant additives; encapsulation
D–F	Recycled plastics	HDPE; PVC; PET; plastic products	High heat release; rapid ignition; dense/toxic smoke	Material modification; flame retardants; encapsulation

(*continued*)

Table 2. (*continued*)

Euroclass	Material Type	Typical Materials	Fire Behavior	Fire Safety Strategy
E–F	Untreated bio-based materials	Straw; bagasse; husk panels; untreated cellulose; some mycelium materials	Rapid ignition; fast flame spread; high smoke production	Fire-retardant treatment; material modification

Mineral-Based Circular Materials: Mineral-based materials exhibit the most favorable fire performance, remaining non-combustible (Euroclass A1–A2) and not contributing to fire growth. Recycled concrete and reused brick can retain these properties provided it is free from contaminants. Recycled aggregate concrete behaves similarly to conventional concrete; although spalling, strength loss (300–600 °C), and cracking may occur, structural integrity is generally maintained [6, 7].

Recycled additions such as rubber, plastics and industrial by-products influence performance [8–10]. Optimized values of rubber may reduce strength but improve ductility, reducing explosive spalling and limiting heat penetration [8], while pozzolanic additives enhance bonding and reduce porosity [10]. Geopolymer concretes show excellent high-temperature resistance [11].

Bio-Based Materials: Bio-based materials (e.g., timber, cellulose, hemp, straw, wood fiber composites) are inherently combustible and undergo pyrolysis, promoting ignition, flame spread, and smoke production. Bio-composites provide low density and insulation but increase fire load; their performance depends on fibre type, treatment, and matrix compatibility [12]. They ignite readily, contribute to fire growth, and may sustain smouldering [13], although char formation can reduce heat release. Fire-retardant treatments can significantly improve performance, enabling classifications up to Euroclass B–C [24].

Engineered systems, such as cellulose-based composite foams with bio-based flame-retardant systems, demonstrate improved fire resistance, low thermal conductivity (~0.050 W/m·K) and good mechanical properties [14]. Timber exemplifies controlled combustibility, forming a protective char layer that slows degradation and maintains structural capacity, with further improvement through treatments and linings [15]. Bio-based flame retardants derived from lignin, cellulose, and tannins act via char formation, heat absorption, and inert gas release. although challenges remain in compatibility and processing [16].

Polymer-Based Circular Materials: Recycled polymers (plastics, rubber, insulation) present the highest fire risk, characterized by rapid ignition, high heat release, dense smoke and toxic gases, and melting or dripping, all promoting fire growth.

Fire behavior varies due to additives, contaminants, and recycling-induced degradation. Expanded polystyrene (EPS) is inherently combustible but can achieve improved performance when treated or protected [17]. Untreated polymers are typically Euroclass D–F, while treated systems may reach B–C depending on formulation [18].

Due to their high fire contribution, polymer-based materials require strict control through material modification, flame-retardant additives, encapsulation, and system-level fire safety design.

Waste-Derived and Hybrid Composite Materials: combine mineral, bio-based, and polymer components, resulting in variable fire behavior governed by composition and structure. Higher mineral content improves fire performance, while increased polymer or organic fractions increase combustibility [19]. Cementitious systems with recycled materials can achieve improved thermal stability and fire resilience despite some strength loss under fire exposure [19], with certain components also reducing heat penetration. Overall, the fire behavior of hybrid composites cannot be inferred from individual constituents and must be evaluated at the system level.

Material treatments further enhance performance; for example, epoxy composites reinforced with carbonized cow bone particles improve flame resistance through char formation and thermally stable mineral phases, reducing flammability and smoke production [20], whereas untreated organic fillers increase fire load.

5 Waste Management and Circularity Indicators

In addition to in-service performance, fire risks also arise during storage and handling of circular materials and waste. Waste storage and management are critical yet often overlooked in circular construction. Improper handling of construction and demolition waste can lead to contamination, inefficiencies, and increased fire risk, particularly from accumulated combustible materials.

Recent research [21] emphasizes integrating storage and stockpiling into circularity indicators. The Storage Circularity Indicator (SCI), based on fire risk assessment, evaluates hazard likelihood and severity, highlighting the need to consider fire safety across the entire material lifecycle [21].

Circularity indicators also assess reuse efficiency through metrics such as recovery rates, energy consumption, and emissions. However, waste reuse introduces challenges related to contamination and material quality, requiring advanced sorting, quality control, and standardized certification to ensure safe application.

6 Regulatory and Design Challenges

Although circular economy strategies are widely promoted, regulatory frameworks have not yet fully adapted to their implementation. Existing fire safety regulations are largely based on standardized testing methods developed for conventional materials and may not be directly applicable to reused or recycled products.

Reuse introduces significant challenges related to certification, traceability, and quality assurance. Materials may require re-evaluation due to ageing, mechanical damage, environmental exposure, or missing documentation, and are often restricted due to uncertainties in performance [3]. In this context, performance-based fire design provides a valuable alternative, enabling analytical assessment beyond prescriptive testing and supporting the broader adoption of circular materials.

Additional risks arise from hazardous substances in recycled materials, including persistent additives such as plasticizers, stabilizers, flame retardants, and heavy metals. Regulatory fragmentation, particularly between REACH and waste legislation, creates gaps in risk assessment and complicates compliance.

Furthermore, both reused and recycled materials exhibit inherent variability. Reused materials may be affected by prior thermal loading or undocumented treatments. Recycled materials introduce uncertainty due to heterogeneous feedstocks, contamination, and reprocessing. Changes in use conditions add another layer of complexity, as materials are frequently redeployed in new assemblies where system-level interactions govern fire response. A structured verification approach is therefore essential, including traceability, condition assessment, evaluation of existing fire performance data, and, where necessary, supplementary testing or engineering-based assessment.

Effective implementation of circular construction thus requires integrated frameworks that combine material evaluation, exposure assessment, and regulatory compliance. These should be supported by decision-making tools and interdisciplinary collaboration to ensure that circularity objectives are achieved without compromising fire safety.

7 Discussion

Fire behavior of circular materials is governed by composition and structure. Mineral-based materials provide the best performance, while bio-based materials are combustible and require fire-retardant strategies, and polymers present the highest fire risk due to rapid ignition, high heat release, and smoke production.

Circular materials do not inherently compromise fire safety; safe use depends on material selection, fire-retardant treatments, and system-level design. Performance-based fire engineering is therefore essential [24].

Although circular strategies offer environmental benefits, their adoption must balance sustainability with safety and regulation. Advances in flame retardants and engineered composites show that fire performance can be improved without compromising environmental goals.

Regulatory frameworks must evolve through harmonization, improved certification, and interdisciplinary collaboration. Timber and façade systems highlight the need for system-level design.

Safe circular construction ultimately requires a holistic integration of materials, design, regulation, and lifecycle considerations.

These findings highlight that fire safety in circular construction is governed not only by material properties but by system-level design and lifecycle considerations.

8 Conclusions

Circular economy strategies improve resource efficiency but introduce materials with diverse and uncertain fire behaviour, governed by both material composition and system configuration.

Mineral-based materials provide reliable fire performance, whereas bio-based and polymer-based materials are combustible and require targeted fire protection strategies, including fire-retardant treatments and system-level design.

Safe implementation is achievable through appropriate material selection, engineered fire protection, and performance-based fire design. Advances in flame-retardant technologies and composite design demonstrate that fire safety and sustainability can be aligned.

However, adoption is constrained by regulatory challenges related to certification, traceability, and hazardous substances, requiring harmonized frameworks and integrated risk assessment.

Future work should focus on advanced fire-safe materials, standardized testing, and lifecycle-based fire assessment. Achieving circular construction requires balancing sustainability with fire safety and structural reliability.

Adaptability as a Driver of Lower Environmental Impacts: Insights from a Life Cycle Perspective

Matteo Fasciolo(✉), Monica Lavagna, and Andrea Campioli

Politecnico di Milano, Milan 20133, Italy
matteo.fasciolo@polimi.it

Abstract. Adaptability is increasingly recognised as a fundamental requirement for sustainability and circularity in the built environment, yet its environmental implications remain largely unexplored within standard assessment practices. Contemporary buildings are often conceived as rigid, monofunctional systems, leading to premature obsolescence, extensive refurbishment needs, and demolition–reconstruction cycles that generate environmental burdens. Concepts such as Adaptive Design and Circular Design demonstrate that separating long-life and short-life layers, enabling reversible configurations, and allowing spaces and technical systems to evolve can mitigate these impacts. However, adaptability is rarely addressed as a quantifiable environmental variable despite its relevance. Specifically, key determinants of adaptability, including flexibility, convertibility, expandability, and the temporal hierarchy of building layers, can reduce waste, extend component service life, and decrease the frequency and intensity of invasive interventions, while supporting long-term resource efficiency through their close relationship with circular strategies. This paper presents a critical analysis of the selected existing tools developed to evaluate the adaptability potential of buildings from an environmental perspective. The review highlights that they predominantly adopt qualitative approaches and lack quantitative environmental data. At the same time, Life Cycle Assessment (LCA) of buildings rarely integrates adaptability among the aspects considered in the modelling. These findings highlight that adaptability remains a crucial but still under-assessed dimension of sustainable building design. By identifying the methodological limitations of existing adaptability assessment tools, the study clarifies how adaptive strategies may influence environmental impacts over the building life cycle and outlines future opportunities to integrate adaptability into LCA-based environmental assessment of buildings.

Keywords: Building Adaptability · Adaptive Design · Low Impacts · Life Cycle Assessment · Circular Design

1 Introduction

Contemporary architecture faces a growing demand for adaptable construction solutions in response to the need for more sustainable, circular and resilient buildings capable of accommodating evolving functional requirements over time.

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 201–209, 2026.
https://doi.org/10.1007/978-3-032-34930-9_24

Consequently, buildings, as a central element of the built environment, are increasingly required to adapt to these changing conditions [1, 2], such as internal, external or building-specific factors [3], including shifts in function [4], socio-economic dynamics [5], population trends, and technological advances [6], which increasingly affect building longevity. This process has been further accelerated by the COVID-19 pandemic, which has significantly influenced the shift in office-space demand due to increased digitalisation and new working cultures. This change has led to a steady increase in office vacancy rates across Europe, which have climbed from 6% to 9.7% in the post-pandemic period. As highlighted by the European Commission, this stock of vacant offices represents an underutilised resource that could potentially be converted to address housing shortages, offering a more climate-friendly and resource-efficient alternative to new construction and urban sprawl [7].

Despite the increasing recognition of adaptability as a strategic design priority, buildings are generally designed and constructed as rigid, static, and monofunctional structures, limiting transformation and often favouring demolition and reconstruction over adaptation [8]. In this context, one of the main challenges for stakeholders is the inability to anticipate the range of possible scenarios, mainly due to the difficulty in predicting short- and long-term variability in relation to the risks and costs of change [9]. In response to these challenges, several tools have been developed to assess how easily a building can be modified during its life cycle, both in the case of new construction and existing buildings, focusing on its capacity to be modified with minimal demolition and material waste [10]. However, these tools are typically based on qualitative criteria and focus primarily on physical, economic, and functional variables, while rarely addressing the environmental implications of adaptability interventions, leaving a significant gap in quantifying the environmental impacts of adaptable solutions over time. This limitation is reflected in the LCA of buildings according to EN 15978:2011 [11], which does not incorporate variables related to the adaptability and transformation capacity of buildings, and LCA studies of buildings rarely incorporate this aspect. This limitation means that the potential environmental benefits of building adaptability remain largely unquantified and insufficiently documented, limiting designers and stakeholders in making decisions based on environmental data.

Institutional recognition confirms the urgency of developing scientifically sound methods to assess and compare adaptability strategies within a life cycle perspective. At the international level, the relevance of adaptability is formally acknowledged in ISO 20887:2020 [12], which explicitly addresses adaptability within a sustainability perspective, while, at the European level, the EU Level(s) framework highlights its relevance through Indicator 2.3 [13], which promotes the design of buildings able to adapt to future changes to reduce environmental impacts from premature demolition and large-scale renovation, while promoting a more comprehensive perspective and encouraging the wider application of LCA.

Against this background, this study investigates how existing adaptability assessment tools address environmental implications and whether they incorporate environmental indicators capable of supporting life cycle-based evaluation approaches.

2 Materials and Methods

The analysis presented in this paper is based on a targeted review of existing tools developed to assess the adaptability potential of buildings. Tool identification was informed by the authors' expertise and further grounded in previous comprehensive reviews conducted by Askar et al. [10] and Mlote et al. [14], which provided an overview of the main methodological approaches developed in this field.

Unlike previous reviews, which mainly examined the conceptual and methodological characteristics of these tools and their capacity to support adaptive design decisions, the present study complements the existing research by analysing these tools from an environmental perspective. Based on these studies, the present work focuses on the most relevant tools operating at the building scale, while tools addressing adaptability at the material or component scale were intentionally excluded.

In particular, the selected tools were analysed according to their objectives, application phase, methodological structure, and their ability to address the potential avoided environmental impacts associated with the implementation of adaptability strategies. In addition, their potential integration into LCA-based assessments was examined in relation to replacement and refurbishment rates, transformation scenarios, disassembly rates, reuse potential, end-of-life streams, and avoided impacts during the reference study period.

3 Results

The analysis of adaptability assessment tools reveals a significant discrepancy between the theoretical recognition of adaptability as fundamental for sustainability and its quantification through environmental metrics. Although previous research [10] identifies adaptability as a critical enabler of circular economy strategies, most of the tools analysed remain within qualitative or purely economic evaluation frameworks, lack validation methods, and do not assess the environmental impacts of implementing adaptable strategies to demonstrate their effectiveness. The following sections analyse the identified tools (Table 1) according to their role within the building process, dividing them into decision-making support tools for existing buildings, design tools for new buildings, and cross-phase tools for new and existing buildings.

3.1 Decision-Support Tools for Existing Buildings

Adaptive Reuse Potential (ARP), 2008. The ARP model [15] is a pioneering framework for ranking existing building stock by their potential for conversion, using physical, economic, functional, technological, social, and legal obsolescence criteria to estimate useful life. Although the model does not include explicit environmental criteria, as one of the earliest systematic contributions in the field, it emphasises the concept of residual value, assuming that extending the use of existing structures can contribute to more sustainable resource management. Although it does not provide a quantitative assessment of environmental impacts, from an LCA perspective, the residual life data could inform reference service life (RSL) assumptions and model realistic adaptive reuse scenarios.

IconCUR, 2012. This model [16] is a conceptual framework that supports property and facilities managers in selecting appropriate management strategies for existing assets, including reconstruction, conservation, renovation, or adaptive reuse (AR). Based on a multi-criteria decision analysis (MCDA), it maps property performance within a three-dimensional space defined by condition, utilisation, and reward. Within this framework, environmental aspects, such as carbon footprint and habitat protection, are included within the reward dimension together with financial, cultural, and community benefits. However, these aspects are assessed through weighted judgement scores rather than through quantitative environmental indicators. By integrating the LCA methodology, these qualitative management assessments could be converted into quantitative environmental weights, enabling a comparative evaluation of different asset management alternatives.

Conversion Potential Assessment Tool, 2018. Also known as the Conversion Meter (CM) [17], this tool evaluates the technical and market feasibility of repurposing vacant office buildings into residential housing through veto criteria for a rapid initial screening and gradual criteria for a detailed classification of an asset's transformation suitability. It focuses on the avoided value loss and the reduced total costs of ownership (TCO), framing life cycle thinking primarily in economic terms. However, it qualitatively frames AR as a strategy to prevent material consumption and "waste of resources" associated with premature demolition. In this regard, CM's technical feasibility criteria can inform the definition of functional transformation scenarios and support assumptions on material retention, replacement needs, and refurbishment intensity within an LCA-based methodology.

3.2 Design-Phase Tools for New Buildings

Adaptable Buildings Design (ABD) Framework, 2010. This framework [18] assesses building adaptability by identifying uncertainties in market demand and technical developments, integrating flexibility options across spatial, structural, and service systems. It applies Real Options Analysis (ROA) and Monte Carlo simulation to show how adaptability can respond to future market and technical changes, although its primary focus remains on financial metrics such as Expected Net Present Value (ENPV). Environmental benefits are considered only indirectly, through extending the building's lifespan and the reduction of the frequency of major interventions and avoiding the waste of resources associated with premature demolition. In addition, the framework aligns with a life cycle planning perspective, simulating how initial construction and subsequent incremental adaptations can be managed to achieve the maximum value of a project. Accordingly, it would be valuable to associate these incremental adaptations with the assessment of avoided environmental impact through reduced renovation cycles, allowing designers to treat adaptability as a strategic reserve for long-term resource efficiency.

AdaptSTAR Model, 2013. This model [19] aims to support adaptability, from the conceptual design stage, through the assessment of the AR potential of future buildings. Through a "star rating" methodology, it evaluates physical, economic, functional, technological, social, legal, and political criteria. Environmental aspects are explicitly included

through criteria such as energy ratings, solar access, and ecological footprint measures. Despite this inclusion, the approach considers lifecycle-related benefits based on best practice design in a qualitative way, lacking the empirical data necessary to measure an asset's actual environmental footprint over time. Therefore, a significant opportunity lies in linking AdaptSTAR's design criteria to predictive material flow models, providing an evidence-based demonstration of how specific strategies, such as Design for Disassembly (DfD), lead to a measurable reduction in material flows and environmental pressure across multiple use cycles.

CIRLAB, 2025. This model [20] is a multi-criteria assessment framework designed specifically for the building sector to bridge the gap between circularity strategies and quantitative environmental performance. Based on Brand's concept of "shearing layers" [21], it assesses four functional building layers, namely Structure, Skin, Space Plan, and Services, considering their different lifetimes and life cycles. Unlike models that consider circularity as a standalone qualitative attribute, CIRLAB uniquely focuses on the environmental dimension, integrating circularity directly with two LCA indicators: Embodied Carbon (EC) and Embodied Energy (EE). This integrated approach ensures that benefits gained from applying circular strategies, such as adaptability or disassembly, are balanced with long-term environmental sustainability, recognising that increased circularity does not automatically lead to a lower environmental impact.

3.3 Cross-Phase Tools for New and Existing Buildings

FLEX 4.0, 2016. This instrument [22], based on the support and infill theory of Habraken [23] and the shearing layers concept by Brand [21], evaluates a building's adaptive capacity across five different life cycle layers: Site, Structure, Skin, Services, and Space Plan. It employs 44 flexibility key performance indicators to measure the ability of the building to respond to changing market demands and user requirements. Although it does not include explicit environmental quantification, its KPI-based structure provides a robust pathway for integration with LCA. Specifically, the adaptability scores for each layer could be used as weighted parameters to refine the estimated service life of components in environmental models. This integration would allow for the translation of qualitative adaptive capacity into measurable environmental outcomes, justifying the environmental value of flexibility in reducing the frequency of major renovation or demolition events.

The SAGA Method, 2019. The Spatial Assessment of Generality and Adaptability (SAGA) [24] method uses graph theory as a mathematical proxy to evaluate the total number of functional organisations a plan layout can support, maximising the functional lifespan of built assets while minimising the need for physical interventions. These spatial data provide a significant starting point, suggesting how geometric versatility can prevent premature building disposal at end-of-life. While this method has been developed with environmental sustainability and waste reduction as primary motivations, the tool does not incorporate explicit ecological indicators within its operational variables.

Table 1. Comparative overview of adaptability assessment tools.

Tool	Application context	Quantitative environmental indicator	Adaptability aspects assessed	Assessment methodology
ARP	Existing building	No	Reuse Potential	Quantitative index
iconCUR	Existing building	Partial	Functional flexibility	Qualitative MCDA
CM	Existing building	No	Conversion feasibility	Semi-quantitative scoring
ABD	New building	No	Spatial/structural flexibility	Real option modelling
AdaptSTAR	New building	No	Adaptive Reuse potential	Weighted checklist
CIRLAB	New building	Yes	Circular adaptability	LCA-based assessment
FLEX 4.0	Both	No	General adaptability	KPI scoring
SAGA	Both	No	Spatial adaptability	Graph-based metrics

4 Discussion

The analysis of existing adaptability assessment tools highlights a clear methodological gap between the recognition of adaptability as a sustainability and circularity strategy and its quantification through environmental indicators. Most of these tools assess *how* to make a building adaptable, including spatial flexibility, functional convertibility and technical modularity, but they rarely demonstrate *how much* these adaptability strategies can effectively reduce environmental impacts over time. In addition, when included, environmental aspects are generally treated using qualitative scores or partial indicators, which are not fully compatible with standardised LCA-based methodologies. Consequently, these tools provide limited support for evaluating the actual environmental benefits of adaptable design strategies or identifying the most effective strategy in terms of whole life cycle impact reduction.

A further methodological challenge concerns the *trade-offs* associated with the implementation of adaptable design strategies. Adaptability may require a higher initial material investment, such as oversized structural elements, redundant service shafts, modular partition systems, or other technical measures, potentially increasing initial embodied carbon emissions [13, 20]. At the same time, these strategies may generate long-term benefits, including fewer invasive interventions, avoiding demolition and reconstruction, the consequent reduction of material waste, and the extension of the service life of building components through easier adaptation to changing functional requirements. An environmental cost-benefit analysis can support the assessment of

the environmental effectiveness of adaptability and circularity strategies, avoiding *burden shifting*. Given this complexity, without a framework that integrates multiple life cycles and post-use scenarios, it is difficult to determine the *break-even point* at which adaptability becomes environmentally preferable to conventional construction.

Operationally, adaptability can be incorporated into LCA not as an additional impact category, but as a set of modelling parameters affecting the timing, frequency and intensity of future interventions (Table 2). In this perspective, layer-based adaptability indicators can inform the RSL of components and the expected recurrence of maintenance, repair, replacement and refurbishment processes, corresponding to modules B2–B5. These assumptions can also be combined with convertibility and spatial flexibility to define alternative transformation scenarios over the reference study period, such as conventional refurbishment, adaptive reconfiguration, or demolition and reconstruction. In parallel, reversibility and design-for-disassembly criteria can support the definition of disassembly losses, reuse rates, residual service life and end-of-life flows, affecting modules B5, C1–C4 and, where appropriate, module D. Finally, the additional material investment required by adaptive strategies should be modelled in A1–A5 and compared with the avoided or reduced impacts generated during later transformation cycles. This would allow the identification of break-even conditions under which adaptability becomes environmentally preferable to conventional design.

Table 2. Potential integration of adaptability tools within an LCA-based methodology.

Tool	Key Modelling Parameter	Modules	LCA modelling implication
ARP/iconCUR	Reference Service Life	B4, B5	Replacement and refurbishment timing
CM/SAGA	Transformation scenario	B5, C1-C4, D	Reuse, adaptation, or demolition scenarios
ABD	Future adaptation uncertainty	B2-B5	Timing of future intervention events
AdaptSTAR	Disassembly/reuse potential	C3, C4, D	End-of-life material flow assumptions
CIRLAB/FLEX 4.0	Layer-based service life	A1-A5, B4, B5	Layer-specific replacement/refurbishment cycles

5 Conclusion and Future Developments

The analysis of existing adaptability assessment tools highlights that adaptability remains an under-quantified but potentially crucial driver of environmental sustainability in the built environment. While current assessment approaches effectively identify the characteristics that enable adaptable buildings, they rarely quantify the environmental implications associated with these strategies over the building life cycle.

The findings highlight the need to move beyond qualitative adaptability assessments towards methodologies capable of translating adaptive capacity into measurable environmental indicators. In particular, integrating adaptability parameters within the LCA methodology would enable the evaluation of avoided environmental impacts associated with extended building lifetimes and improved resource efficiency. Among the analysed tools, CIRLAB [20] represents a crucial advancement, as it integrates circular strategies with quantitative environmental metrics such as Embodied Carbon (EC) and Embodied Energy (EE). The model demonstrates that it is possible to transform adaptability from a theoretical concept to a measurable variable, although its integration within life cycle–based methodology remains partial.

In this perspective, adaptability should no longer be considered exclusively as a design attribute but as a quantifiable parameter capable of supporting environmentally informed decision-making and contributing to the transition towards a more circular, resilient and resource-efficient built environment. Future research should therefore focus on developing operational approaches capable of linking adaptability indicators with life cycle-based environmental metrics, enabling the systematic evaluation of adaptability strategies within building sustainability assessment frameworks.

Abstract. The European Union's (EU) climate neutrality targets and renovation-focused policy initiatives highlight the urgent need to reduce embodied carbon in the existing building stock. While circular renovation strategies applied in adaptive reuse projects are increasingly promoted, limited quantitative evidence demonstrates their performance under regulation-aligned assessment frameworks. This study addresses this gap by providing empirical evidence from a major adaptive reuse project in Sweden, involving the conversion of an academic building to office facilities. To evaluate the environmental performance of renovation strategies, two scenarios were defined: a linear scenario assuming full material replacement and a circular scenario incorporating reuse, upgrading, and selective new procurement of building components. Embodied carbon impacts were assessed using two parallel approaches: Sweden's national climate declaration-based model and a product-specific Environmental Product Declaration (EPD)-based model. Both assessments were conducted within life-cycle modules A1–A5, representing material production and construction stages, under identical system boundaries. Results show that the circular renovation scenario reduced embodied carbon by 31% using the climate declaration model and by 39% using EPD-based model. Interior components demonstrated greater reuse potential, while envelope elements were more constrained by technical and regulatory performance requirements. By delivering regulation-aligned, building-scale quantitative evidence, the study positions major renovation as a significant decarbonization pathway. The structured assessment methodology presented in this study can support future renovation projects and policy frameworks aiming to integrate embodied carbon reduction into building regulations and climate strategies.

1 Introduction

Buildings account for more than 30% of the EU's environmental footprint, approximately one-third of material consumption, 42% of energy use, and 35% of greenhouse gas (GHG) emissions [1]. In response to the climate crisis, the EU has committed to achieving climate neutrality by 2050 [2], while Sweden has adopted a legally binding net-zero GHG target for 2045 [3]. Achieving these goals requires decarbonizing the existing building stock as almost half of Europe's buildings are over 50 years old and energy inefficient. To support this, the EU's Renovation Wave promotes accelerated and deep renovation of old buildings to meet climate objectives [4].

Adaptive reuse refers to the process of repurposing existing buildings for new functions while preserving much of their original structure and materials. It is increasingly recognized as an alternative to conventional linear renovation [5, 6]. While linear construction typically follows a sequence of extraction, production, use, and disposal, adaptive reuse emphasizes circular strategies. In this context, circular renovation prioritizes the retention, upgrading, and reuse of existing building components, along with the integration of recycled materials, thereby reducing the demand for new resource production [7]. Because material manufacturing typically dominates embodied carbon emissions, circular renovation is widely regarded as a key mitigation pathway [6, 8]. Empirical studies show that retaining structural systems can substantially reduce embodied carbon compared to demolition and new construction [5, 6, 8]. However, recent systematic reviews show that most of the circular construction research focuses on isolated material strategies and recycling technologies, while holistic building-scale renovation assessments remain limited [7, 9]. Furthermore, embodied carbon results are sensitive to data source selection, with documented differences between generic database factors and product-specific EPDs [10, 11].

Despite growing research and policy attention, limited quantified evidence demonstrates how major renovation projects contribute to decarbonization under existing regulatory assessment frameworks. In Sweden, climate declaration requirements apply to new buildings, while substantial renovations are not yet systematically included [12]. This creates a gap between climate policy ambition and measurable implementation. This study aims to provide regulation-aligned empirical evidence from a major adaptive reuse project by comparing linear and circular renovation scenarios using both standardized climate declaration factors and product-specific EPD data. By providing quantified, building-scale evidence, this study demonstrates how embodied carbon reductions from renovation can support Swedish and EU climate neutrality pathways.

1.1 Case Study

The case study concerns the southern academic building at Mälardalen University, known as the S-Building, situated in Västerås, Sweden. The three-storey building was constructed in 1994, with a total gross floor area of 6,778 m^2. In 2024, a major renovation was initiated, scheduled for completion in 2026. Rather than pursuing a conventional renovation approach, the project employed an adaptive reuse strategy, converting the academic building into office facilities. The conversion required significant spatial and

functional reconfiguration. The original classroom-based layout was adapted to accommodate office functions, resulting in internal modifications and selective upgrading of building components to meet contemporary technical and performance requirements.

The renovation was undertaken with high environmental ambition. The project aimed to achieve a 25% reduction in embodied carbon compared to a conventional baseline scenario and to obtain highest grade (gold) under Miljöbyggnad Ombyggnad, a Swedish environmental certification system [13]. The certification framework includes requirements for circular material flows, including thresholds for preservation, reuse, and recycled content in newly added materials. To guide implementation, the project followed a four-step material strategy: preservation of existing elements, upgrading of retained components, internal reuse, and introduction of new products with recycled or low-impact materials only where necessary. This implementation context forms the basis for the methodological approach described in the following section.

2 Methodology

The overall research design is illustrated in Fig. 1. The study follows a structured quantitative workflow comprising data collection, material inventory development, climate impact modelling, and scenario-based comparison. Two parallel calculation approaches: (i) Swedish national climate declaration model and (ii) Specific EPD-based model, were applied to assess embodied carbon performance. The final stage compares a linear renovation baseline with a circular renovation scenario to quantify potential climate savings expressed as total Global Warming Potential (GWP).

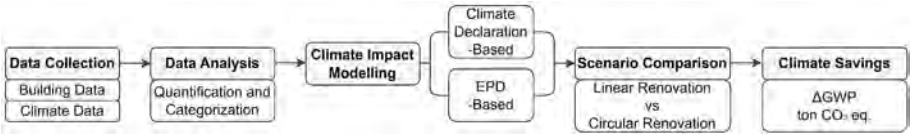

Fig. 1. Research design and quantitative workflow for embodied carbon assessment.

The scope of the analysis is defined by building components affected by adaptive reuse intervention. Figure 2 shows an exemplary section of the adaptation of existing facilities. The conversion from classrooms to office use required substantial spatial and functional reconfiguration, resulting in internal modifications and selective upgrading of building elements. Internal partitions and doors were dismantled to accommodate new layouts, while selected external components, including windows and glass façade elements, were replaced to meet updated technical, fire safety, acoustic, and energy performance requirements. The assessment includes primary construction materials directly influenced by these spatial and technical adjustments. To represent material flows, building components were classified into four categories: (i) preserved components retained without modification, (ii) dismantled components for spatial reconfiguration or technical non-compliance, (iii) upgraded and reused components after necessary interventions (e.g., surface treatment and window glazing replacement while preserving frames), and

(iv) new materials installed to fulfil functional and regulatory requirements. Building data was derived from existing and updated architectural and construction drawings, together with documentation of new materials including technical specifications and product information. Material quantities were extracted from the drawings and compiled into a structured inventory using consistent measurement units.

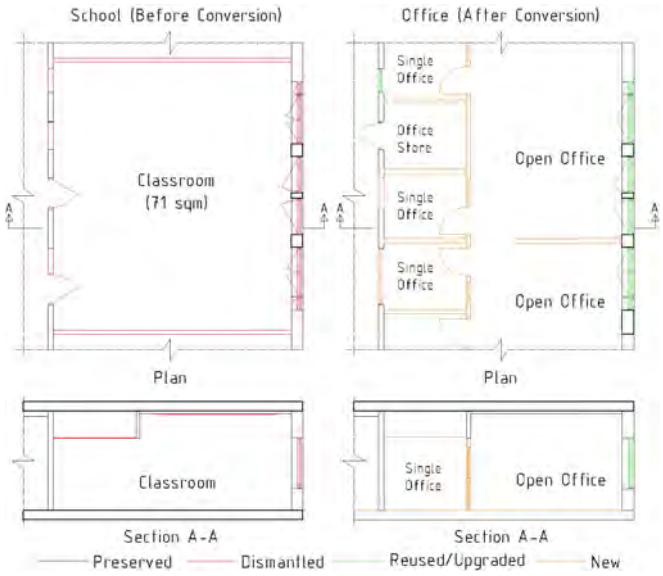

Fig. 2. Conversion of internal layout from academic to office facilities with material flow.

Climate impact modelling was conducted using two parallel approaches. The first model followed the Swedish climate declaration methodology and applied emission factors from the national climate database, supplemented where necessary by the Finnish SYKE database [14, 15]. The second model applied product-specific EPD data for new materials, reflecting manufacturer-specific environmental performance. A total of 17 purchased product-specific EPDs were used, all third-party verified, valid at the time of assessment, and issued under recognized program operators. Both models used the same quantified material inventory to ensure scenario comparability. Sources were documented material-by-material to ensure transparency and reproducibility. During the calculations, factors were normalized per component area (m^2) using appropriate conversion factors, enabling aggregation of embodied carbon at building level, expressed as total GWP (ton CO_2 eq.).

The system boundary for embodied carbon assessment was defined in accordance with EN 15978:2011 [16]. For new materials, the assessment included production and construction stages (A1–A5). For reused or upgraded components, the deconstruction stage (C1) associated with dismantling was included, together with A1–A5 for materials requiring upgrading or partial replacement. Within this boundary, the linear renovation scenario assumes complete replacement of dismantled and upgraded components with newly manufactured materials fulfilling the same technical and functional requirements,

without reuse or material recovery. In contrast, the circular renovation scenario incorporates reused and upgraded components supplemented by selective new procurement. Preserved components retained in situ were excluded from both scenarios, as no additional production or construction processes were associated with them. Climate savings were calculated as the difference in total GWP between the linear renovation baseline and the circular renovation scenario.

3 Results and Discussion

The results present the quantified material flows and associated climate impacts of the renovation, providing the basis for evaluating the effectiveness of circular strategies implemented in the project. Table 1 presents the material inventory of the circular renovation, categorized as preserved, dismantled, reused/upgraded, and new materials.

Table 1. Material inventory categorized by intervention type, expressed in m^2.

	Component	Material	Preserved	Dismantled	Reused/Upgraded	New
External	Window	Wooden	0	946	887	59
	Glass Façade	Wooden	0	410	0	410
	Door	Steel	30	33	0	33
Internal	Flooring	Textile	0	0	0	3101
		Ceramic	39	0	0	48
		Vinyl	29	0	0	36
		Linoleum	1508	0	0	810
	Ceiling	Gypsum Panel	3701	2939	2710	386
	Partition & Door	Wooden Door	69	167	79	92
		Steel Door	17	8	0	8
		Glass Partition	391	283	209	285
		Gypsum Panel	5590	5077	1751	3240

Figure 3 illustrates the proportional distribution across component groups. The results reveal a clear distinction between internally driven spatial transformation and externally driven technical upgrading. Internal modifications were primarily motivated by the conversion from classroom layout to office configuration, requiring reorganization of partitions, doors, and ceilings. Despite this spatial restructuring, internal systems retained substantial circular potential: ceilings achieved 54% preservation and 40%

reuse/upgrading, while internal partitions and doors retained 52% of material with an additional 17% upgraded. Flooring systems showed lower reuse feasibility, with 72% being replaced due to aesthetic and acoustic performance requirements associated with office standards.

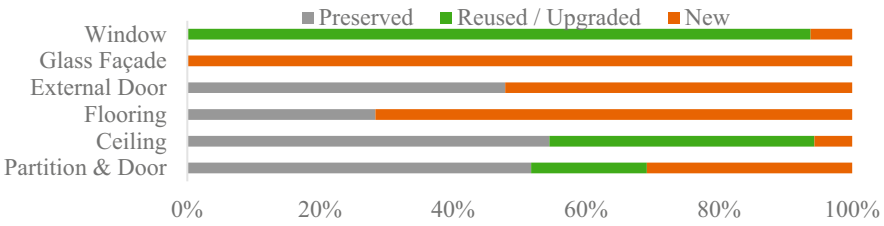

Fig. 3. Percentage distribution of implemented circularity by material quantity (m^2).

External components, by contrast, were governed primarily by technical and regulatory performance thresholds, including acoustic requirements, durability, and operational energy efficiency. Window systems demonstrated this dynamic: although 94% of the window area was upgraded and reused, glazing performance was improved from double to triple pane to meet energy standards. The glass façade exhibited no reuse potential and was fully replaced to comply with updated acoustic requirements, as mentioned in the project documents. The comparison indicates that circular feasibility is more strongly constrained by technical performance requirements than by spatial reconfiguration. Interior layout changes do not necessarily prevent material reuse, as many internal components can be preserved, relocated, or upgraded during renovation. In contrast, external components are more constrained by technical performance requirements such as energy efficiency, durability, and acoustic standards. However, reuse feasibility remains case-specific and depends on the objectives of the building adaptation. Different conversion goals can require different technical upgrades that affect how much material can be reused. The combined climate impact results are presented in Fig. 4. Under the climate declaration model, total embodied carbon amounted to 302 ton CO_2 eq. for the linear renovation scenario and 208 ton CO_2 eq. for the circular renovation scenario, corresponding to a reduction of 31%. Under the EPD-based model, emissions were 161 ton CO_2 eq. for linear renovation and 98 ton CO_2 eq. for circular renovation, yielding a reduction of 39%.

These results demonstrate that implemented circular strategies, combined with selective upgrading and targeted material replacement, can substantially reduce embodied carbon in renovation projects. This finding is consistent with previous building-scale adaptive reuse assessments. Gursel et al. [6] reported reductions of 34–48% when comparing adaptive reuse with new construction, while other case studies similarly show that retaining existing structural systems and materials significantly lowers embodied carbon impacts [5]. Although the scope of the renovation varies across studies, these findings confirm that circular strategies can deliver substantial climate benefits. The two calculation approaches provide important methodological and regulatory insight. The climate declaration model reflects standardized national emission factors, ensuring comparability across projects, whereas the EPD model captures product specific environmental

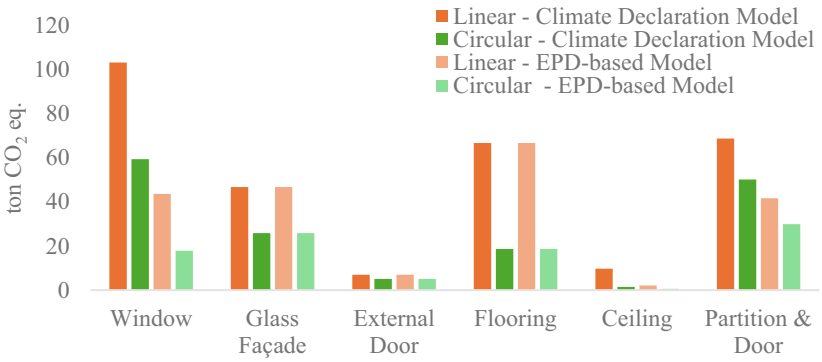

Fig. 4. Embodied carbon comparison between linear and circular renovation scenarios.

performance. The lower embodied carbon obtained in the EPD model primarily results from the use of manufacturer specific data for products with optimized production processes, recycled content, and lower carbon material compositions. In contrast, the climate declaration database applies conservative generic values intended for regulatory comparability. Consequently, the EPD model captures procurement driven climate reductions that are not fully visible in standardized datasets. This highlights that strategic material selection plays a crucial role in maximizing climate savings. Furthermore, the results expose a regulatory gap. Current Swedish climate declaration requirements apply to new buildings, while major renovation projects are not formally included yet. Given the scale of the old building stock across Europe and indicated 31% climate savings, systematic integration of circular renovation into national climate declaration frameworks could contribute meaningfully to achieving long-term climate neutrality targets. Supporting this statement, Sweden is planning to bring major renovation projects under climate declaration from 2027 [17].

4 Conclusion

This study provides empirical, implementation-based evidence on the embodied carbon implications of circular strategies in a building adaptation project. By quantifying material flows and assessed climate performance under Swedish climate declaration model and specific EPD-based model, the results demonstrate that circular renovation can reduce embodied carbon by 31% and 39%, respectively, compared to conventional linear renovation. These reductions were achieved through preservation, reuse, upgrading, and selective replacement combined with strategic low-carbon material procurement. The findings highlight the significant potential of major renovation projects, which can deliver substantial embodied carbon reductions through circular material strategies. Despite this potential, such projects are not yet systematically included in national climate declaration frameworks. Integrating major renovation into these frameworks could improve embodied carbon transparency and support progress toward Swedish and EU climate neutrality targets. However, the study is subject to several limitations, including climate data

availability, estimation of material quantities from construction drawings, and restriction to life cycle modules A1–A5. The transferability of the quantified climate savings depends on project-specific factors such as functional & technical requirements, regulatory constraints, level of renovation and availability of reusable components, although the methodological framework itself could be applicable to other renovation contexts. Future research should integrate comprehensive life cycle cost and environmental assessments to evaluate economic–environmental trade-offs and to support evidence-based development of renovation-focused climate policies.

Abstract. Reusing and recycling in construction reduce the need for new raw resources, minimize greenhouse gas emissions and decrease material waste. Studies show that reclaimed concrete elements can reduce CO_2, equivalent emissions by up to 75% compared with new concrete construction and can lower upfront greenhouse gas emissions by about 80% in floor system designs. Following the principles of reuse, recycling, and sustainable structural design, a case study of a student dormitory is presented in the paper. The process of circular design and selecting final solutions for the global environment is shown to be a feasible target.

More specifically, the dormitory is constructed by materials taken from a disassembled old industrial building. The new facilities consist of four buildings, two of which are constructed from structural steel and two of reinforced concrete, aiming to optimize the available materials. Through this case study, a reuse/recycling rate of up to 49% has been achieved, while the benefits in terms of cost efficiency and material savings are clearly demonstrated.

Keywords: Circular Design · Reuse and recycle · Disassembly · Case Study

1 Introduction

The infrastructure sector remains one of the largest consumers of raw materials and a major contributor to construction and demolition waste, highlighting the urgent need for circular design strategies and systematic reuse of building materials in architectural design and urban development. In this context, the industry must adopt more sustainable practices capable of reducing its carbon footprint and supporting the transition towards a circular economy. One approach is the application of the 3Rs waste management hierarchy (Reduce–Reuse–Recycle) in structural engineering, which can promote innovative design approaches and structural systems that minimize environmental impacts while improving material efficiency [1–4].

In recent years, significant efforts have been made in Europe and worldwide to establish design rules and recommendations for the recycling and reuse of materials in construction. The Waste Framework Directive 2008/98/EC [5] defines the waste hierarchy, prioritizing prevention, reuse, and recycling, and sets a target requiring that at least 70% of non-hazardous construction and demolition waste be recovered. For concrete

structures, EN 206 [6] and EN 12620 [7] permit the use of recycled aggregates under specific quality requirements, while in steel construction, EN 1993–1 [8] and CEN/TS 1090–201 [9] provide guidance for the design and assessment of reused structural steel components. These regulations and standards collectively support the safe integration of recycled materials and reused structural elements in construction, while maintaining structural reliability and environmental performance.

Within this framework, the present study investigates how circular design strategies and reusing of construction materials can be incorporated into the development of student housing. The design proposal responds to the increasing demand for student accommodation in large metropolitan areas and explores the role of reclaimed materials in contemporary architectural design. In the examined scenario, an existing industrial building is assumed to be disassembled, allowing its structural steel components and concrete aggregates to be reused in the new construction.

This case study highlights the benefits of material reuse in terms of environmental performance and cost efficiency, while contributing to the broader discussion on circular construction practices, adaptive reuse, and sustainable campus development.

This project was carried out in the context of the national student competition "ecoDomus 2025", organized by Democritus University of Thrace.

2 Reusable Materials

As mentioned in Sect. 1, in the present case study an old industrial building is dismantled, and its materials and structural components are subsequently reused for the construction of a new infrastructure. Table 1 summarizes the available quantities of the materials that can be reused.

Table 1. Available Materials for Reuse.

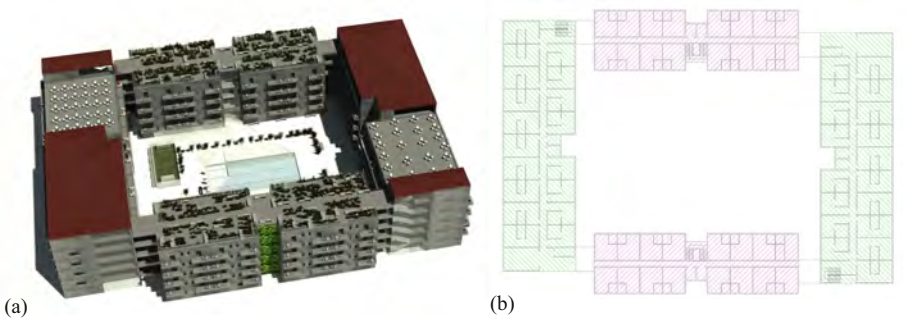
Materials	Quantities	Cross-sections
Concrete	1,322.14 m^3	–
Steel members	2,210 pieces	HEA180, IPE120, SHS70x5, SHS90x5 & SHS100x5
Steel panels	1,010 pieces	–
Glasses	85 pieces	1.5 m × 3.0 m
Ceramics	5,54.72 m^3	–

The reuse of structural steel elements presents significant environmental benefits, as it reduces the need for both new extraction activities and production of primary raw materials [4]. The process of dismantling the existing metal components rends them easily adaptable to the requirements of the new construction; modification of bolted holes, cutting of sections or welding them facilitate their compliance with the required dimensional and structural specifications of the new structure. In addition, if large spans are required, the recommendations of Ref. [10] may be applied to design the connections between the elements.

Although concrete cannot be reused in its original form in the new structure – except in the case of prefabricated concrete panels – its aggregates can be reused if they meet specific technical requirements. The reuse of existing aggregates significantly reduces construction waste and supports the objectives of the European Green Deal, while also aligning with the principles of sustainable financing in the construction sector [11]. In addition to the reuse of primary construction materials, further benefits in terms of cost reduction and waste minimization can be achieved through the reuse and recycling of secondary materials, such as glass and ceramics. Pollutant emissions from glass recycling are relatively lower than those from steel and concrete, saving up to 30% of energy compared to the production of primary glass, thereby enhancing the environmental efficiency of construction projects. The reuse of the glass panels is permitted when they comply with the requirements of the new project, while ceramic materials can be reused after processing to remove adhered residues of concrete, mortars, and roughcasts, which prevent their direct use. However, according to EN 12620, the fragments can be used as recycled aggregates in low-demand applications [7].

Obviously, material and components that cannot be directly integrated into the new structure can be either recycled or sold, allowing the generated revenue to offset the procurement cost of additional materials.

The implementation of the above practice can be supported by the "material passport" methodology, which involves the systematic documentation of the origin, technical characteristics, and suitability of reusable construction materials. In addition to improving traceability, this approach facilitates the structural assessment and certification process of reclaimed elements through the availability of documented inspection, testing, and maintenance records. Consequently, the reliability and compliance of reused materials with current structural safety requirements and Eurocode provisions [5–11] can be more effectively evaluated before their reintegration into new construction projects. This methodology therefore strengthens both the application of circular economy principles and the safe reuse of structural components in the construction sector [12].



3 Description of the Case Study

3.1 Architectural and Functional Details

A 3D view of the studied residential complex (dormitories) is illustrated in Fig. 1a. The proposed complex includes single- and double-occupancy rooms, as well as fully accessible accommodation units for people with disabilities (PwD), responding to the growing demand for student housing. The architectural composition is organized into four distinct four-story wings that are interconnected through short-span bridges; two constructed of reinforced concrete and two of structural steel and concrete slabs, as distinguished in Fig. 1b. The reason for using different materials in the various substructures aims of using all the available resources resulting from the disassembly of the industrial building, which prevents the development of four structures of the same structural system. The concrete wings have dimensions of 44.40 m × 13.20 m × 16.50 m, while the steel ones measure 54.37 m × 15.80 m × 19.50 m.

In the steel-framed building, a repetitive spatial configuration is applied across the first four floors. Each floor comprises 8 single residential units designed for people with

disabilities (PwD), each with a floor area of 28.32 m^2 and a private balcony of 7.5 m^2. Additionally, 10 double residential units of 36.48 m^2 are provided per floor, also featuring private balconies of 7.5 m^2 and an ergonomic layout designed to comfortably accommodate two students. The reinforced concrete building consists of 15 single residential units per floor across the first four levels. Each unit provides a net floor area of 26.92 m^2 and includes a private balcony of 5.85 m^2, offering a functional and comfortable living environment.

(a) (b)

Fig. 1. (a) Perspective view of the dormitories, (b) Floor plan view where reinforced concrete is in purple and composite in green.

The independent housing units lack integrated kitchens, with shared cooking and dining areas promoting collective use of infrastructure and reducing resource consumption. In addition, the development provides shared facilities supporting academic and social activities, including a dining area, reading room, gymnasium, multi-purpose hall, student association spaces, communal recreational areas, a commercial space for lease, and supporting technical and operational facilities. Furthermore, and in line to the sustainability principles, the project incorporates an accessible green roof, a glazing system with movable shading louvers, photovoltaic panels and solar water heaters, and high-efficiency appliances to improve overall energy management.

3.2 Site and Urban Context

The proposed complex is planned to be located within the Ancient Olive Grove Campus of the University of West Attica, in the Municipality of Egaleo, Western Attica. The available site covers approximately 100,000 m^2 with a floor area ratio (FAR) of 0.5, allowing the development of student housing in close proximity to the university's educational facilities. The spatial configuration of the site and its relationship with the surrounding campus infrastructure are shown in Fig. 2a and b. This arrangement enhances the functional integration between student accommodation and academic facilities, supporting the creation of a cohesive campus environment.

The intervention follows international brownfield redevelopment practices, transforming underutilized areas into active urban environments that combine educational, residential, and cultural functions. Comparable examples include the EUREF Campus

in Berlin and the NDSM Wharf in Amsterdam. In addition, the proposal aligns with contemporary sustainable planning principles and the concept of the "15-min city", which promotes accessibility, mixed land uses, and reduced dependence on long-distance commuting. Any tree removed from the site during development will be carefully transplanted elsewhere in the project area or in a nearby designated green space to ensure its preservation.

3.3 Structural Design

This study presents a preliminary design of the sub-structures considering permanent and variable loads, as well as wind and seismic actions. The design of reinforced concrete elements is carried out according to EN 1992-1-1 [13], while steel structural elements are designed following the provisions of EN 1993-1-1 [8]. The aim of this predesign is to ensure the adequacy of the materials available for reuse, estimate the additional materials that need to be procured, and provide an initial cost assessment. To demonstrate the benefits of the circular design, the methodology establishes a comparative framework between two distinct scenarios: a baseline Conventional Scenario (100% new materials) and the proposed Circular Scenario.

3.4 Reuse of Construction Materials

The distribution of the available recycled concrete is intending first to comply with the 30% limit prescribed by EN 206, according to which only this proportion of the concrete in the new structure may consist of reused material. Therefore, a total volume of 772.73 m^3 is allocated in the two reinforced concrete structures (representing the 30% of the concrete in the two new structures and the 58% of the available reusable concrete, see Fig. 3), while 383.51 m^3 is used for the slabs of the composite structures. The remaining quantity of 160.23 m^3, which cannot be directly incorporated in the structural

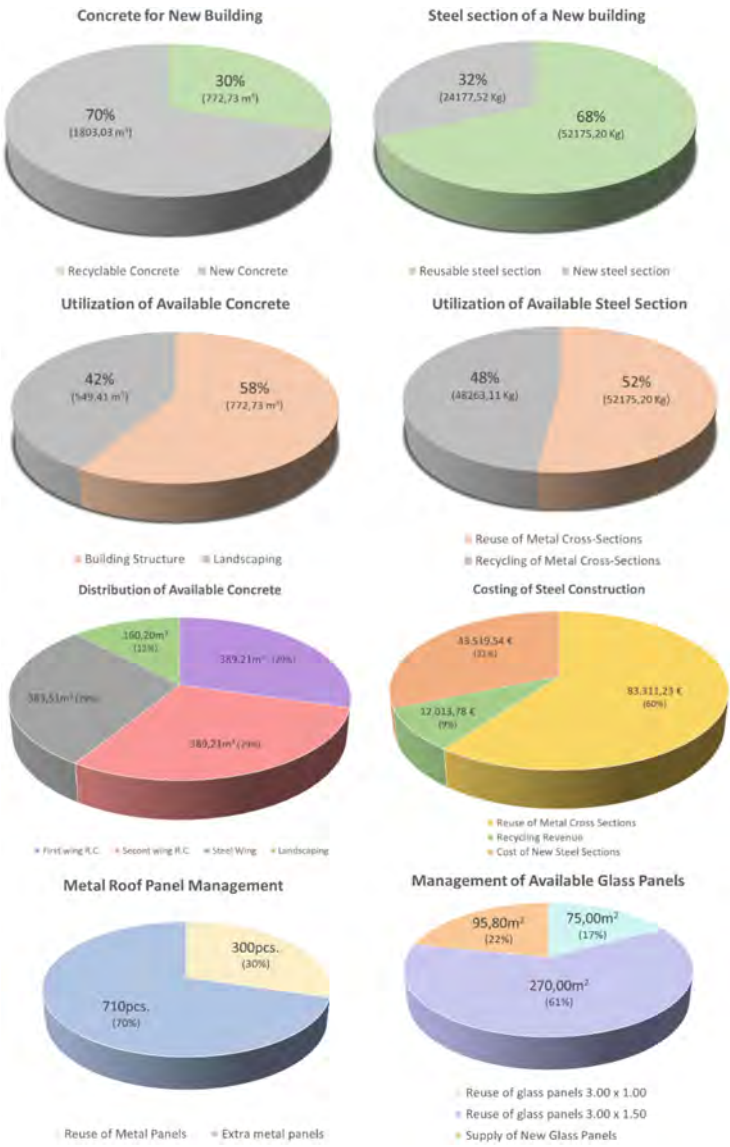

Fig. 3. Distribution of new and recycled materials.

frames, is intended for complementary and secondary construction applications, thereby contributing to the most efficient use of the available resources and eliminating waste.

The total weight of steel required for the steel-framed building is approximately 77,135.86 kg. From the recycling of the existing industrial building, a total of 102,489.51 kg of steel sections was reclaimed, of which 52,175.20 kg – representing 68% of the total required steel and 52% of the available one – are suitable for reuse within the new construction, based on the project's architectural and structural requirements

(HEA 180, IPE 120, SHS 100 × 5, SHS 120 × 5, SHS 90 × 5). To offset the procurement cost of the additional steel sections required (i.e. 48% of the available material, see Fig. 3), it is proposed that the economic value of the surplus and non-reusable sections be realizes through their sale. This is also clearly quantified in Fig. 3, where 60% of the total cost for the steel-framed building is covered by reusing existing components, while from the remaining 40%, a gain of almost 10% is achieved through the recycling of waste material.

It can be seen from Fig. 3, all available metal and glass panels have been reused in the new construction, representing 30% of the total metal panels and 78% of the total glass panels of the new infrastructure, respectively. This further enhances resource efficiency while simultaneously minimize environmental impacts and costs.

Table 2. CO_2 emission per unit, according to EU generic factors.

Materials	Units		Factors [$kgCO_2^e$/un]	Emission [tons CO_2^e]	Percent [%]
Concrete [m^3]	Recyclable	772,73	260,00	200,91	62,86
	New	1.803,30	300,00	540,99	
Steel [kg]	Reusable	52175,20	1,61	84,00	52,99
	Recyclable	48.263,11	0,82	39,58	
	New	24.177,52	1,64	39,65	
Glass [m^2]	Reusable	345,00	13,56	4,68	61,73
	New	95,80	18,69	1,79	

Additionally, a preliminary calculation of the CO_2 emissions has been performed and summarized in Table 2, where material quantities are multiplied by their respective emission factors obtained through Ref. [14]. This assessment highlights that the total carbon footprint is heavily driven by absolute material masses rather than individual coefficients alone. Consequently, since new concrete quantities are more than double of the reused one, concrete emissions inevitably dominate the overall structural footprint, vastly outweighing the contributions of structural steel and glass panels. The last column of Table 2 demonstrates also the percentage reduction in CO_2 emissions achieved by using recyclable materials instead of new ones.

4 Conclusions

The paper investigates the reuse and recycle of materials in construction and demonstrated the benefits of circular design through a case study. More precisely, the design of a student dormitory is presenting, aiming to utilize all available materials resulting from the disassembly of a former industrial building. The study shows that integrating recycled construction materials within sustainable design strategies can improve environmental performance while supporting economic and urban regeneration goals. The design of the studied structure reveals that:

- the use of recycled materials combine with energy-efficient systems and renewable technologies can improve both structural performance and energy efficiency;
- reusing existing materials minimize the need for new raw material and lead to lower energy consumption and fewer air pollutant emissions;
- proper design and management of the materials in the infrastructures could lead to complete elimination of construction waste (100% of available concrete was reused and 52% of the available steel members);
- secondary materials such as glass panels and ceramics could also bring benefits to the circular design process;
- considerable financial gains can be claimed for the new structure.

Abstract. Durability and resilience have become central themes in current discussions on the modernization and long-term performance of the built environment. Although both are essential to more sustainable and circular construction, they have evolved through distinct scientific pathways and continue to reflect different priorities in the assessment of building performance. Durability is generally associated with the long-term preservation of material properties, structural capacity, and energy-related performance under normal operating conditions, as reflected in frameworks such as ISO 15392, EN 15978, and national energy assessment methodologies. Resilience, by contrast, introduces a dynamic and hazard-oriented perspective, referring to the capacity of buildings to withstand, absorb, adapt to, and recover from disturbances such as earthquakes, floods, heatwaves, or energy disruptions, as reflected in performance-based seismic engineering and risk-informed design approaches. This paper presents a critical review of how durability and resilience have been defined, interpreted, and operationalized in relation to structural and energy performance. The analysis highlights the fragmentation of durability-related research, often addressed through separate energetic, environmental, or lifecycle perspectives, while resilience research has developed more strongly in connection with structural safety, climate adaptation, and recoverability. Despite their different origins, the review identifies important complementarities between the two concepts and argues that their integration is necessary for a more coherent whole-life approach to building performance. The paper also outlines emerging directions involving composite performance metrics, multicriteria assessment, and data-informed methods, which may support renovation strategies that jointly address energy efficiency, structural robustness, and climate adaptation in the existing building stock.

Keywords: durability · resilience · structural performance · energy performance · lifecycle performance

1 Introduction

The transition toward a low-carbon and resource-efficient built environment requires more integrated approaches to building performance assessment. The construction sector remains one of the most resource-intensive domains, accounting for approximately 40%

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 228–235, 2026.
https://doi.org/10.1007/978-3-032-34930-9_27

of global energy demand, up to 50% of extracted raw materials, and around 37.5% of the total waste generated in the European Union (EU) [1]. In response, European policy frameworks such as the European Green Deal [2], the Circular Economy Action Plan (CEAP) [3], and the Renovation Wave [4] increasingly emphasize the long-term improvement of the existing building stock.

Despite this policy momentum, the assessment of building performance remains fragmented in both research and practice. Durability is commonly addressed through domain-specific perspectives, including service life prediction, material degradation, hygrothermal behaviour, energy performance, or lifecycle assessment [5, 6], whereas resilience has developed mainly through risk-based frameworks focused on structural safety, climate adaptation, and post-event recovery [7]. As a result, the two concepts are often treated separately, even though both are directly related to the ability of buildings to maintain performance over time under changing conditions.

This separation is particularly relevant in the context of existing buildings, where renovation decisions must simultaneously address energy efficiency, structural reliability, service life extension, and adaptation to future risks. From a circularity perspective, this implies moving beyond short-term efficiency gains and considering the long-term preservation of building value, function, and performance while minimizing resource consumption and avoiding premature replacement or demolition [8]. In this regard, durability may be understood as the ability of a building, component, or material to maintain required performance under expected service conditions, including structural adequacy, envelope integrity, and energy-related behaviour [9]. Resilience, in turn, refers to the capacity of buildings and building systems to withstand, absorb, adapt to, and recover from disturbances such as earthquakes, floods, heatwaves, or energy supply disruptions [7]. While durability is associated with continuity of performance, resilience introduces a dynamic perspective centered on adaptive capacity and recovery.

This intersection is increasingly important in light of recent regulatory developments, including the recast Energy Performance of Buildings Directive (EPBD) [10], which reinforce the need for broader performance frameworks capable of informing renovation strategies beyond isolated technical targets. Against this background, this paper critically reviews how durability and resilience have been defined, interpreted, and operationalized in relation to structural and energy performance. The review aims to clarify their conceptual relationship, identify methodological overlaps and divergences, and discuss their integration within whole-life approaches to building performance.

The paper is based on a narrative and critical review of literature addressing durability, resilience, structural performance, energy performance and circular construction. The sources were selected to capture the conceptual evolution of these concepts and their integration within whole-life-cycle approaches. The review synthesizes key conceptual and methodological contributions in order to identify overlaps, gaps and directions for integrated assessment.

The following section examines the conceptual foundations of durability and resilience in circular construction, with emphasis on their relevance for structural and energy performance over time.

2 Conceptual Framework Analysis of Durability and Resilience in Circular Construction

In the context of reshaping the built environment, durability must be understood beyond its traditional association with material stability and service life alone [11]. In contemporary construction practice, its core meaning remains the ability of a building to maintain its essential functions, safety requirements, and technical performance throughout its intended service life [9]. This understanding is grounded in established frameworks such as ISO 15392 [12] and EN 15978 [13], which support the assessment of long-term material properties, structural capacity, and energy performance under normal operating conditions [14]. Within a circular construction perspective, however, such assessments cannot remain fragmented. They need to be integrated into a whole-life-cycle (WLC) framework structured around five interrelated dimensions: material, energetic, structural, economic, and social [5]. Rather than representing isolated metrics, these dimensions collectively support value retention, resource efficiency, and the prevention of premature obsolescence [11].

In this perspective, durability is relevant not only because it extends service life, but also because it preserves the functional and economic value of buildings through continued use, adaptability, and reduced replacement needs [15, 16]. This aspect is particularly important for existing buildings, where structural adequacy and energy-related performance must be maintained while accommodating changing regulatory, climatic, and operational demands.

Durability alone, however, is insufficient to address extreme climatic events and broader systemic disruptions. In this context, resilience has emerged as a complementary paradigm, defined as the capacity of a system to withstand shocks, maintain operational functionality under adverse conditions, and recover within an acceptable timeframe. This perspective has been advanced through performance-based seismic engineering and risk-informed design approaches [7]. At the same time, resilience literature increasingly links the concept to vulnerability, adaptive capacity, and recoverability, thereby extending its interpretation beyond resistance alone [17]. While durability addresses gradual and predictable degradation over time, resilience introduces a dynamic, hazard-oriented perspective focused on response, adaptation, and recovery [9].

An increasingly relevant component of resilience is passive survivability, namely the ability of a building to remain safe and habitable even in the absence of critical energy services [10]. Recent studies further relate this dimension to thermal resilience during heatwaves and power outages, showing that building performance should not be assessed only through operational energy savings, but also through indoor habitability under disruption [19]. This makes the intersection between durability and resilience particularly relevant in relation to structural reliability and energy performance, especially in the renovation of existing buildings.

A truly circular built environment ultimately requires stronger integration across disciplines and the development of frameworks that can support coherent decision-making in practice [9, 18]. Within such a perspective, durability and resilience should be regarded as complementary dimensions of building performance. Durability supports adaptive reuse, lifecycle optimization, and resource conservation, while resilience strengthens the ability of buildings and their users to withstand and recover from environmental

and socio-technical disturbances. Considered together, they offer a more robust basis for assessing whole-life building performance through the combined lens of circularity, structural reliability, and energy resilience [6].

3 Durability Pillars in the Circular Economy and Resilience Framework

To support the interpretation of durability within circular construction, the reviewed literature frames building performance through five interrelated pillars: material, energetic, structural, economic and social [5, 11]. Within this perspective, durability is understood as a multidimensional condition related to the long-term preservation of building performance, value retention, resource efficiency and reduced obsolescence across the building life cycle. Figure 1 illustrates the conceptual relationship between circular construction, durability, resilience, the five pillars and integrated performance outcomes.

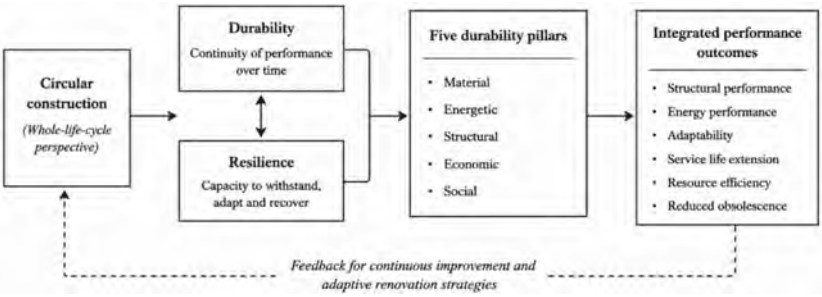

Fig. 1. Conceptual framework linking durability, resilience and whole-life-cycle building performance in circular renovation.

To clarify these relationships, Table 1 maps each durability pillar to the corresponding sustainability and circularity practices identified in the literature, while also highlighting their links to resilience-related outcomes. Although all five pillars contribute to whole-life building performance, the structural and energetic dimensions remain central to the present discussion, whereas the material, economic, and social dimensions are considered supporting factors that shape the long-term viability and wider implications of renovation strategies. A critical limitation of current approaches is that durability and resilience are often assessed through separate indicators, although their effects are interdependent in existing buildings. This fragmentation may lead to renovation strategies that improve one performance dimension while unintentionally compromising structural reliability, resource efficiency or long-term adaptability.

Table 1 further maps each durability pillar to circularity-oriented WLC practices and resilience-related outcomes.

The reviewed literature suggests that integrating these durability pillars requires a shift from fragmented design approaches toward more advanced digital and multicriteria assessment frameworks. In this regard, Building Performance Simulation (BPS) and

Table 1. Durability pillars in relation to circularity and resilience.

Durability Pillar	Circularity-oriented WLC practices	Resilience contribution
1. Material	Life Cycle Assessment (LCA) based reduction of embodied carbon [20]; use of biogenic or recyclable materials [10]; extended component lifespan to reduce raw material demand and construction waste.	Maintaining physical and mechanical integrity under aggressive environmental exposures and unpredictable climatic shocks [9].
2. Energetic	Implementation of nZEB/ZEB standards [20]; optimization of the building envelope and Technical Building Services (TBS) to reduce operational energy use over the building life cycle.	Ensuring thermal resilience, limiting overheating, and reducing reliance on active systems during energy grid disruptions.
3. Structural	Design for long-term structural integrity; functional adaptability and adaptive reuse of existing assets instead of demolition and new construction [8].	Providing robustness against extreme hazards (e.g., seismic events and extreme weather) to prevent collapse and reduce post-disaster downtime [7].
4. Economic	Life Cycle Cost (LCC) optimization; focus on long-term value creation and avoidance of premature obsolescence or replacement [11].	Ensuring financial stability by reducing the impacts of energy price volatility and post-disaster repair costs.
5. Social	Promotion of ethical, human-centred design; improved indoor environmental quality [19]; reduction of energy poverty and support for intergenerational equity [5].	Guaranteeing passive survivability, i.e., the ability of the building to remain safe and habitable for occupants during prolonged crises or heatwaves (evaluated via SET indicators).

digital twins, combined with LCA and LCC analyses, are increasingly used to support the joint evaluation of structural robustness, energy efficiency, and climate adaptation. Overall, these perspectives reinforce the need to interpret circularity and resilience as interrelated dimensions of whole-life structural and energy performance rather than as isolated design objectives [6].

4 Implications for Circular and Resilient Renovation

Building on the framework outlined in the previous section, the practical relevance of durability and resilience becomes most evident in the renovation of the existing building stock. In the European context, the main challenge is no longer limited to the construction of new high-performance buildings, but increasingly concerns the upgrading of aging and inefficient assets. A substantial share of the European building stock predates contemporary energy and structural standards: approximately 35% of EU buildings are

more than 50 years old, while nearly 75% remain energy inefficient. This aging profile reveals not only a major energy performance deficit, but also an increased vulnerability to climatic stressors and evolving performance requirements. At the same time, deep renovation rates remain critically low, at around 0.2% across the EU [4], reinforcing the need to translate broad sustainability objectives into practical and scalable renovation strategies. From a circular economy perspective, these conditions strengthen the case for shifting away from demolition-and-reconstruction models and toward adaptive reuse, service life extension, and performance upgrading of existing buildings.

Within this context, the integration of durability and resilience provides a useful interpretative basis for renovation decision-making. Considered through the five durability pillars and a whole-life-cycle perspective, renovation strategies can move beyond fragmented approaches in which structural safety, energy efficiency, material impacts, and occupant-related aspects are assessed separately. Such fragmentation is particularly problematic in existing buildings, where energy retrofit measures may affect not only thermal behaviour, but also the structural response, durability, and long-term serviceability of building components. Conversely, structural upgrading measures may influence envelope configuration, moisture behaviour, and the feasibility of energy-related interventions. Renovation strategies should therefore be assessed in terms of both trade-offs and synergies between structural reliability and energy performance over time.

One of the clearest examples is the tension between winter energy optimization and summer thermal performance. Although highly insulated envelopes may support compliance with nZEB/ZEB targets under the EPBD framework [10], such measures may also increase overheating risk if not accompanied by appropriate ventilation, shading, and adaptive design strategies [19]. A resilience-oriented perspective is therefore essential, as it extends energy renovation beyond efficiency targets alone to include passive survivability, namely the ability of buildings to remain safe and habitable during heatwaves or power interruptions. In this sense, energy-related durability becomes directly linked to occupant safety and functional continuity.

The literature also suggests that the large-scale implementation of such renovation strategies depends on overcoming the persistent dominance of initial-cost-based decision-making [4]. In this regard, LCC provides a more appropriate basis for evaluating renovation interventions, as it captures long-term economic performance rather than short-term affordability alone [7]. Investments in durable materials, adaptable TBS, and integrated retrofit measures may involve higher upfront costs, but they can reduce repair needs, delay obsolescence, and improve long-term value retention. From this perspective, circular and resilient renovation should be understood not as a collection of isolated technical upgrades, but as a long-term performance strategy that supports structural reliability, energy efficiency, reduced vulnerability, and value preservation over time.

5 Conclusions

This review has shown that the transition toward a sustainable and circular built environment depends largely on the renovation of the existing building stock. In this context, fragmented or isolated green interventions are insufficient to address current structural, energy, economic, and climatic challenges [11]. The analysis indicates that bridging

the gap between theoretical sustainability objectives and practical renovation strategies requires an integrated perspective in which durability and resilience are treated as complementary dimensions of whole-life building performance [6, 9]. Structured through five interconnected pillars, respectively material, energetic, structural, economic, and social [5], this perspective supports service life extension, value retention, resource efficiency, and reduced obsolescence across the WLC [14].

The review further suggests that circularity requires a shift from demolition-and-reconstruction practices toward renovation strategies better suited to the aging European building stock. In this regard, durability supports the long-term preservation of structural and energy-related performance under normal conditions [9], while resilience extends the assessment toward adaptability under climatic extremes and infrastructure-related disruptions [18]. Concepts such as passive survivability [10] and LCC [19] reinforce the need for renovation approaches that simultaneously address environmental performance, occupant safety, long-term functionality, and economic viability [18].

Future research should therefore focus on the operational integration of these dimensions through digital and multicriteria assessment methods. In particular, the use of predictive climate scenarios for the 2050–2080 horizon, together with BPS, Digital Twins, and composite performance metrics [19], may support a more robust evaluation of energy efficiency, structural robustness, and climate adaptation. Such approaches are essential for strengthening whole-life renovation strategies and advancing the sustainable, circular, and resilient rehabilitation of existing buildings [6].

Abstract. Industrial buildings represent a significant component of the global building stock, contributing to global CO_2 emissions: in 2022, the building and construction sector accounted for around 37% of global energy- and process-related CO_2 emissions. Given the large embodied-carbon footprint associated with construction materials and structural components, there is urgent need for circular renovation strategies. Design-for-disassembly (DfD) offers an approach by enabling reversible interventions, component recovery, and material reuse instead of demolition. This paper proposes a KPI-based framework specifically customized for assessing circular performance in industrial building renovation. The framework is illustrated through a representative industrial building (IH-1) as a proof-of-concept, using circularity indicators drawn from literature, standards, and policy-oriented assessment logic. The proof-of-concept demonstrates the practical feasibility of structuring and comparing circular performance in existing industrial assets and provides a structured tool for comparing renovation scenarios, for evidence-based circular renovation strategies in industrial building stock. The methodology applies a circular KPI scoring matrix to evaluate multiple renovation scenarios, focusing on disassemblability, material recovery potential, and adaptability. Results show that the framework strengthens decision-making by revealing performance differences between renovation options and guiding practitioners toward circular strategies that improve resource efficiency and support long-term industrial building regeneration.

1 Introduction

The building and construction sector represents one of the most resource-intensive and environmentally impactful sectors globally. Recent assessments indicate that it accounts for approximately 37% of global energy- and process-related CO_2 emissions, positioning it at the center of climate change mitigation efforts [1]. Within the European context, the challenge is further intensified by the age and condition of the existing building stock. A considerable proportion of buildings were constructed before the implementation of modern energy performance standards and now require substantial renovation to meet contemporary environmental and functional requirements [2–4]. Industrial buildings are characterized by material-intensive construction, long spans, and durable steel or reinforced-concrete systems, contributing substantially to lifecycle resource use and embodied impacts [5]. At the same time, conventional redevelopment practices often rely on demolition and reconstruction, leading to considerable waste generation. Construction and demolition waste represents approximately one-third of total waste produced in the European Union, reflecting the inefficiencies of current linear approaches to building transformation [6]. Such practices not only result in the loss of valuable materials and embedded energy but also increase environmental burdens through additional resource extraction and emissions [7].

Industrial buildings also represent an important component of cultural and industrial heritage, embodying historical, architectural, and socio-economic values [8]. Despite their structural resilience and long service life, these buildings face significant challenges during renovation. Conventional approaches frequently involve partial or complete demolition of structural components, leading to substantial material waste and the irreversible loss of reusable elements [9]. Furthermore, the absence of design considerations for disassembly in many existing structures limits the potential for material recovery and reuse. As a result, renovation practices often fail to capitalize on the inherent value embedded within industrial buildings, while also neglecting the integration of circular economy principles [10]. The circular economy promotes resource retention, reuse, refurbishment, and material recovery instead of demolition-led redevelopment [11]. In industrial heritage renovation, circular strategies can reduce embodied emissions while improving adaptability and extending service life [12]. By prioritizing material recovery and reuse, circular renovation reduces the demand for virgin materials and lowers embodied carbon emissions. Additionally, adaptive reuse strategies improve building flexibility and resilience by enabling structures to accommodate changing functional requirements over time. A core concept supporting circular construction is design-for-disassembly (DfD), defined here as the intentional planning of building systems, components, and connections so that they can be separated, recovered, repaired, reused, or recycled with minimal damage and material loss. DfD enables buildings to be dismantled in a controlled and systematic manner, allowing components and materials to be recovered and reused [13]. Unlike traditional construction methods, where elements are often permanently fixed, DfD emphasizes reversible connections, modular design, and material separability. These principles facilitate efficient disassembly processes, improve material recovery rates, and reduce demolition waste [14]. Moreover, DfD improves adaptability by enabling buildings to be reconfigured or repurposed in response to evolving needs. Despite its potential, the application of DfD has been predominantly limited to new

construction projects, with relatively little attention given to its integration into the renovation of existing industrial buildings. Although significant progress has been made in the development of circularity assessment tools, lifecycle assessment methodologies, and DfD strategies, these efforts have largely focused on new building design rather than the renovation of existing structures [15]. Current frameworks, such as Level(s), provide valuable guidance for assessing sustainability performance but are not specifically tailored to the unique characteristics and challenges of industrial building renovation [16, 17]. There is a lack of systematic approaches for evaluating circular performance in existing industrial buildings, as well as limited methods for comparing alternative renovation scenarios using quantitative indicators. Furthermore, existing studies rarely integrate DfD principles with measurable performance metrics, which limits their applicability in practical decision-making contexts. In response to these gaps, this paper proposes a structured framework based on KPIs for assessing circular renovation strategies in industrial buildings. KPIs are defined as quantifiable metrics used to evaluate the performance of a system relative to defined objectives, and in this context, they enable the measurement of circular performance across multiple dimensions, including disassemblability, material recovery potential, adaptability, and resource efficiency. The proposed framework integrates DfD principles into a scenario-based evaluation approach, allowing for the systematic comparison of different renovation strategies. A representative industrial building is used as a proof-of-concept case to illustrate the applicability, transparency, and internal consistency of the framework, while recognizing that full empirical validation requires future testing on documented renovation projects.

2 Literature Review

The circular economy has emerged as a transformative paradigm aimed at decoupling economic growth from resource consumption by eliminating waste, circulating materials, and regenerating natural systems [18]. In the built environment, this approach requires a shift from conventional linear practices toward lifecycle-oriented strategies that prioritize durability, reuse, and recovery of materials and components [19]. Industrial heritage buildings provide a particularly relevant context for the application of circular economic principles. These structures are not only significant from a cultural and historical perspective but also represent substantial material reservoirs due to their resilient construction and long service life [8]. Adaptive reuse has been increasingly recognized as a sustainable strategy that allows existing buildings to be repurposed while avoiding the environmental impacts associated with new construction. Empirical research demonstrates that retaining structural elements can significantly reduce embodied carbon emissions by minimizing the need for new material production [9].

The main enabler of circular construction is the concept of DfD, which focuses on enabling buildings to be dismantled in a controlled and systematic manner, thereby facilitating material recovery and reuse. The international standard ISO 20887:2020 provides a comprehensive framework for implementing DfD and adaptability principles across multiple hierarchical levels, including systems, elements, components, and materials [12]. Previous studies highlight methodological challenges in assessing circularity and allocating environmental impacts across multiple reuse cycles, particularly during early-stage decision-making [13]. Consequently, KPI-based semi-quantitative approaches are

increasingly used for comparative circular assessment under data uncertainty. Despite these findings, the main limitation identified in the literature is the fragmentation of circularity indicators and the disproportionate focus on material flow metrics. Many existing frameworks emphasize quantities of recycled or reused materials while underrepresenting critical aspects such as adaptability, disassemblability, and long-term reuse potential [14]. There is a clear need for integrated assessment frameworks that combine DfD principles with comprehensive KPI systems specifically tailored to existing industrial buildings. Such frameworks would enable more effective evaluation of renovation strategies and support the transition toward circular and sustainable construction practices [20].

3 Methodology

A scenario-based circular performance assessment is applied in this study, specifically designed to support early- and mid-stage renovation decision-making processes, where detailed LCA inventories are often incomplete or unavailable. The methodology combines KPI selection, scenario definition, semi-quantitative scoring, and comparative aggregation of circular renovation performance. The development of the KPI framework is grounded in circular economy principles and DfD logic. Five KPI categories were defined: structural disassemblability, material recovery, component reuse, adaptability, and resource efficiency. Circular documentation and recovery strategies are informed by materials passport approaches developed within the BAMB project, which highlights the importance of structured information for enabling material recovery and reuse [17]. Policy alignment is ensured by linking these KPIs to European Union priorities on construction and demolition waste reduction and circular renovation strategies. The KPI definitions used in the assessment are summarized in Table 1. Each KPI category captures a specific aspect of circular performance, supported by measurable indicators and methodological anchors derived from standards, policy frameworks, and scientific literature.

A semi-quantitative scoring system is applied to evaluate each KPI category. Scores range from 1 to 5, where 1 represents very low circular performance and 5 represents very high performance. Scores range from 1 (low circular performance) to 5 (high circular performance), reflecting increasing levels of reversibility, reuse potential, and adaptability. The use of a simplified scale enables practical application in situations where detailed quantitative data are not available, while still providing meaningful differentiation between renovation scenarios. All KPI categories are assigned equal weights in the baseline assessment, unless project-specific stakeholder priorities suggest otherwise. The aggregated circular performance score for each scenario is calculated using Eq. (1), which represents a weighted average of individual KPI scores:

$$S_j = \frac{\sum_{k=1}^{5} w_k \; s_{k,j}}{\sum_{k=1}^{5} w_k} \tag{1}$$

where $s_{k,j}$represents the score of KPI category $k$under scenario j, and $w_k$represents the weight assigned to each KPI category. Under equal weighting conditions, where $w_k = 1$,

Table 1. KPI definitions used in the assessment

KPI category	Definition	Typical evidence for scoring	Primary methodological anchors
Structural disassemblability	Ability to separate structural systems with minimal damage	Reversible connections; accessibility of joints; independence of layers	ISO 20887 principles [12]
Material recovery	Ability to recover materials into high-value loops	Selective dismantling plans; waste segregation; recovery paths	EU waste and renovation policy [6, 7]
Component reuse	Direct reuse potential of building elements	Standardization; deconstruction feasibility; recertification paths	Structural reuse studies [9]
Adaptability	Capacity for functional transformation with minimal intervention	Flexible layouts; modular partitions; service zoning	ISO adaptability principles; Level(s) [12, 15]
Resource efficiency	Reduction of virgin material use and waste generation	Retained structure ratio; recycled content; waste reduction	Circular economy policy and Level(s) [11, 15]

Eq. (1) simplifies to the arithmetic mean of the five KPI scores. Eq. (1) defines the overall circular performance of each renovation scenario and enables direct comparison across alternatives. The assessment is intended as a proof-of-concept rather than a fully validated empirical case study. IH-1 therefore represents a typical industrial building model used to test the consistency and applicability of the KPI framework under limited-data renovation conditions. Future work should validate the framework using real renovation projects and BIM-based inventories. The case study is based on a representative industrial building, referred to as IH-1, which serves as a proof-of-concept model for the proposed framework. Given the absence of a specific real-world building dataset, IH-1 is defined as a typical industrial hall in Southeast Europe. It is characterized as a single-storey structure with a long-span structural system, typically consisting of steel portal frames or truss configurations commonly used in industrial construction. The building envelope is assumed to consist of mixed cladding and masonry systems typical of legacy industrial facilities, while building services are considered to have undergone multiple upgrades over time, resulting in partial obsolescence. This representation is consistent with the heterogeneous nature of non-residential building stock, which includes diverse industrial and warehouse typologies with varying material and energy characteristics (Table 2).

Three renovation scenarios are defined to evaluate different levels of circularity integration. The first scenario represents conventional renovation practices, involving partial demolition, replacement of structural elements, and limited material recovery.

Table 2. Representative construction characteristics of IH-1 and relevance for scenario scoring

IH-1 characteristic	Representative assumption	Relevance for scenarios and KPI scoring
Structural system	Steel portal-frame/truss industrial hall	Affects reuse and disassembly potential across scenarios
Connections	Mixed bolted and welded legacy connections	Influences reversibility and disassembly efficiency.
Building envelope	Mixed masonry infill, aged cladding panels, and roof covering with different levels of separability	Influences material recovery and waste generation. Scenario 1 replaces mixed assemblies; Scenario 2 selectively dismantles recoverable parts; Scenario 3 uses modular and separable envelope interventions.
Services	Electrical, ventilation, and utility systems upgraded over time, with partial obsolescence and limited documentation	Affects adaptability and future maintenance. Scenario 3 introduces service zoning, documentation, and easier access for future replacement.

The second scenario reflects circular renovation principles, incorporating selective dismantling, increased reuse and recycling of materials, and partial retention of structural components. The third scenario represents a DfD approach, emphasizing reversible connections, modular interventions, maximized component reuse, and systematic planning for future disassembly through documentation and information transfer.

4 Results and Discussion

The circular performance of the three renovation scenarios was evaluated using the KPI framework presented in Sect. 3. The results are summarized in Table 3, which reports proof-of-concept scores for the representative industrial building (IH-1). The scoring reflects the evidence logic defined in Table 1 and typical differences between demolition-led renovation practices and circular and DfD approaches. The results show a clear improvement in circular performance from Scenario 1 to Scenario 3. The conventional renovation scenario achieves the lowest score due to its reliance on partial demolition and replacement, which typically involve irreversible connections and mixed-material assemblies that limit disassembly and reuse potential. This outcome is consistent with the principles outlined in ISO 20887, which emphasize the negative impact of non-reversible construction methods on circular performance [12]. The circular renovation scenario shows moderate improvement, particularly in material recovery and resource efficiency, due to the implementation of selective dismantling and improved waste management practices.

Table 3. Circular KPI category scores for IH-1

KPI category	Scenario 1 Conventional	Scenario 2 Circular	Scenario 3 DfD
Structural disassemblability	2	3	5
Material recovery	2	4	4
Component reuse	2	3	5
Adaptability	3	3	4
Resource efficiency	2	4	4
Aggregated score (S_j)	2.2	3.4	4.4

Scenario differences are directly linked to IH-1 construction characteristics. Scenario 1 scores lowest due to demolition-led replacement and limited recoverability. Scenario 2 improves material recovery through selective dismantling and retention of structural elements. Scenario 3 achieves the highest circular performance through reversible connections, modular interventions, and planned future disassembly.

5 Conclusion

This paper shows that circular renovation strategies for industrial buildings can be systematically evaluated using a KPI-based framework that integrates DfD principles. The results from the representative industrial building case (IH-1) show that the DfD-based renovation scenario significantly outperforms both conventional and partially circular approaches, particularly in terms of structural disassemblability and component reuse potential. The proposed methodology provides a transparent and practical decision-support tool that can be applied in early-stage renovation planning, where data availability is often limited. However, the presented IH-1 application should be interpreted as representative proof-of-concept rather than a fully empirically validated case study. The main limitation is the absence of a complete as-built material inventory, detailed connection survey, and measured post-renovation data. Future work should test the framework on real industrial heritage renovation projects, include expert-based weighting of KPIs, and integrate BIM or material passport data to improve scoring accuracy and validation resilience. The approach is adaptable and can be extended to multiple case studies, integrated with BIM, and linked with lifecycle assessment methods to provide more comprehensive sustainability evaluations.

Towards Distributed and Circular Construction: Pop-up Factories as Hybrid on-Site Manufacturing Models

Federica Pradella(✉), Giorgio Castellano, and Ingrid Maria Paoletti

Politecnico di Milano, Piazza Leonardo da Vinci 32, Milan 20133, Italy
federica.pradella@polimi.it

Abstract. The increasing complexity of architectural projects and the demand for circular and resource-efficient practices are driving exploration of decentralised production models for the built environment. Among these, pop-up factories represent a temporary production paradigm situated between off-site prefabrication and traditional on-site construction. Their implementation requires an integrated assessment of technical, environmental, and regulatory factors, helping to evaluate their potential to reduce logistics, activate local supply chains, and enable circular material flows. This research proposes a conceptual assessment framework for pop-up factory planning in the early design stages. The study adopts a qualitative and exploratory approach, combining a literature review, selected case studies of Distributed Manufacturing (DM), Design for Manufacturing and Assembly (DfMA), and regulatory benchmarking within European policies. Variables influencing system performance are identified and grouped into three categories: technical-operational conditions, environmental and socio-economic considerations, and regulatory and governance constraints. The resulting screening tool supports stakeholders in assessing temporary factories under specific project conditions, from renovation to new construction. By organising the interaction between design characteristics, manufacturing constraints, local resources, and regulatory frameworks, the model contributes to more distributed, circular, and context-sensitive construction approaches.

Keywords: Pop-up Factories · Distributed Manufacturing · Circular Construction · Hybrid On-site Manufacturing · Evaluation Framework

1 Introduction

The Architecture, Engineering, and Construction (AEC) sector is undergoing significant transformations [1], driven by the need to reduce environmental impacts and respond to economic and social pressures. This transition is influenced by European policy frameworks such as the European Green Deal [2] and the Circular Economy Action Plan (CEAP), which promote the transition towards more resource-efficient and low-carbon construction systems [3]. However, compared with other industrial sectors, construction is characterised by much slower processes of evolution due to the high customisation of

L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 245–253, 2026.
https://doi.org/10.1007/978-3-032-34930-9_29

buildings and project-based workflows, which limit continuous improvement and subsequently hinder large-scale adoption of innovative and sustainable practices [4]. As a result, the sector relies on heterogeneous manufacturing paradigms, ranging from industrialised approaches which offer fundamental tools for more efficient and circular design and production processes [5] to craft-based practices that remain widespread in many contexts. Nevertheless, construction remains among the most resource-intensive industries in terms of material consumption, waste generation, and greenhouse gas (GHG) emissions [2].

Modern Methods of Construction (MMC) have historically addressed challenges in productivity, quality control, and resource management, particularly in projects involving multiple stakeholders [6]. However, centralised off-site production is often hindered by high investment costs, supply chain dependency, and logistical constraints, limiting the adaptability to diverse project scales and local conditions [7–9]. Conversely, Small and Medium Enterprises (SMEs)-led projects typically rely on on-site work for its flexibility and adaptability, but often remain affected by inefficiencies, fragmentation, and limited capacity to integrate innovation and low-carbon practices.

In response to these limitations, increasing attention has been directed towards decentralised production models capable of adapting to local constraints, temporary project conditions, and fragmented supply chains [4], while redistributing production capacity closer to construction sites, local value chains and material flows [10]. Within this context, the pop-up factory arises as a hybrid, temporary, and site-specific manufacturing system bridging off-site prefabrication and on-site construction [11–13]. Supported by Design for Manufacturing and Assembly (DfMA), and Distributed Manufacturing (DM) approaches [12], it enables more adaptable production configurations and closer integration between design, fabrication, and construction. Despite growing interest in decentralised production models, existing research has mainly focused on technological aspects or isolated case studies, while integrated approaches for evaluating their feasibility in construction projects remain limited.

To address this gap, this study proposes a conceptual evaluation framework for assessing pop-up factories in early-stage construction planning, integrating technical, organisational, economic, and regulatory factors. The approach aligns with the European Union (EU) policy landscape, including the Level(s) framework [14, 15], and the new EU Construction Products Regulation (CPR) [16]. The research contributes to the emerging debate on decentralised manufacturing in construction by introducing a multi-domain decision logic that connects design, production, and regulatory considerations.

2 Research Design and Method

The research adopts a qualitative and exploratory multi-criterion methodology that combines literature review, case study exploration, and regulatory benchmarking. The literature review addressed Industrialised Construction (IC) [4], DfMA, DM [17], mobile production models [11], and circular construction strategies, using scientific databases (e.g. Scopus and Web of Science). Exploratory case studies of decentralised production systems were examined (Table 1) [18, 19], while policy and regulatory documents were analysed to identify relevant environmental and circularity indicators. By comparing literature, case study characteristics, and regulatory indicators, recurring factors

influencing decentralised production feasibility were identified. An iterative process of abstraction and synthesis translates these factors into framework variables, clustered into three evaluation dimensions to ensure a comprehensive decision-support logic.

Table 1. Illustrative comparison of selected decentralised manufacturing cases [18, 19].

Equipment	Workforce	Logistics	Digital integration	Circular strategies
Case study, small scale: WikiHouse				
CNC router(s) standardized digital fabrication workflows	Local network of partners	Delivery of material, storage, fabrication, waste collection, assembly, component storage, loading	Open-source CAD-CAM data and file-to-factory workflows	Nesting strategies; dry assembly; possible disassembly; offcut reuse and recycling
Case study, large scale: Assembly OSM				
Industrialised component production systems Assembly-oriented technologies	International network of experts	Integrated off-site/on-site production workflows and coordinated supply systems	Digital coordination across project fabricators	Electric off-site facility; waste and CO_2 reduction through off-site production; supply chain management

3 Evaluation Framework for Pop-Up Factory Planning

Given the multi-domain nature of on-site manufacturing systems, the framework operates on two complementary levels: variables describe the functional nature of the parameters of the pop-up factory configuration, while clusters evaluate the domain through which each variable is assessed.

3.1 Variables Inventory

The first level includes 13 variables (Table 2) categorised as design, enabling, and boundary variables. These support a qualitative feasibility assessment of decentralised production systems and may be adapted according to site-specific project conditions.

Design Variables. This group of indicators describes the physical and operational characteristics of the production environment. Size is a primary parameter and varies depending on the application field, including new construction, renovation, temporary works,

and emergencies. According to the production requirements and component types, pop-up factories may be configured as small, medium, and large units. Spatial context concerns the organisation of the site into functional areas, including delivery, storage, fabrication plants, assembly, waste collection, and final product loading [10]. The hybrid nature of the model requires the integration of different materials and equipment, opening opportunities for locally sourced bio-based and waste-derived materials, and the integration of both traditional and advanced technologies [20].

Enabling Variables. These support the implementation of the system by improving coordination, innovation, and adaptability. Digital integration through Building Information Modelling (BIM), Digital twin (DT), and Artificial Intelligence (AI)-based optimisation can improve information flow and material traceability [21]. In parallel, site management strategies, potentially supported by drones and automated monitoring systems, improve scheduling, logistics control, and emissions tracking [20].

Boundary Variables. Safety requirements and regulatory compliance define the external constraints of the system. On-site safety must comply with national construction site regulations, while regulatory compliance embraces both production activities and component performance. At the EU level, the CPR prioritises digital traceability and circular economy principles through environmental performance declarations and digital product passports [16]. Renewable energy integration is also considered a sustainability-related condition. At this stage, no fixed minimum renewable energy threshold is proposed; the variable is qualitatively assessed as low/partial/high integration, ranging from grid-dependent temporary production to on-site temporary generation.

Table 2. Variables and indicators of the pop-up factory feasibility framework.

Variable	Evaluation cluster	Data type	Assessment mode	Indicator reference
Size	Technical-operational	Quantitative	Selection	–
Spatial context	Technical-operational	Qualitative	Selection	–
Project duration	Technical-operational	Scoring	Weighted scoring	–

Site phasing	Technical-operational	Binary	Tick-box	–
Safety compliance	Regulatory	Binary	Tick-box	National law
Energy autonomy	Environmental	Qualitative	Annotation	EU Green Deal

3.2 Variables Clustering and Framework Structuring

The variables are grouped into three evaluation domains (Table 2).

Technical and Operational Conditions. These assess the compatibility and adaptability between design variables and different construction scenarios [14].

Environmental and Socio-Economic Considerations. This second layer evaluates CO_2 reduction, activation of local supply chains, workforce availability on-site and near-site, circular material flows, and supporting SMEs' access to innovation, in line with the European Sustainability Reporting Standards (ESRS) E1, E5, S2 and S3 [22].

Regulatory and Governance Constraints. The third layer investigates the alignment with current EU and national regulations, including CPR, Criteri Ambientali Minimi (CAM), and Life Cycle Assessment (LCA) protocols, identifying enabling or limiting conditions for system deployment to pursue sustainability targets.

4 Decision Support Logic for Feasibility Assessment

The framework operates through a cascade system. Variables are interpreted in relation to site-specific conditions, allowing stakeholders to identify enabling factors and potential constraints for pop-up factory implementation. The decision support logic is ensured by associating each variable with a data type and an assessment mode, allowing its interpretation within one of the three evaluation clusters. At this preliminary stage, assessment methods are expert-informed based on relevance to project constraints, contribution to circularity, and impact on regulatory viability. First, a preliminary resource mapping, identifying available materials, equipment, technological capabilities, and know-how available close to the construction site is performed. This supports renovation scenarios, fostering re-action practices and material audits, and new construction, helping in identifying local supply chains and stakeholders [23]. Afterwards, the information collected is

integrated into the design stage, in which material quantities, production requirements, and construction constraints are defined. Finally, the framework is applied to evaluate the applicability of the pop-up factory model, supporting a multi-criteria comparison between conventional construction workflows and a decentralised scenario (Fig. 1) [24].

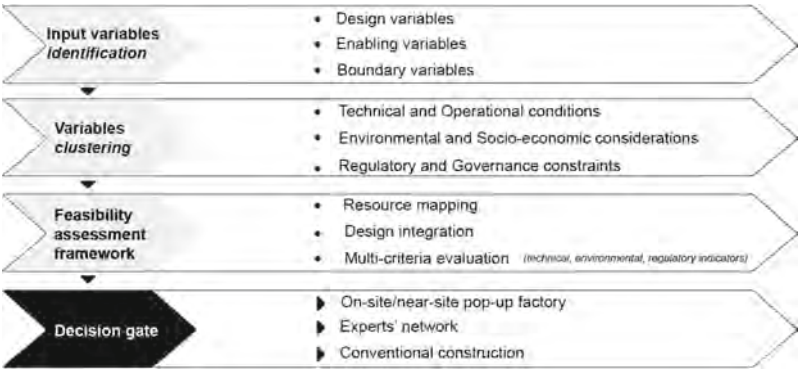

Fig. 1. Cascade-based decision-support framework for assessing pop-up factory feasibility in construction projects.

5 Application Example

Although the framework is primarily conceptual, it can be illustrated through two typical situations. In the deep renovation of public housing buildings in dense urban contexts, medium–long project duration and high logistics constraints may favour on-site sorting, remanufacturing, and reuse practices [14]. In new developments with limited industrial supply chains and high transport distances, near-site manufacturing may support the production of customised components while reducing logistics and transport-related impacts. In both cases, the framework does not provide a deterministic yes/no outcome but rather supports a comparative screening between alternative production configurations, including on-site, near-site, and conventional models, highlighting bottlenecks, such as workforce skills, energy autonomy, and safety constraints (Fig. 1).

6 Discussion

The results suggest that the performance of pop-up factories is not only a technical matter but requires a systemic understanding of multiple factors, including regulatory conditions, site-specific constraints, circularity principles, and stakeholder involvement [25]. By structuring the variables within an integrated evaluation system, the research contributes to advancing decision-support approaches for decentralised and hybrid manufacturing systems in construction.

A key finding is the importance of preliminary resource mapping. Identifying locally available materials, machinery, and expertise allows potential synergies to be evaluated

among design requirements and production capabilities. In renovation projects, this preliminary inventory may facilitate material audits and re-action practices [14, 15], whereas in new construction, it can activate local supply chains and networks of experts and SMEs [26]. At the same time, the coexistence of manufacturing and construction activities within the same perimeter necessitates complex planning, requiring coordination of material flows, logistics, and safety procedures. Digital integration may play a cross-cutting role in supporting this coordination, enabling real-time process monitoring. Dismantling is also relevant: temporary foundations, service connections, storage units, and design and production shelters should be conceived as reversible elements to avoid permanent site disturbance. Beyond transportability and modular set-up stored in standard containers [11, 27], further framework developments should consider circularity aspects such as the residual value of equipment and the reuse potential of the temporary production infrastructure across multiple projects.

The widespread diffusion of pop-up factories depends not only on technological readiness but also on the ability of regulatory frameworks to accommodate hybrid production models. EU initiatives such as the CPR and Level(s) may progressively improve distributed and traceable production systems. From an industry perspective, the proposed framework supports stakeholders in evaluating the applicability of pop-up factories in specific project planning contexts, fostering the use of local resources, reducing logistics, and supporting circular material flows. However, limitations are mainly related to the lack of validation through real construction projects and quantitative data. The proposed weighted scoring is preliminary and currently relies on expert-informed judgement; future research will concentrate on developing a scoring system based on design data and EU indicators. Overall, pop-up factories may be interpreted not only as a technical innovation but also as a potential catalyst for more adaptive, circular, and locally embedded construction practices.

7 Conclusion

Within the current transformation of the construction sector, the demand for hybrid manufacturing models that integrate industrial efficiency with site-specific constraints is becoming increasingly evident. In this context, pop-up factories should not be interpreted merely as temporary production infrastructures, but rather as a comprehensive operational ecosystem integrating physical resources, organisational processes, and regulatory conditions. This research provides a conceptual and methodological contribution to the ongoing discussion of decentralised manufacturing in construction by proposing a structured framework for evaluating the feasibility of pop-up factories during early-stage project planning. By integrating design, manufacturing, construction, and logistics in a unique site-based ecosystem, the framework highlights the potential of decentralised production systems to respond to local needs and to strengthen regional construction ecosystems, especially in SME-dominated contexts. Further research will focus on the validation and refinement of the framework through real-world application, enabling a more systematic comparison between decentralised and conventional construction configurations.

Abstract. The construction sector is a major contributor to global environmental pressures, responsible for 40–50% of resource extraction, 60% of waste generation, and roughly one-third of CO_2 emissions. Transitioning to a circular economy (CE) is an essential pathway to resource efficiency and carbon reduction. Urban Mining (UM), as the systematic recovery of materials and components from the built environment, offers significant potential to reduce embodied impacts and resource dependency. However, the integration of UM into renovation and new-build design processes remains limited, particularly for industrialised façade systems, where modularity could enable more circular practices. This paper presents a UM-based approach for circular façade renovation, with a focus on the recovery and direct reuse of legacy resources that avoid the embodied energy of new production. Evidence shows that reused components consistently demonstrate lower Global Warming Potential (GWP) and primary energy demand compared with recycled or virgin materials. A modular, multifunctional façade renovation system is used as a case study to evaluate component recoverability, technical suitability, and logistical feasibility. Alternative materials for insulation and cladding is evaluated concerning their potential as reused or recycled resources. Applied to a school renovation project, reclaimed resources are integrated in the process for the cladding design strategies. Findings demonstrate that UM can support scalable, modular renovation solutions aligned with broader sustainability goals.

Keywords: Renovation · Façade · Circularity · Reuse · Urban Mining · Design process

1 Introduction

The construction sector remains one of the most resource-intensive industrial domains, responsible for 40–50% of global raw material extraction, 60% of waste generation, and nearly one-third of total CO_2 emissions. These numbers place the sector in a pivotal position for the current climate and resource-efficiency agendas, making the transition toward

https://doi.org/10.1007/978-3-032-34930-9_30

a circular economy (CE) a necessity. This transition is commonly interpreted through frameworks such as Cradle-to-Cradle [1] and the R-strategies, prioritizing reduce, reuse, recycle, repair, refurbish, remanufacture, and repurpose [2].

Within building life cycles, material production represents a major environmental impact, contributing up to 50% in new and low-energy buildings [3]. Among building subsystems, façades are particularly critical because they influence both operational energy demand and embodied carbon. Although their mass is relatively limited compared with structural systems, façade systems account for 10–30% of total embodied carbon emissions [4]. Consequently, façade design is of strategic importance in reducing environmental burdens while maintaining performance requirements.

This challenge is amplified in the renovation of existing buildings, which must be achieved at scale. More than 85% of Europe's building stock does not comply with current energy-efficiency standards. Achieving net-zero targets requires deep renovation that reduces energy demand by 60–90%, and double the annual renovation rates by 2030 [5]. Modular and industrialized renovation can support in achieving these objectives [6]. Yet, large-scale façade retrofitting may intensify material demand, and the related environmental burdens, unless circular strategies are embedded from the earliest design stages [7].

Reuse and recycling of existing components reduce end-of-life impacts while avoiding the production of virgin materials, thereby extending material utility according to CE principles. Urban Mining (UM), understood as the systematic recovery of materials and components from existing buildings, offers significant potential to reduce embodied impacts and dependence on primary resources. However, its implementation in façade renovation remains limited, despite industrialized systems' modularity could facilitate component recovery, replacement, and future reuse.

This paper addresses that gap by presenting a UM-based approach for circular façade renovation, focusing on the recovery and reuse of legacy resources as substitutes for primary materials. Legacy resources refer to materials that are no longer in active use and are undergoing the process of being repurposed into new products or application, on the original site, at a different location, or through transfer to another party for future reuse [3]. The study discusses the feasibility of secondary resource reuse in a modular façade renovation system, by evaluating the potential of alternative materials for insulation and cladding. moreover, the paper presents how the design process of a school renovation particularly regarding the selection of the cladding material for the modular system integrated UM consideration.

2 Methodology

The methodological approach aims to assess the integration potential of legacy resources within a modular façade renovation system under an UM perspective.

1. **Analyse material recovery potential for the insulation and cladding of the façade system**

   The approach is applied to the AEGIR [8] façade system, an industrialised, modular renovation solution based on a structural mesh comprising vertical and horizontal load-bearing elements. Each module (Fig. 1) integrates internal and external

enclosures, structural elements, insulation, and cladding, while selected applications incorporate photovoltaic panels, automated windows, and shading systems. Next to the objective of energy upgrade, the development of the module aims to improve the resource efficiency of the renovation, with the use of circular design principles. The modular configuration future disassembly makes it a relevant case for investigating how UM principles can support circular façade renovation at scale. The study focuses on the material selection considerations, by, firstly, conducting a systematic inventory of alternative materials for the insulation and cladding components.

2. **Exploring the complexity of implementing reclaimed materials in a Case-study application**

   The framework is tested in a school renovation case study in Spain (Fig. 2), where the modular façade system is applied to increase the energy performance and thermal comfort. This study focuses on the material selection process for cladding.

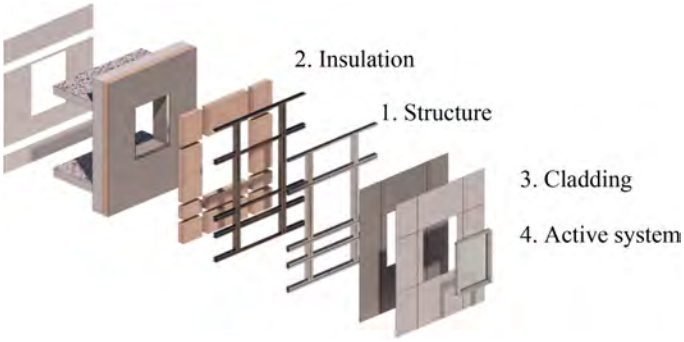

Fig. 1. Exploded view of the modular façade system AEGIR (Image courtesy of AEGIR project and UN Studio).

Fig. 2. The case study, an educational building in Margrat, Spain (source: project AEGIR [8])

3 End-of-Life (EoL) Potential for the Insulation and Cladding Component of the Modular Renovation System

To evaluate the potential for UM, the different components of the systems need to be investigated separately. The study further focuses on the alternative materials and their End-of-Life (EoL) scenarios of insulation and cladding, in particular.

3.1 Insulation

The selection of insulation materials is critical for circular façade design, influencing embodied impacts, recoverability, and EoL pathways. Biobased and recycled, post-consumer material alternatives offer improved environmental performance compared to conventional materials, but their circularity depends on composition, installation, and recovery strategies.

Biobased Insulation – Cellulose: Cellulose insulation, produced from recycled paper, offers low embodied energy and strong reuse potential, particularly in loose-fill applications where non-destructive removal is possible. However, the use of borate-based fire retardants limits recyclability and compatibility, while also raising health concerns during installation. Its circular performance therefore depends on reversible installation methods and reduced reliance on hazardous additives.

Biobased Insulation – Wood Fiber: Wood fibre insulation provides the benefit of carbon storage and is suitable for façade applications due to its panel format. While reuse and composting are theoretically possible, the presence of additives such as paraffin and synthetic binders often limits these pathways. In practice, energy recovery remains the dominant EoL route. Improving circularity requires minimizing additives and enabling mechanical disassembly.

Textile-Based Insulation: Textile insulation utilizes recycled fibres, contributing to waste valorisation and offering good handling properties. However, its circularity is constrained by the use of synthetic binders and the environmental impacts of the original textile production. Although recyclable, it is often downcycled or landfilled in practice. Design strategies should focus on maintaining material purity and enabling efficient recovery.

PET-Based Insulation: PET insulation incorporates recycled plastic fibres and benefits from existing recycling systems, including take-back schemes. Despite this, actual recycling rates remain limited (47%) due to collection and contamination challenges. As a fossil-based material, its sustainability is conditional on effective recycling. Design for disassembly is essential to improve recovery and maintain material value.

3.2 Cladding

The modular façade system has the possibility to apply different types of cladding materials, making the renovation adaptable to the project's ambition, context, design intent, environmental consideration, as well as circularity. Common cladding materials,

such as metals, timber, composites and concrete, were examined as legacy resources, with regard to reuse and recycling.

Aluminium and Steel: Metals exhibit high circularity potential due to their ability to be recycled with minimal quality loss. Aluminium recycling potential is well-established. The 75% of the aluminium produced to date is still in use today due to its infinitely recyclable properties. In 2018, over 90% of the aluminium used in the transportation and construction sectors was recovered [9]. Despite strong recycling systems, direct reuse of structural elements remains limited. From a design perspective, circularity depends on material traceability, standardised components, and reversible connections to enable high-quality recycling or reuse.

Timber: Timber follows a cascading use model, where recycling often results in down-cycling into lower-value products such as chipboard [10] . Material quality is affected by coatings, preservatives, and contamination, limiting recycling potential. In contrast, reuse of structural timber offers higher circular value, particularly for large sections that can be reprocessed or integrated into engineered wood products [11]. However, most demolition wood is currently incinerated. Design strategies should prioritise non-destructive disassembly, minimise chemical treatments, and preserve structural dimensions to enable reuse and maintain material value across multiple life cycles.

Concrete: Concrete recycling is widely practised, with most waste processed into aggregates for low-value applications such as road construction. This represents down-cycling, as only a small share is reused in new concrete due to quality and contamination constraints. Reuse of concrete elements offers higher circular potential by preserving structural integrity and embodied energy, but requires selective deconstruction and adapted connection design [12]. This requires the careful disassembly of outdated structures into relatively large pieces, employing methods such as a diamond saw or high-pressure waterjets. To improve circularity, design approaches should focus on modularity, standardisation, and reversible connections to facilitate future recovery and reuse.

4 A Case Study of Urban Mining Considerations in the Design Process of a School Renovation

The discussed Urban Mining (UM) considerations were integrated into the renovation design of a school building serving as the Spanish demonstration site. As part of the circular design strategy, alternative materials with lower embodied environmental impacts were explored for the cladding layer of the modular renovation system, which required further specification in the context of this project. In particular, the building owner expressed interest in exploring reclaimed timber as a façade cladding solution, prompting a more detailed assessment of reuse opportunities, utilising the UM considerations and reclamation routes. To support the design decision, the material selection process considered multiple criteria, including durability, availability, and economic feasibility.

4.1 Identification of Reused Timber Sources

To evaluate the feasibility of reused timber within the façade system, a systematic search for potential material sources was conducted. This process included both local supply investigations and digital platform screening. Local material suppliers located near the construction site were contacted, in order to identify reclaimed timber streams originating from demolition activities or secondary material markets. The suppliers were asked to provide information regarding available material volumes, dimensions, species, and expected delivery timelines. Furthermore, digital material exchange platforms were explored as additional procurement channels.

Following this market screening for availability, three representative timber sources were selected for further analysis: demolition timber, pallet wood, and eucalyptus elements recovered from mussel farm structures. Details on the volume, price and maintenance are shown in Table 1.

Table 1: Reclaimed wood sources

Product	Timber from building demolishing	Pallets	Eucalyptus from mussel farms
			
Volume	limited	Available within 1 year	Available within 1 year
Price (€)	€100/m	€26/m^2 + 20 €/h work (1200 €/m^3 + 20 €/h)	€37/m^2 (700–1300 €/m^3)
Durability	No naturally durable wood (pine)	No naturally durable wood	Moderately durable

4.2 Durability and Additional Design Considerations

For the timber cladding application of this project, resistance to weathering and fungal decay represents a critical design parameter. The durability of wood species is classified according to EN 350–2, which defines natural resistance to biological degradation. Several wood species relevant to the Spanish region were considered as reference materials for comparison with reused timber. These include sweet chestnut, European oak, and Douglas fir.

Timber recovered from building demolition can consist of both durable species, such as oak and chestnut, and non-durable species, such as pine, depending on the original building. These elements often originate from beams or rafters and require reprocessing into suitable cladding dimensions, increasing labour effort but enabling adaptation to modular façade systems.

Pallet wood represents another potential source of reclaimed timber. Pallets are typically manufactured from pine or poplar and therefore lack natural durability against biological degradation. However, they are often available in standardised sizes and can be processed into façade cladding elements with relatively low material costs. Additional protective treatments are required when such materials are used in exterior conditions.

The third identified material stream consists of eucalyptus elements recovered from mussel farming structures. These components are typically available as planks of approximately 40–50 mm thickness and 150–200 mm width. The wood species exhibits moderate durability and can therefore be applied in protected façade areas or where architectural design features such as overhangs reduce direct weather exposure. Thus, durability depends not only on material properties but also on façade detailing. Strategies such as protected placement, ventilation, and surface treatments are essential.

Finally, due to the difficulty in finding naturally durable reused wood from the same supplier in quantity enough and to address the challenges associated with sourcing a sufficient volume of reclaimed wood, a strategic decision has been made to utilise reclaimed wood in a limited amount and in areas which are protected from weather. In this way, no treatment will be needed in the wood for cladding, but a superficial protection (a coating commercially named "lasur"). It is estimated that up to 27% can be reused [13], as a third life strategy. For the exposed areas, biobased composite panels were selected for their reduced environmental impact as they are crafted from natural, renewable components like plant fibres or agricultural waste, which are then combined with biobased resins. Figure 3 illustrates the placement of the materials and the considerations for their life-cycles.

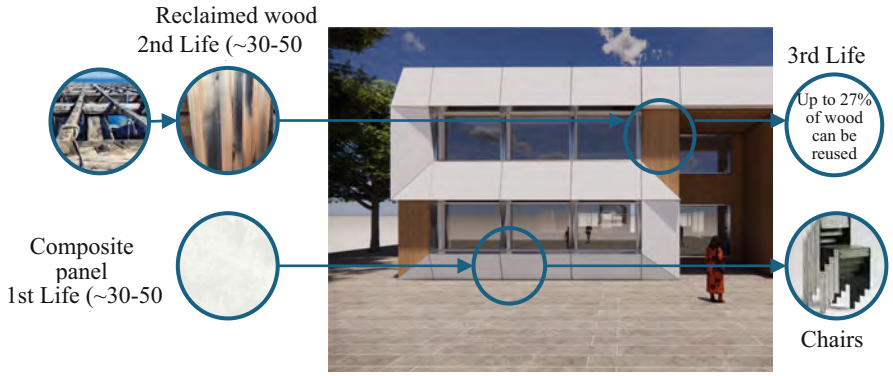

Fig. 3. Resulting material selection for timber cladding of reclaimed and treated Eucalyptus from mussel farms and biobased composite, with the AEGIR system application (Image courtesy of AEGIR project and UN Studio).

5 Conclusion: Impact of UM in Circular Façade Design

The study demonstrates how Urban Mining principles can be integrated into the design process of façade renovation systems. From a circular design perspective, early identification of available legacy resources is essential. By integrating material availability into the design process, architects and engineers can align façade system configuration with locally available reused materials. This approach not only reduces reliance on primary materials but also supports regional material cycles and reduces transportation-related environmental impacts.

The investigation revealed that reclaimed timber can be successfully incorporated into façade systems when the design accommodates variability in material dimensions and durability. Logistics, such as storage but also short transportation from the production site to the construction site, is a key element. Modular façade systems provide a suitable framework for such integration because they allow adaptation of cladding elements without affecting the structural performance of the overall system.

[2] Technical Sciences Academy of Romania, Bucharest, Romania

Abstract. The construction sector is one of the largest consumers of natural resources and generators of waste, making the transition to circular economy (CE) principles increasingly important. Modular construction systems offer significant opportunities for circularity through design adaptability, industrialized production, material reuse, and flexible configurations. However, existing CE assessment frameworks often fail to capture the specific circular potential of modular residential buildings throughout their lifecycle, particularly in relation to modular design, component reuse, and adaptability. This paper proposes a new assessment framework called REALM (Residential Modular Circular Economy Assessment and Lifecycle Management), designed to evaluate circular economy performance in modular housing. REALM integrates modular design assessment criteria, material circularity indicators and lifecycle stage evaluation within a unified analytical framework. The methodology combines design for disassembly, material flow analysis and adaptability metrics to assess circular performance from early design stages to end-of-life recovery. The framework is structured around four core components: (1) modular design assessment criteria, (2) material circularity indicators, (3) lifecycle stage evaluation covering design, use, adaptation, and deconstruction phases, and (4) operational circularity indicators, including module relocation, reuse cycles, maintenance and refurbishment. REALM treats modularity as a key enabler of circularity and proposes a structured set of indicators to support the evaluation of circular performance in modular residential buildings.

Keywords: Circular Economy · Modular Construction · Residential Buildings · Sustainability Assessment · Building Lifecycle Management

1 Introduction

The environmental impact of the construction sector has reached critical levels, accounting for around 40% of global carbon emissions, 50% of extracted materials, and 35% of total waste [1]. The European Commission Circular Economy Action Plan identifies construction as a priority sector for circular economy (CE) practices, setting ambitious targets for material recovery and waste reduction [2]. However, translating CE principles

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 263–271, 2026.
https://doi.org/10.1007/978-3-032-34930-9_31

into practical assessment tools remains challenging, particularly for modular residential building systems. The residential sector faces specific challenges, as buildings must balance technical performance with occupant comfort, adaptability to changing family needs, and long-term affordability [3]. Traditional construction generates significant waste during construction (10% of materials) and demolition (up to 90% becomes waste) [4], with limited reuse potential. Modular construction offers advantages for circularity through standardization, prefabrication quality control, and design for disassembly [5]. Factory-based production can reduce material waste by 52% compared to on-site methods [6], while enabling material passports and end-of-life recovery strategies [7]. Despite this potential, existing frameworks do not adequately capture modular-specific circular benefits [8]. Level(s) requires extensive data and LCA expertise, creating barriers for practitioners [9].

This paper presents REALM as a CE assessment framework tailored to modular residential buildings. The framework is intended to address gaps in existing approaches by incorporating modular and residential-specific criteria, providing indicative performance thresholds, and enabling tiered assessment approach that may improve accessibility for projects with limited data or LCA expertise.

2 Background

The circular economy (CE), as defined by the Ellen MacArthur Foundation, is a systemic approach to economic development benefiting businesses, society, and the environment [10]. In the built environment, CE promotes waste elimination, keeping materials at their highest value, and regenerating natural systems [11], contrasting with the linear "take-make-dispose" model. Research shows circular construction can reduce primary material use by 80%, cut carbon emissions by 75%, and generate economic value through reuse and recovery [12]. However, achieving these outcomes requires robust lifecycle-based assessment methodologies.

Several key sustainability and circularity frameworks are reviewed below, highlighting their scope and limitations for modular residential construction:

- Level(s), developed by the European Commission, assesses sustainability across six macro-objectives, including emissions and material lifecycles. Yet, it demands extensive data, LCA expertise, and time, limiting accessibility [8, 9].
- The Ellen MacArthur Foundation Material Circularity Indicator (MCI) evaluates material flows [13] but is resource-intensive for buildings and excludes broader design and social aspects [14].
- Madaster is a digital material passport platform that registers and tracks building materials at the product and building scale, enabling material reuse and residual value assessment [15]. However, it focuses primarily on material registration rather than circular design evaluation or residential-specific performance.
- The Circular Building Indicators (CBI), developed by the Dutch Green Building Council, provide a set of quantitative indicators for assessing circular performance at the building scale [16].

Existing frameworks only partially address modular construction features, residential functional needs, practitioner accessibility, and multiple CE dimensions. REALM is proposed as a framework intended to respond to this gap (see Table 1).

Table 1. Comparison of Circular Economy Assessment Frameworks for the Built Environment.

3 Theoretical Framework

3.1 Theoretical Framework Integration

REALM integrates three established theoretical foundations to ensure a comprehensive and credible assessment approach, as presented in Fig. 1.

Ellen MacArthur Foundation Circular Economy Principles, where REALM is grounded in the Foundation's three CE principles [10].

REALM integrates circular economy principles by reducing waste through mono-material design and design for disassembly, extending material use through durability, system independence, and residential adaptability, and supporting natural regeneration through bio-based materials and resource efficiency.

Stewart Brand's Shearing Layers: In How Buildings Learn [17], Brand describes buildings as dynamic systems composed of layers (Site, Structure, Skin, Services, Space plan, Stuff) operating at different timescales. This theory informs REALM's Building Systems Independence dimension, ensuring that faster-changing elements can be replaced without disrupting long-life components, which is an advantage particularly relevant to modular construction.

ISO 20887:2020 Design for Disassembly and Adaptability: ISO 20887:2020 defines principles such as component independence, reversible connections, material identification, and hierarchical disassembly [18]. By aligning with this standard, REALM supports end-of-life recovery, adaptability, and compliance with emerging regulatory and industry best practice.

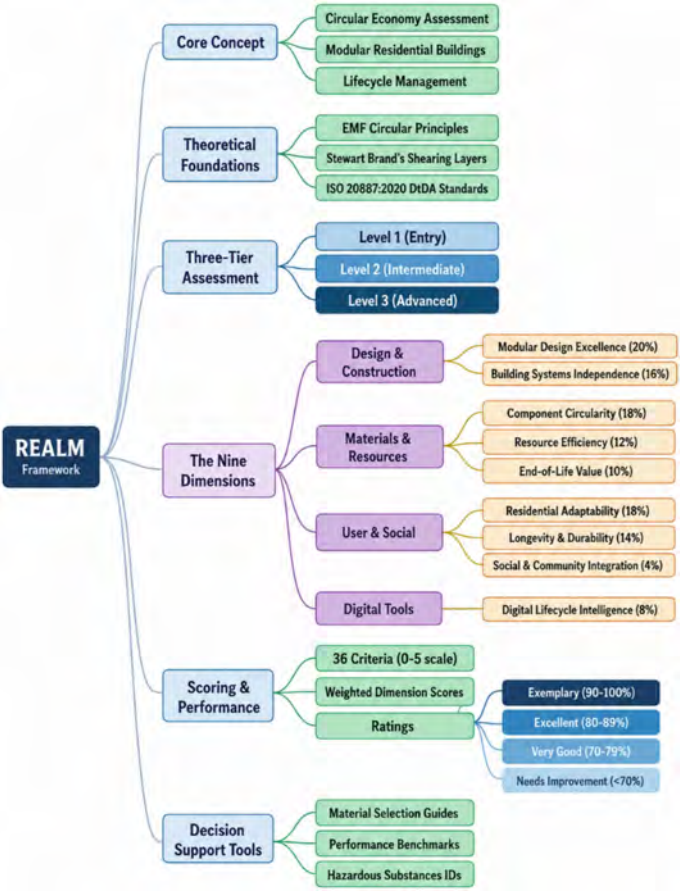

Fig. 1. REALM Framework, Dimensions, Weighting Distribution, and Scoring.

3.2 Framework Overview

REALM is structured around nine thematic dimensions, comprising 36 measurable criteria, each assessed at three requirement levels (Level 1, Level 2, and Level 3). The framework applies a weighted scoring system to generate an overall circularity index (0–100%) and is designed to be supported by decision-support tools, including material guides, performance benchmarks, and comparison tables.

Each criterion is assessed at one of three levels of increasing rigor and data requirements, aligned with the progression of project development. Level 1 corresponds to early conceptual design stages, where assessment relies on visual inspection and manufacturer declarations without requiring specialized tools or LCA expertise. Level 2 corresponds to the design development stage, where basic material inventories and simple calculations are available. Level 3 corresponds to detailed design and documentation stages, where full lifecycle assessment, lifecycle costing, and digital tools such as material passports

can be employed. Results are calculated through a weighted scoring system to generate a transparent circularity index (0–100%). Supporting tools, such as material guides and benchmarks, enhance usability from early design to post-occupancy stages.

3.3 Weight Determination Methodology

The expert panel comprised fifteen professionals from academia and industry. Dimension weights were established through structured AHP-based elicitation, informed by circularity literature and practitioner knowledge [19]. AHP is well-suited for circular economy assessment, as it enables consistent relative comparisons rather than direct weight assignment. The process followed four stages:

- *Expert Panel Formation*: An interdisciplinary panel of fifteen experts (architects, engineers, sustainability consultants, and researchers in modular construction and circular economy);
- *Pairwise Comparisons*: All nine dimensions were compared using Saaty's 1–9 scale;
- *Consistency Checking*: Logical coherence was verified using the consistency ratio (CR), with a result of 0.08 (below the 0.10 threshold), indicating acceptable reliability;
- *Weight Synthesis*: Judgments were aggregated using geometric mean and eigenvalue analysis.

The resulting weights prioritize Modular Design Excellence (20%) and Component Circularity (18%), followed by Residential Adaptability (18%), Building Systems Independence (16%), Longevity (14%), Resource Efficiency (12%), End-of-Life Value (10%), Digital Intelligence (8%), and Social Integration (4%), ensuring balanced and comprehensive circular economy coverage.

4 Demonstration Application of REALM Using the BoKlok Modular Housing System

To illustrate the applicability of the REALM framework, a demonstration assessment was conducted using the BoKlok modular housing concept as a reference case. This application is intended as an illustrative proof-of-concept rather than a full validation study. BoKlok is a residential system developed by IKEA and Skanska, based on standardized prefabricated timber modules manufactured in factory environments and assembled on site [20, 21].

The system relies heavily on off-site construction, with a large proportion of the building completed in controlled factory conditions. Prefabrication improves material efficiency, reduces construction waste, and enhances quality control compared with conventional construction methods. In addition, the modular configuration facilitates standardized components and potentially improved disassembly and material recovery at the end of the building lifecycle. These characteristics make the BoKlok (see Fig. 2) concept a suitable reference case for evaluating circular economy potential in modular residential construction.

As an example: The Modular Design Excellence dimension has a weight of 20% and includes four criteria. Based on documented characteristics of the BoKlok system,

such as standardized modular design and a high level of prefabrication, two criteria were evaluated at Level 3 and two at Level 2.

Fig. 2. BoKlok modular housing system: factory-assembled module being craned into position (left) and interior finishing in a controlled factory environment (right) [21].

These levels were converted into percentage scores (Level 1 ≈ 60%, Level 2 ≈ 75%, Level 3 ≈ 90%). The average score for the four criteria resulted in a dimension score of approximately 85%. Applying the dimension weight produced the weighted contribution: 85 × 20% = 17.0. All other dimension scores were calculated using the same evaluation and weighting procedure. The resulting values should therefore be interpreted as indicative outputs of the proposed framework, based on available documented characteristics of the reference case (Table 2).

Table 2. REALM Circular Economy Assessment Results for the BoKlok Modular Housing.

Dimension	Weight (%)	Score (%)	Weighted Result
Modular Design Excellence	20	85	17
Component Circularity	18	72	13
Residential Adaptability	18	70	12.6
Building Systems Independence	16	68	10.9
Longevity & Durability	14	75	10.5
Resource Efficiency	12	80	9.6
End-of-Life Value	10	65	6.5
Digital Lifecycle Intelligence	8	55	4.4
Social & Community Integration	4	78	3.1

Overall REALM Circularity Index: ≈ 74%, corresponding to a "Very Good" circular performance level. The results highlight strong performance in modular design and resource efficiency, while improvements could be made in digital lifecycle documentation and end-of-life recovery strategies.

5 Discussion

REALM presents several potential advantages compared with existing circular economy assessment frameworks for modular residential construction. The framework recognizes circular design elements through standardization, prefabrication, and disassembly-ready design, while fulfilling residential requirements for adaptable and permanent use. The three-tier Level 1–3 structure improves accessibility by allowing engagement according to available data, project stage, and expertise. The BoKlok demonstration illustrates practical applicability, suggesting REALM can generate understandable circularity metrics and identify improvement opportunities, particularly in digital lifecycle documentation and end-of-life recovery. However, further validation through additional case studies across different building types, climate conditions, and regulatory environments is needed, as is comparative testing against Level(s), MCI, and CBI. Although REALM is material-agnostic, benchmark calibration across steel and precast concrete systems would ensure equitable assessment. Regarding digital integration, IFC-compliant BIM models providing material specifications, connection reversibility data, and component service life estimates could enable partial automation of Level 2–3 assessments, with Digital Twin integration further supporting operational circularity monitoring.

6 Conclusion

REALM proposes a circular economy assessment framework for modular residential construction, structured around design, material, lifecycle, and operational considerations, grounded in the Ellen MacArthur Foundation principles, Stewart Brand's Shearing Layers, and ISO 20887:2020. While existing frameworks such as Level(s), MCI, and Madaster provide valuable circularity methods, they are not designed to capture modular-specific circular potential, lacking indicators for modular design, adaptability, component reuse, and operational circularity. REALM responds to these gaps through nine weighted dimensions and 36 measurable criteria across a three-tier assessment system, balancing accessibility with methodological rigor. The BoKlok application illustrates its practical use, while further comparative testing and multi-case validation remain needed to confirm robustness and usability.

Abstract. The transition to a circular economy requires reimagining waste as resource, particularly in post-disaster contexts where temporary infrastructure often becomes obsolete after its initial use. This study aims to operationalise a circular framework by repurposing nearly 215,000 container units from the 6 February 2023 earthquakes in Türkiye into affordable student dormitories. By designing a dual-use lifecycle, the research addresses the chronic shortage of university accommodation while ensuring these units remain maintained and ready for rapid deployment in potential future disasters. Using the Erciyes University campus as a case study, the methodology focuses on architectural strategies for modular retrofitting and the establishment of scalable site typologies. These designs integrate residential units with essential social and study areas, allowing for rapid implementation in diverse campus locations without requiring site-specific modification. Initial results indicate that the integration of high-standard units into permanent urban infrastructure secures the long-term economic value of the initial investment, with projections suggesting this model could yield 56.7 billion TL national savings. The research concludes that how circular strategies can transform disaster waste into resilient and permanent social infrastructure, contributing to Türkiye's 2053 net-zero emissions target.

1 Introduction

The management of post-disaster recovery remains a significant challenge within the global humanitarian landscape, particularly concerning the provision of adequate shelter. Following the catastrophic earthquakes of 6 February 2023 in Türkiye, the immediate necessity for housing resulted in the rapid deployment of approximately 215,000 container units [1]. While these structures provide essential protection during the acute phase of displacement, they are frequently associated with long-term logistical and environmental burdens. Historically, temporary housing has been characterised by a linear produce-use-dispose model, often leading to the abandonment of units or their degradation into waste [2].

This linear approach is further complicated by the prolonged nature of temporary settlements, where units remain on-site far beyond their intended lifespan due to slow reconstruction and a lack of alternative housing [3]. Consequently, the substantial financial investment required for procurement and assembly is rarely recovered, as the infrastructure is treated as a single-use asset [4]. Türkiye faces a critical student housing shortage, which was further exacerbated by the earthquakes.

The research presented here is grounded in the necessity to transition towards a circular adaptive reuse model, viewing the container inventory as a valuable resource rather than a waste liability. By repurposing these surplus units into affordable student dormitories, a dual-purpose lifecycle is established to address the chronic accommodation shortage while ensuring units are maintained for future disaster redeployment. Using the Erciyes University campus as a case study, this study demonstrates how circular strategies can transform disaster waste into resilient social infrastructure, contributing to Türkiye's 2053 net-zero emissions target.

2 Post-Disaster Housing & The Circular Economy

2.1 The Post-Disaster Inventory & The Student Accommodation Gap

On 6 February 2023, two powerful earthquakes of magnitude 7.8 and 7.5 struck southern and central Türkiye, representing the most significant seismic events recorded in the country since 1939. In the immediate aftermath, the Disaster and Emergency Management Presidency (AFAD) coordinated the establishment of 414 container cities, comprising a total of 215,224 units across 13 affected provinces. Despite the unprecedented scale of this deployment, a comprehensive policy regarding the long-term utilisation or end-of-life management of these units has not been developed. Given that compliant container prices range between 200,000 and 250,000 TL, the current market value of this idle inventory is estimated at approximately 50 billion TL [5]. Maintaining these units in a state of storage while awaiting potential future disasters is anticipated to yield adverse economic and sociological consequences, as the initial capital investment remains unproductive.

Parallel to these disaster recovery challenges, the Turkish higher education sector faces a persistent accommodation crisis. Data from the Council of Higher Education (YÖK) indicate that the student population has risen to 3.7 million for the 2024–2025

academic year [6]. A 2022 report revealed that 60.4% of students were placed in institutions outside their family's city of residence [7], suggesting that over 2 million students require housing in different cities. This demographic trend has amplified the pressure on the Credit and Dormitories Institution (KYK), which serves as the primary provider of student housing. Currently, the Ministry of Youth and Sports reports a total capacity of 950,000 beds across 822 state dormitories [8]. This capacity remains considerably below the actual demand, leaving more than one million students to seek alternative, often more expensive, housing solutions.

2.2 Critical Challenges in Temporary Housing

Post-disaster housing is conceptualised as a transitional process encompassing four stages: emergency shelter, temporary shelter, temporary housing, and permanent housing. While temporary housing is intended to facilitate a return to normalcy during permanent reconstruction, the distinction between these phases is frequently blurred, as modular solutions often persist for years beyond their intended lifespan [9].

Three primary challenges exist in this context: balancing low-cost options with fully-equipped units, placing housing near destroyed dwellings to ensure resident participation, and managing high investment costs. Systematic research into these issues enhances management efficiency and accelerates recovery [10]. Furthermore, temporary housing design directly influences the transition to permanent solutions [11]. To provide comfort, these structures are often built with a durability that far exceeds their short-term purpose, remaining functional much longer than originally intended.

Spatial Allocation. . The design of temporary housing significantly influences the well-being of displaced populations by functioning as social environments that support dignity and privacy. While proximity to disaster zones is preferred, securing vacant state-owned land is often difficult. Consequently, institutions often favour remote areas due to reduced administrative complexity. However, such peripheral locations necessitate additional services and are often unsuitable for employment, potentially leading to the social isolation of relocated households. A common failure in temporary housing design is the lack of communal spaces, which can erode community ties and increase psychological distress [2]. Successful recovery is dependent on housing that fosters a sense of belonging and the restoration of social routines. Furthermore, placing temporary housing in permanent locations is identified as a critical factor in preventing the social disruptions typical of post-disaster phases.

Environmental Challenges. Environmental sustainability remains a primary concern in the deployment of temporary units. Many existing models suffer from poor thermal insulation and inadequate ventilation, resulting in internal environments that are often unsuitable for extreme climatic conditions. This lack of thermal comfort leads to increased energy consumption as residents rely on inefficient heating or cooling systems, thereby increasing the carbon footprint of the settlement. Additionally, the reliance on non-renewable or non-recyclable materials in the manufacturing process contributes to significant waste generation. The absence of an end-of-life strategy for these units often results in their abandonment, leading to land degradation and long-term environmental liabilities [4, 12].

Economic Inefficiency. The economic viability of temporary housing is frequently questioned due to the high costs associated with its short lifespan. Financial investments are required for the procurement of units, complex logistical transportation, site preparation, and eventual decommissioning, often reaching costs that are disproportionate to the quality of the housing provided. Under the traditional linear model, these costs are treated as sunk costs, as the infrastructure is rarely reused or repurposed. The lack of maintenance protocols for units further diminishes their value, making them unsuitable for redeployment in future emergencies without significant reinvestment [4, 13]. This perspective emphasizes that temporary units should not be limited to meeting immediate shelter needs; instead, their operational lifespans can be extended by integrating them into post-disaster reconstruction processes and repurposing them for alternative functions.

The circular economy transforms post-disaster housing by applying adaptive reuse, allowing structures like container units to serve productive social functions during stable periods. This dual-use lifecycle prevents units from becoming waste, ensuring continuous maintenance and rapid readiness for future emergencies. Integrating these assets into permanent urban infrastructure minimizes the environmental impact of material extraction while protecting the long-term economic value of the initial investment [14, 15].

3 Methodology & Design Criteria

To effectively manage and distribute the massive inventory of approximately 215,000 container units currently in the post-disaster stock, a highly modular and scalable design approach is essential. This methodology ensures that units can be deployed rapidly in varying configurations and expanded as demand grows or as specific site conditions evolve. By treating the container not as a static object but as a flexible building block, the system can transition between high-density clusters and smaller, more integrated arrangements without compromising social or functional standards. To demonstrate the practical viability of this modular framework, the Erciyes University campus in Kayseri has been selected as a primary case study.

The proposed design is situated within the Erciyes University campus. The site was selected to address the chronic shortage of student accommodation while utilizing existing urban infrastructure to maintain social stability. The campus offers significant strategic advantages, including designated reserve areas suitable for immediate unit placement and adjacent land availability that allows for future expansion of the housing clusters. This site-specific application serves to validate how circular adaptive reuse can transform disaster assets into a resilient, permanent part of the urban fabric. By placing the units within a permanent campus environment, the project ensures that the housing remains maintained and ready for rapid redeployment during potential future disasters.

The baseline units feature relatively high production standards, maintaining internal comfort under varying climatic conditions because of mandatory AFAD procurement specifications. The factory envelope integrates a 40 mm sandwich panel with rockwool insulation and double-glazed windows built directly into the baseline container shell. The default material configuration is sufficient with basic building energy performance

targets, helping to mitigate severe seasonal heating and cooling spikes without requiring immediate campus-side retrofitting budget.

4 The Proposed Architectural Model

The spatial configuration of the Erciyes University case study is organised to provide high-density accommodation while meeting the specific social requirements of the student population. This model repurposes 182 container units as permanent social infrastructure (Fig. 1). Within this site plan, 126 containers are allocated for student housing to alleviate the accommodation deficit in the Turkish higher education sector. A further 56 units are designated for social and service infrastructure. This allocation is intended to reduce social isolation and support the restoration of daily routines, addressing common failures in standard temporary settlements.

Fig. 1. Proposed site plan and ground floor plan designed for Erciyes University campus

A modular six-unit sub-cluster serves as the fundamental architectural component of the site. This configuration consists of a staggered vertical arrangement, with four units on the ground level and two units on the upper level. This multi-level layout provides semi-private outdoor areas and terraces, which are necessary to ensure resident privacy. To support community cohesion and logistical requirements, localised common areas are integrated for every 42 residential units. These zones include study spaces, laundry facilities, and small cafeterias, ensuring the even distribution of essential services across the various site typologies (Fig. 2).

A centralised dining hub, constructed from 30 units, functions as the primary social facility for the campus village. This central facility is intended to prevent the psychological distress and erosion of community ties often caused by a lack of communal

Fig. 2. Axonometric view of the proposed housing units

space in traditional temporary housing. The arrangement of modular sub-clusters creates sheltered, semi-private outdoor spaces between buildings that serve as quiet zones for individual study or rest. These areas are integrated with soft landscaping and green buffers to enhance the ecological quality of the site and provide a natural environment for resident well-being (Fig. 3). The integration of these units into the university's permanent infrastructure is intended to preserve the long-term economic value of the initial investment.

Fig. 3. Perspective views of the proposed housing units

The projected public financial savings (S_{nat}) are substantiated by comparing the capital expenditure of conventional dormitory construction against the adaptive reuse of the container inventory. According to official unit construction cost benchmarks [16], the standard investment for a conventional higher education dormitory is approximately 234,000 TL per student. In contrast, by allocating two students per repurposed container

unit (with an initial unit cost of 200,000 TL) the effective expenditure is reduced to 100,000 TL per student, yielding an immediate capital savings of 134,000 TL per student space. To formalize this cost avoidance across the nationwide asset base, the financial optimization model is defined in Eq. (1):

$$S_{nat} = N_{students} \times (C_{new} - C_{retro}) \quad (1)$$

Where $N_{students}$ represents the total projected housing capacity of 430,000 students (utilizing the nationwide pool of 215,000 container units), C_{new} is the conventional dormitory construction cost per student (234,000 TL), and C_{retro} is the effective container procurement/retrofitting cost per student (100,000 TL) which explicitly incorporates a baseline 15% allocation for regional logistics, site utility integration, and unit repair based on post-disaster inventory depreciation standard benchmarks. Consequently, this circular management strategy is projected to prevent a critical public expenditure, securing an estimated 57.6 billion TL in national treasury savings (S_{nat}) while simultaneously bridging the active student accommodation deficit.

5 Conclusion

This research demonstrates a systematic transition from a linear produce-use-dispose model of post-disaster housing toward a circular adaptive reuse framework. Using the Erciyes University campus as a primary case study, the paper provides a scalable architectural typology for the nationwide conversion of disaster-related assets into permanent social infrastructure. By repurposing approximately 215,000 container units from the 2023 Türkiye earthquakes into affordable student accommodation, the proposed model operationalises a dual-use lifecycle that simultaneously resolves post-disaster waste management and chronic university housing shortages. This strategy effectively transforms a significant environmental and financial liability into a resilient socio-economic asset, projected to yield nationwide public savings of 57.6 billion TL. Beyond these financial metrics, the developed architectural model prioritises thermal comfort, social well-being, and community cohesion through modular design, semi-private outdoor spaces, and integrated social facilities. Ultimately, this study offers a practical, replicable pathway for post-disaster resource efficiency, contributing directly to Türkiye's 2053 net-zero emissions targets by minimizing new material extraction and securing the long-term value of public investments.

Abstract. Having pre-demolition inspection data in a semantic structured format offers significant benefits. It enables seamless integration into Building Information Models (BIM), allowing for advanced analysis, visualization, and decision-making regarding material reuse, recycling, and deconstruction. It is the first step towards a truly circular BIM, a system capable of integrating Digital Material Passports into BIM software and allowing designers to use materials, products or even complex assemblies from the donor building in their new projects. Manually creating structured data is a complicated and time-consuming task prone to errors and inconsistencies, and therefore most of today's pre-demolition audit datasets are tabular. This paper introduces automated process of reconstruction of material and product database obtained by manual inspection of a residential building in Svalbard, Norway into a semantic representation formatted according to ISO 16739-1:2024 (IFC 4X3 ADD2). The conversion from tabular data to a standard Building Information Model requires identification and composition of the spatial context and process workflows. The inputs from the pre-demolition audit have unique material and product identifiers by Block Materials and are classified according to their reusability, recyclability, deconstructability, separability and preuse by Concular platform. The outputs will be further linked to 3D geometry obtained by Augmented Reality Mobile Mapping System combined with Li-DAR scan and additional surface features obtained by Active Hyperspectral Sensing and internal structures obtained by Ground Penetrating Radar.

Keywords: Circular Economy · Building Information Modelling · Pre-demolition Audit · Industry Foundation Classes · Digital Material Passport

1 Introduction

The construction sector generates significant demolition waste, while valuable materials remain underutilized due to fragmented documentation practices [1, 2]. Pre-demolition audits produce important data, but this information is typically stored in tabular formats without semantic structure or spatial context, limiting its reuse potential [2]. The lack of structured integration and storage of audit data into Building Information Modelling

(BIM) environments signals a lower digital maturity than other construction processes [3] and therefore risks preventing scalable circular workflows from developing. Manual reconstruction of BIM models from spreadsheets is time-consuming, error-sensitive, and not economically viable for large-scale implementation [4].

Regulatory developments such as the Construction Products Regulation (CPR) [5] and the Ecodesign for Sustainable Products Regulation (ESPR) [6] are increasing the demand for Digital Product Passports (DPPs), requiring interoperable and machine-readable product information. BIM standards such as Industry Foundation Classes (IFC) ISO 16739 [7] provide a machine-readable, semantically rich data structure capable of representing materials, components, assemblies, and lifecycle information, offering a potential backbone for circular construction workflows. Furthermore, IFC is the default format for digital communication in the construction sector [8]. Existing research and industry platforms support material inventories, urban mining databases, and circular documentation (e.g., [9, 10]), yet they largely rely on manual modelling processes [1, 4]. Although earlier automation efforts have shown the potential of applying computer vision techniques to building documentation [2, 11], the automatic processing, transformation and storage of tabular audit data into IFC-compliant BIM models has, to the knowledge of the authors, not been researched yet.

A clear research gap therefore exists in the absence of validated, automated pipelines that convert tabular pre-demolition audit records into semantically structured BIM models capable of supporting DPP generation and interoperability. This paper addresses that gap by answering the following research question: How can tabular pre-demolition audit data be automatically transformed into an IFC-compliant BIM model that enables Digital Product Passport generation and supports circular construction workflows? To answer this question, we propose and develop an automated transformation and enrichment pipeline that reconstructs spatial context, classifies materials and components using deep learning systems for semantic mapping, and generates IFC-compliant models. The pipeline further enables the extraction of DPP-compatible datasets aligned with open JSON specifications and integrates deconstruction workflows within the IFC structure. The proposed approach is then demonstrated using a residential building case study, contributing toward circular BIM operationalization through automated semantic integration of pre-demolition audit data.

2 Classification of the Inspection Records

Building audits usually generate a bill of materials and components, providing detailed data on their quantity and quality. However, these records often lack thorough documentation of spatial configuration, location, and the relationships between materials and components within the building. Such details are essential for efficient reuse and recycling, as they help identify which items can be recovered, where they are located, and how they interact with other elements, thereby streamlining deconstruction and material selection for new projects. To overcome this gap, we apply a design science research approach [12] to develop an automated transformation and enrichment pipeline.

2.1 Basic Concept

The processing of pre-demolition audit records for further recovery and reuse of the materials and components has to ensure regulatory compliance and clarity, and therefore it should be based on the CPR [5] definition that a product is *formed, or formless physical item or a kit designed for or utilized with a purpose and placed on the market or put into service*. In this study, formed items are referred to as components, formless items as materials, and kits as assemblies. All such product shall be related to their DPPs according to the ESPR [6] and Annex V of the CPR.

The goal of our study was to generate DPP data format for products recovered from the building demolition based on the BIM and structured according to the latest version of IFC standard [7] IFC4X3 ADD2. This data format may not be fully compliant to the ESPR requirements because the relevant Delegated Acts were not yet adopted by the European Commission at the time of writing this manuscript. However, the published example of structural steel component [13] is aligned to the Technical Specification for the current harmonized product standard [14].

To generate DPP of the identified products, a full IFC transformation, enrichment and validation pipeline was developed to turn tabular pre-demolition audit data into interoperable BIM and circular-economy-ready datasets.

2.2 Unique Identifiers

One of the Building Logbooks in the Sum4RE project, Cirdax, uses a blockchain module to link materials passport to the Ethereum Blockchain and provides Universally Unique Identifiers (UUIDs) to these materials. Materials can be verified by registering the ownership of the passport in the blockchain, which also gives the possibility to see that registration as a property right at the time of registration.

The UUID blockchain registration serves as a property right that is also included in the material passport by means of its hash, i.e., the blockchain identity of the material passport. This is an essential characteristic of an UUID, as not only location, or traceability are organised in this way, it also accounts for the organisation of immutable property rights that can be used as legal framework for the reuse of materials in digital marketplaces. Therefore, the owner of the materials is always known. This enables organizing important tasks related to the circular requirements for materials, both in terms of delivery and the quality of the materials in the future. Information aspects that can get its place in the IFC-format, making it Circular BIM (or C-BIM).

2.3 Assessment of the Environmental Performance

Reusable materials have social, environmental and a financial value. The social and environmental value of materials is broader than their financial value because they also include qualitative benefits that cannot be directly recorded in monetary units. An example of these externalities is the value of saved CO_2 emissions due to the reuse of materials and components from a building because their reuse avoids the production of new materials and the environment is not further affected. Such savings can only be achieved if these materials and components can be used in an alternative way. This means that

they can be detached and separated without much damage and can once again provide a function in a real estate object with complete information for the buyer and seller.

An example of automated evaluation of reusability of building materials and components and their associated environmental impacts is provided by Concular [9]. However, without any future integration in the construction works the environmental performance of a materials is not guaranteed and most of the time of very little value. Since establishing property rights in Cirdax platform [10] also organises this kind of value, the assessment of the environmental performance can be linked to the information on that right by using UUID's as part of the general C-BIM information infrastructure,

3 Mapping the Inventory to the Building Information Model

3.1 IFC Structure

Industry Foundation Classes (IFC) are an open data model for describing built assets across their lifecycle (design, construction, operation, and decommissioning) with entities, relationships, properties, and geometry defined in a machine-interpretable way. In most cases IFC substitutes 3D geometric models of the buildings and their services that are used for visualization and collision-checking. However, geometry is only one of the aspects of the IFC semantics, and a valid model can exist without specific geometric definitions. Such model can be reconstructed from the inventory of materials and components with the option to provide geometric representation of the entities later, for instance obtained by LiDAR scanning.

The minimum functional structure of the inventory-based IFC model is illustrated in Fig. 1 where the materials are assigned to *IfcMaterial* entities, components to any subtype of *IfcBuiltElement* entity, kits to *IfcElementAssembly* entities and related external documents to *IfcDocumentInformation* entities. The recommended waste treatment and recovery from the pre-demolition audit are represented as *IfcTask* entities within the *IfcWorkSchedule.*

3.2 Automated Processing of the Tabular Data

The pre-demolition audit data obtained from the Concular and Cirdax platforms were converted into a standards-compliant IFC models using a dedicated tool developed by VTT. The tool automatically creates or enriches existing IFC models with a spatial structure (storeys, spaces), classifies building elements, materials, product types, and quantities, and generates links to the Environmental Product Declarations (EPDs), and work schedules for deconstruction and demolition. The resulting IFC is validated using both IFC schema validation and Information Delivery Specification (IDS) rules as described in the following section.

To provide a consistent IFC structure, entities defining the project, site and building are created if needed, and SI units defined. The spatial structure follows the information identified in the inventory (e.g. room and storey of the building) if available. Then the appropriate IFC entity types are identified using Large Language Model (LLM)-based classification mechanism from the free text descriptions and tabular data provided by the

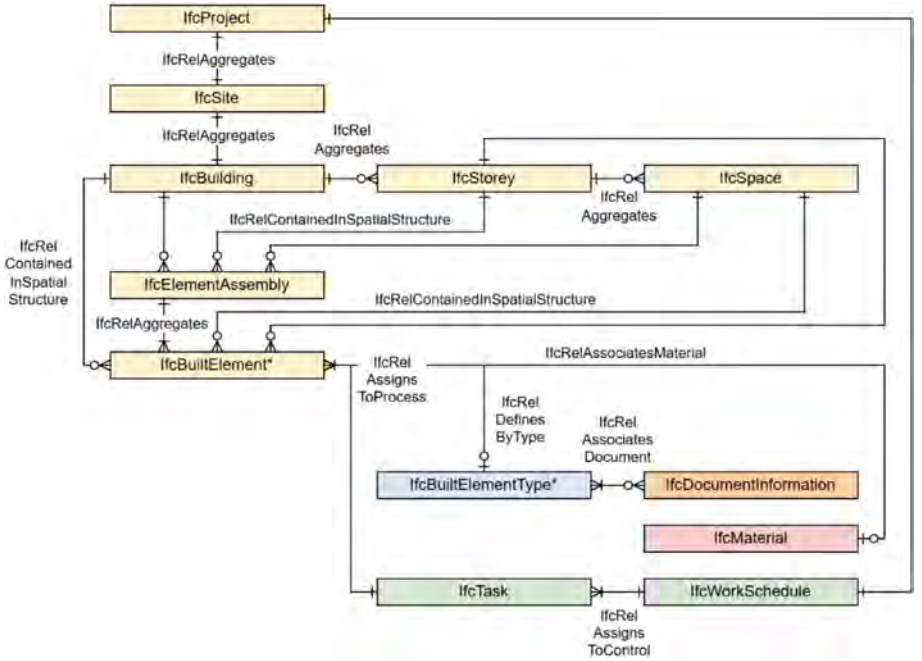

Fig. 1. IFC structure of the essential building information elements extracted from the inventory of materials and components

material audit. The used model, gemma3:27b [15] ensures that the classification can be done locally, protecting the sensitive data, and on the information provided in different languages. Since the text fields in the audit records are often repeated, the classified terms are stored in the local cache. Material definitions and building element types are updated according to the pattern pre-defined according to the JSON schema [13] for each format of the material inventory. This configuration file ensures that the specific properties of the materials and components are stored in appropriate places. For instance, the exported inventories from the Concular database were transformed according to the schema published in the GitLab project [13].

3.3 Generating IFC Work Schedule

One of the important aspects of the pre-demolition audit of the building is to identify and recommend the most environmentally efficient recovery options for the materials and components and propose further testing and measurement. Recommendations are sometimes given as scores (such as reusability or recyclability) to assist owners and contractors with future decisions for example according to the Concular methodology [16]. Based on this information it is possible to create a sequence of tasks represented as *IfcTask* elements with related entities from the inventory. The relevant information; types for such tasks are *INSPECTION*, *TESTING*, *DEMOLITION*, *DISMANTLE*, *DISPOSAL*,

and *LOGISTICS*. The tasks are generated under *IfcWorkSchedule* element assigned to the *IfcProject* as illustrated in Fig. 1.

3.4 Validation and Information Delivery Specification

The integrity of the generated IFC models is validated using the offline version of buildingSMART validation service [17] and the completeness of the information is checked using the Information Delivery Specification (IDS) standard [18].

4 Extraction of the Data for the Digital Passport

When the elements of the inventory of products and materials are integrated in the Building Information Model (BIM), it is possible to generate a digital passport for specific product (material, component or kit) with all the relevant links extracted from the BIM structure. For instance, the digital passport of the material may be linked to the component(s) where it is used, the digital passport of the component may be linked to the relevant material(s) and buildings(s) and the digital passport of the kit may be linked to the sub-component(s) and building(s). This structure is combined in our study with the existing open JSON specifications of DPPs by United Nations Economic Commission for Europe (UNECE) [19] and Material Identity [20] and illustrated in Fig. 2. The elements from Material Identity such as transaction data, test results, chemical composition, standards and validation were extended or directly imported in the schema for the compatibility reasons, while the draft UNECE schema was used as is. The examples

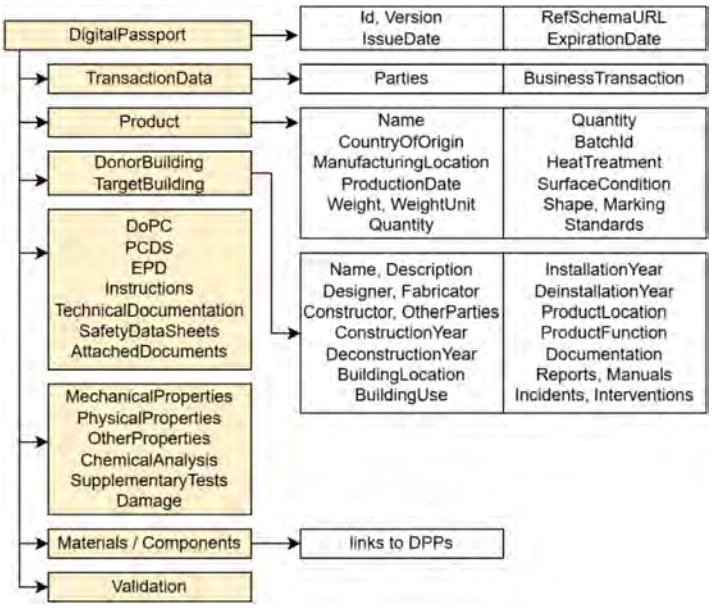

Fig. 2. Basic structure of the DPP generated from BIM according to Material Identity [20]

of generated DPP outputs are published in the GitLab workspace of the project [13]. The extraction was successfully demonstrated on several IFC models converted from Concular database, Cirdax database and created by Autodesk Revit 2026, proving compatibility with different input sources. The source files are also included in the GitLab project and open to examination.

5 Summary and Conclusions

This paper addresses the limited interoperability of pre-demolition audit data, which is typically generated and stored in tabular formats not suitable for circular construction workflows. It describes a transformation process of such data into a semantically structured, IFC–compliant BIM. The approach reconstructs the essential IFC structure by generating spatial hierarchies, classifying materials, components, and assemblies using LLM-based semantic mapping, and linking products to environmental data, documentation, and deconstruction tasks.

Audit data from Concular and Cirdax platforms are preserved through UUIDs, and their completeness is validated using IFC schema checks and IDS. The geometry-independent semantic BIM reconstruction is feasible, and the model is suitable for later enrichment using sensing technologies and extraction of elements for the new design workflows. It also reduces manual modelling effort, supports DPP generation, and provides a standards-based pathway toward a scalable C-BIM.

It should be noted that the integration and testing of Concular and Cirdax workflows is ongoing work at the time of writing this manuscript, and therefore the final examples and schema definitions published in GitLab project may slightly differ.

Abstract. Reducing embodied CO_2 emissions is critical for decarbonizing the construction sector, particularly in Brazil, where housing demand is high and structural systems account for a substantial share of life-cycle impacts. Yet embodied carbon assessments are typically conducted late in the project lifecycle, when major design and supplier decisions have already been defined, limiting their mitigation potential. This study investigates the conditions necessary to enable embodied CO_2 estimation in the early stages of residential building design. As the first phase of a Design Science Research approach, it combines a literature review with structured discussions involving Brazilian structural designers and specialists in cement and concrete technologies. The findings indicate that effective early-stage assessment requires incremental calculation accuracy aligned with the progressive availability of project information, explicit management of uncertainty through mitigation ranges rather than single values, and the use of transparent, regionalized emission factor inventories grounded in open data. Digital integration through interoperable Building Information Modelling (BIM) workflows is also essential to ensure traceability and automated quantity extraction. These principles informed the conceptual development of an iterative benchmarking platform designed to provide feedback during design evolution. By repositioning embodied carbon calculation as a proactive, design-integrated process, the framework enhances decision-making, risk management, and low-carbon specification in housing projects.

1 Introduction

The built environment is responsible for more than one-third of global greenhouse gas (GHG) emissions [1]. Rapidly reducing GHG emissions from buildings is central to mitigating global climate change. To date, carbon mitigation efforts have focused primarily on the operational phase [2]; however, embodied carbon emissions from the manufacturing of construction materials already account for approximately 18% of global buildings-related emissions [1]. As advances in heating, cooling, lighting, and ventilation technologies reduce operational emissions, embodied carbon is becoming increasingly significant from a life-cycle perspective [3]. In the Global South, this proportion is often even higher, as emissions during use and maintenance phases are lower due to limited need for space heating [4]. Accordingly, leading engineers and researchers have highlighted the need for a standardized global methodology to estimate embodied carbon dioxide emissions in the building sector [3].

In Brazil, the housing deficit is estimated at nearly 8% of the total housing stock [5], while 40.8% of urban households experience some form of inadequacy [6]. This scenario will inevitably drive growth in the construction industry; however, expanding supply must be accompanied by improved performance, particularly through reductions of carbon emissions associated with construction materials. In this context, each construction technology presents trade-offs in terms of (i) embodied carbon, (ii) material costs, and (iii) sectoral innovation potential. A clear understanding of these trade-offs is essential to identify cost-effective construction solutions that minimize carbon impacts in the early stages [7].

Mitigating embodied carbon in housing requires quantifying construction materials and estimating their associated carbon footprints; however, there is limited knowledge of the embodied carbon of residential buildings in Brazil. To support consistent CO_2 mitigation policies across the housing life cycle, it is essential to establish a standardized, systematic inventory of housing carbon footprints, enabling the definition of a national baseline for Brazilian dwellings. In this context, the objective of this paper is to propose a framework that enables embodied carbon calculation in the early design stages, proposing an incremental-accuracy approach based on publicly available supply-chain data for the predominant structural materials. By anticipating embodied carbon scenarios during the design phase and presenting results as mitigation potential ranges, the proposed system aims to support informed, low-carbon decision-making in housing projects.

2 Research Design

The research adopted the Design Science Research approach comprising (1) problem understanding; (2) generation of alternatives; (3) artifact development; and (4) evaluation [8]. This paper addresses only the first stage, including a literature review, experts' discussions, and the conceptual modeling of an iterative carbon calculation system. Expert discussions and consultations with an advisory committee were conducted to validate the conceptual assumptions and align the model with current industry demands. The committee included specialists from the cement industry, design software sector, and architectural and engineering design firms. Discussions occurred iteratively as the model's

technical advancement progressed, enabling continuous assessment of its feasibility, applicability in design workflows, and alignment with carbon-reduction requirements in the construction sector.

Problem understanding was organized into sequential steps: (i) identification of research gaps and critical variables in recent literature; (ii) assessment of the technical and operational conditions required to enable carbon estimation in early design stages; and (iii) development of a logical-sequential model grounded in incremental precision and mitigation ranges as outputs. This stage concludes with the definition of an initial briefing to support the subsequent generation of artifact alternatives [8].

3 Research Gaps and Model Proposal

3.1 Diagnosis of Reactive LCA and Mitigation Potential

The calculation of embodied carbon in construction is typically carried out at a late stage, when main construction decisions have already been consolidated [9]. Under these conditions, conventional Life Cycle Assessment (LCA) primarily operates as a retrospective verification tool — valuable for diagnosing the existing situation but less effective as a decision-support mechanism during design [10]. Because it requires detailed supply chain data, results are often delivered when the potential for design changes is minimal, limiting technically significant interventions [11].

The availability of a technically robust yet strategically delayed instrument reduces mitigation potential, turning carbon assessment into a record of performance rather than a driver of design change [12]. To influence outcomes, carbon data must be available in time to inform design decisions that determine material use and supplier selection [13]. Integrating carbon estimates into the conceptual stage requires aligning calculation methods with information generated by the design team [14], particularly structural typology, material quantities, and geometric parameters. Adapting calculations to these early inputs enables influencing technical specifications and increasing mitigation potential [15].

Recent approaches propose benchmark-based strategies [16], parametric models [17], and predictive methods that estimate emissions under controlled uncertainty [18], thereby shifting LCA from a post-design specialization to a design-oriented tool [19]. Recognizing that sectoral decarbonization depends less on measurement precision than on repositioning calculations within the design process, these studies advocate agile methods with varying levels of automation compatible with collaborative digital technologies such as BIM [11]. Current discussions focus on managing uncertainty, ensuring estimates are simple and rapid enough for the design workflow, identifying which information is available at each project stage [15], and defining output that best supports mitigation efforts [20].

3.2 Level of Information Obtained in Design Projects

In Brazil, CO_2 emissions in the built environment are predominantly associated with embodied carbon, which encompasses emissions from extraction, transportation, processing, use, and end-of-life of building materials. Operational CO_2 emissions derive

from energy use during building operation, water consumption, and associated wastewater generation [21]. The analysis is restricted to CO_2, as it accounts for approximately 75% of total global warming potential and more than 90% of that of major construction materials [22].

Embodied carbon in buildings is mainly in the structure and scales with material quantities. In structural masonry housing, each m^2 of wall maps to set amounts of blocks, mortar, grout, and reinforcement steel, each with a CO_2 emission factor. Using these quantities, you can calculate $kgCO_2/m^2$ and the total emission from the wall area. This approach highlights the biggest carbon drivers and can be refined as design details become available.

3.3 CO_2 Calculation Framework in Design

Figure 1 illustrates the conceptual logic of the benchmarking system, in which successive design versions can be evaluated iteratively until user validation is achieved.

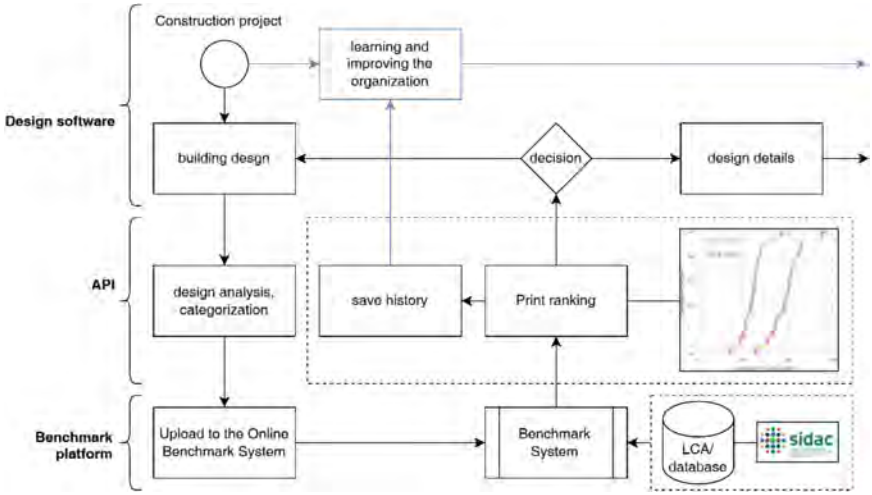

Fig. 1. Flowchart illustrating the conceptual logic of the benchmarking system.

The system calculates embodied CO_2 based on project inputs and positions the result within a ranking relative to comparable projects. Emission factors are obtained from publicly available inventories, such as the SIDAC (Information System for Environmental Performance in Construction) [23]. Continuous system use is expected to expand the project inventory and progressively refine benchmarking criteria.

3.4 Incremental Accuracy and Uncertainty Management

A single index cannot define a building's embodied carbon, as this approach tends to obscure the uncertainty arising from undefined suppliers and the lack of project detailing—issues that are often unresolved or undocumented in early design stages [24].

Likewise, it is inappropriate to require calculation through a single formula: if extensive data are demanded, the estimate can only be produced in later project phases, when opportunities for meaningful design changes are already limited; conversely, if minimal data are required, the method fails to capture and leverage the progressive increase in information that characterizes different design processes and stages [10].

Calculation accuracy should be incremental, evolving alongside project development and reducing uncertainty as information becomes available, rather than being concealed within a single aggregated value, as observed in global approaches [24]. This implies expressing results as a range representing the mitigation potential of embodied CO_2 through design, defined by minimum and maximum values. As project detailing advances and supplier-specific embodied carbon inventories become more granular, this range progressively narrows [23]. In subsequent phases—particularly those dependent on supplier selection—the interval becomes a concrete estimate of the project's mitigation potential [15].

3.5 Transparency: Empirical Grounding and Digital Integration

The reliability of embodied carbon estimates in design depends less on computational complexity than on the integrity of the informational ecosystem that supports them [23]. Sectoral diagnostics indicate that the main barriers to calculation stem from industry fragmentation, which hinders access to consistent data; the absence of clear parameters for interpreting model outputs; and the lack of verification mechanisms, particularly when data sources are not traceable—either due to limited digitalization or because results are generated by black-box models employing sophisticated algorithms, such as neural networks [25]. Transparency and trust, therefore, depend primarily on the integrity of the information ecosystem supporting the calculation [26].

Generic, synthetic, or internationalized databases—commonly embedded in design software for embodied CO_2 calculations—often overlook regional specificities, production technologies, and logistical conditions [23]. A systemic response requires publicly available, open inventories fed by primary input data and linked to supply chain origin, variability, and seasonality [23]. This empirical grounding reduces extrapolation bias and aligns calculations with actual execution conditions [20]. However, such grounding alone is insufficient without digital instrumentation supported by open modelling standards and automated quantity extraction [16]. Integrating CO_2 estimation into the design workflow depends on interoperability with CAD-BIM systems, enabling traceability between design parameters and emission factors [17].

These conditions support the structuring of a design-support system that integrates data, modelling, and verification layers. The system architecture comprises three layers: a data layer with regionalized emission factors, a modelling layer that links these factors to design parameters, and a verification layer that ensures traceability and version control. Within this framework, embodied carbon calculation becomes a verifiable technical process embedded in project development and specification.

3.6 Implications and Limitations

Anticipating embodied carbon calculations offers benefits, including greater investment predictability, as key financial commitments are often made during the early design stages of a building [13]. By explicitly acknowledging existing variability rather than concealing it, the data provide valuable input for risk management, enabling the anticipation of possible scenarios and continuous monitoring of the project's trajectory throughout the building's development and production lifecycle [23]. The system's limitations are primarily related to the automated extraction of robust project data, the lack of standardization in BIM models, and the still-limited availability of carbon emission factor data for construction materials in Brazil.

4 Conclusions

This study addressed a structural gap in the Brazilian construction sector: the lack of an information infrastructure to support embodied carbon mitigation during the early design stages of residential projects. Based on a Design Science Research approach, the study identified conditions to reposition embodied carbon assessment from a reactive verification exercise to a decision-support instrument. The findings indicate that effective early-stage mitigation depends on three core principles: incremental accuracy aligned with the progressive availability of project information; transparency based on open, regionalized, and empirically grounded emission factor inventories; and digital integration through interoperable BIM workflows ensuring traceability and automated data extraction.

Expressing results as mitigation ranges, rather than single values, allows uncertainty to be explicitly managed while maintaining relevance for design decision-making. These principles informed the conceptual development of an iterative benchmarking framework designed to provide feedback during design evolution. By embedding carbon estimation into design iterations, the proposed system enhances predictability, risk management, and the capacity to influence technical specifications. Although developed within the Brazilian housing context, the framework offers transferable insights for integrating embodied carbon mitigation into early-stage design processes in other settings.

Acknowledgments. This research was developed within the framework of the project "CO_2 Mitigation and Quality of Life in Housing: MCMV & Self-Managed Housing," with the support of Caixa Econômica Federal, Fundação para o Desenvolvimento Tecnológico da Engenharia (FDTE), and Universidade de São Paulo (USP). The National Council for Scientific and Technological Development (CNPq), Brazil, also provided financial support (grant 172046/2023-8).

Abstract. Transitioning the built environment towards a circular economy requires standardized assessment methods to effectively measure and track circularity progress. Building upon our recently published review of academic studies, this work investigates complementary grey literature to understand how circularity is assessed by 1) analyzing existing standards, policy frameworks, Green Building Rating Systems, and specialist toolkits, and 2) conducting a comparative analysis to identify alignments and gaps between policy, practice, and academic approaches. Results show that circularity indicators primarily focus on the building level. Assessment methods vary, from quantitative approaches in standards, policy frameworks, and toolkits to semi-quantitative scoring in Green Building Rating Systems. A focus alignment is observed between grey literature and academic studies. Environmental aspects, particularly material and energy flows, and technical aspects such as design-for-disassembly receive the most attention, while social, economic, and managerial dimensions are less assessed. However, in terms of applicability, academic studies propose a more diverse set of indicators, which are often complex and difficult to apply in practice. Overall, the findings highlight fragmented methodologies for circularity assessment with varying levels of detail and inconsistent scoring approaches, which reduces comparability and hinders the development of a standardized assessment. Based on this, this study recommends future research to further refine existing methods to facilitate standardization. By synthesizing insights from policy and practice against academic studies, this study offers a basis for developing more consistent circularity assessment methods and, in turn, supporting the transition to a circular built environment.

1 Introduction

The built environment represents a key sector in the transition towards a circular economy (CE) [1, 2]. Countries and regions have introduced policies and strategic frameworks to support this transition, such as the new Circular Economy Action Plan of the European Union [3] and the revised Energy Performance of Buildings Directive [4]. Despite these efforts, the effective implementation of circular strategies in the built environment requires assessment methods to measure and track circularity progress. ISO 59004:2024 defined circularity assessment as the evaluation and interpretation of results and impacts derived from a circularity measurement [2]. However, current ISO standards (e.g., ISO 59020:2024 [5]) do not specifically address circularity assessment of the built environment [6]. In the absence of standardized guidance, a variety of circularity assessment approaches has been developed. Existing research has attempted to synthesize these approaches. For example, the authors' previous work [7] conducted a systematic literature review to examine circularity assessment methods in the built environment, analyzing 66 academic studies. However, as highlighted by Khadim et al. [8], focusing solely on academic studies does not capture the full picture, as grey literature also contributes significantly to the development of existing approaches. Thus, a critical research gap remains: there is a lack of comprehensive understanding of how circularity in the built environment is assessed within grey literature, as well as a lack of comparative synthesis between these approaches and those in academic research.

To address the research gap, this work builds upon our previous review [7] of academic approaches and extends the scope to grey literature. Specifically, the work aims to: (1) identify circularity assessment methods in the built environment across building, neighborhood, city (and beyond) levels within grey literature, and (2) conduct a comparative analysis of the findings against the results of our previous review of academic literature [7] to identify alignments and gaps. By synthesizing insights from policy and practice with academic studies, this work serves as a foundation for the development of more consistent circularity assessment methods, thereby supporting the transition towards a circular built environment.

2 Methods

A review of grey literature was conducted to investigate how circularity is assessed in the built environment across building, neighborhood, and city (and beyond) scales. In this study, grey literature refers to non-peer-reviewed documents produced by governmental bodies, international organizations, industry associations, and professional initiatives. Five key categories of sources were targeted to capture both policy- and practice-oriented approaches: (1) global indicator frameworks, (2) European standards, (3) European policy-driven frameworks, (4) Green Building Rating Systems (GBRS), and (5) specialist toolkits including technical reports and project deliverables.

Only documents published in English were considered and document screening was conducted based on two main criteria: (Criterion 1) the focus on the built environment, including only documents at building, neighborhood, or city and beyond scales; and (Criterion 2) whether documents proposed indicators for circularity assessment,

either explicitly mentioned as CE assessment indicators or implicitly addressing the key resource principles of CE (e.g., close, slow, narrow, regenerate resource loops) [9, 10]. This resulted in a total of fourteen sources included in the review, which will be scrutinized in the next Section. Relevant information was extracted and organized in an Excel table, including source type, name of source, name of indicator, assessment methods, spatial scale of application, and CE dimensions and aspects addressed.

Following the analysis of grey literature, a comparative analysis was conducted against the findings of our previous systematic review of academic studies [7]. This comparison was structured around three aspects: (1) assessment method, (2) spatial scale of application, and (3) the coverage of circularity dimensions and aspects.

3 Results and Discussion

Fourteen sources were analyzed, and their respective circularity assessment indicators were collected. An overview of the reviewed sources, categorized by type, as well as the number of indicators identified in each, is provided in Table 1. The following subsections first examine the assessment methods, the circularity dimensions and aspects addressed, and the spatial scales considered. This is followed by a comparative analysis between the grey literature and academic studies.

3.1 Content Analysis

Quantitative, semi-quantitative, and qualitative methods are applied for circularity assessment across the selected grey literature. For instance, the European standards EN 15978 [13] and EN 15804 [12] include the indicator "Components for reuse," which is quantitatively assessed using Life Cycle Assessment. Semi-quantitative methods use ratings or scores to translate qualitative criteria into numerical values. The New European Bauhaus [15], for example, introduces the "Durability" indicator to measure the capacity of building to maximize the interval between refurbishments and renewals, which is scored on a scale from 0 to 100 based on a predefined scoring table. Qualitative methods consist of design criteria that are not intended to be quantified. For example, in LEED for Building Design and Construction [17], the "Planning for zero waste operations" is defined as a prerequisite that projects must meet in order to be eligible for certification, without assigning a numerical score. Compliance is instead evaluated based on specified strategies applied and documentation. Overall, quantitative methods are the most frequently applied, accounting for half of the assessment indicators identified across the reviewed grey literature. They are predominantly used in global indicator frameworks, European standards and policy-driven frameworks, and specialist toolkits. Semi-quantitative methods are also widely applied, particularly within GBRS, but are also found in European policy-driven frameworks and specialist toolkits. In contrast, qualitative methods are rarely applied and limited to GBRS, where they appear as prerequisites. Notably, in all reviewed grey literature, circularity assessment indicators are never applied individually; instead, multiple indicators are applied to capture different dimensions and aspects of circularity. For instance, the Level(s) framework [14] applied three quantitative and one semi-quantitative indicators for circularity assessment.

Table 1. Overview of analyzed sources and number of indicators.

Source category	Source	Indicator (n)
Global indicator framework	UN Sustainable Development Goals indicator framework [11]	2
European standard	EN 15804 [12] and EN 15978 [13]	4
European policy-driven framework	EU Level(s) [14]	4
	New European Bauhaus [15]	14
Green Building Rating System	BREEAM Communities [16]	5
	LEED for Building Design and Construction [17]	8
	LEED for Neighborhood Development [18]	7
	LEED for Cities and Communities [19]	9
	DGNB for Urban Districts [20]	5
	WELL [21]	2
	DGBC – Framework for Circular Buildings [22]	6
Specialist toolkits	Circular Construction in Regenerative Cities [23]	26
	ARUP Circular Building Toolkit [24]	12

A total of five circularity dimensions are covered by the reviewed grey literature, namely environmental, economic, social, technical, and managerial. Among these, the environmental dimension is the most extensively addressed, accounting for 70% of the identified indicators. Within this dimension, material efficiency represents a key aspect, which captures different stages of material flows, including inflows (e.g., use of low-impact materials), outflows (e.g., quantities of construction and demolition waste), as well as circular flows connecting them (e.g., percentage of materials for energy recovery). Energy is another frequently addressed aspect, with indicators focusing on demand-side energy efficiency and reduction, supply-side renewable energy generation, and the interaction between energy demand and supply amongst others through energy flexibility. Other environmental aspects, although less frequently covered, include water use, emissions, land use, and impacts on ecosystems and biodiversity. The technical dimension, which includes design and construction processes that enable circularity (e.g., design for adaptability, disassembly, deconstruction, longevity, and innovative construction methods), is the second most frequently addressed, covered by 18% of the identified indicators. In contrast, the economic (e.g., financial performance), social (e.g., cultural heritage conservation), and managerial (e.g., business models and innovation) dimensions receive considerably less attention.

Regarding the spatial scales of circularity assessment, most sources focus on the building level, particularly European standards and policy-driven frameworks, and specialist toolkits. Neighborhood and district scales are also considered, especially within GBRS. Larger spatial scales, such as the city and beyond, are captured by both global indicator framework and specialist toolkits, such as CIRCuLT [23]. While the majority of frameworks focus on a single scale, the LEED system offers different rating schemes that operate across different spatial scales, ranging from individual buildings to neighborhoods and cities. At the building level, indicators target improvements in the efficiency of water, energy and material use [17]. At the neighborhood level, the assessment shifts toward synergies between buildings and the shared systems that connect them, such as the indicator "District heating and cooling" [18]. At the city level, the focus expands further to include data-driven strategies, such as the indicator "Responsible sourcing for infrastructure" [19]. Overall, circularity assessment is not one-size-fits-all; the selection of indicators should be aligned with the targeted spatial scale, as the scale shapes the scope of analysis and the types of circular strategies that can be meaningfully implemented and evaluated.

3.2 Comparative Analysis

Following the analysis of how circularity is assessed in policy and practice, the results are further compared with the findings of our previous systematic review of academic studies [7] to identify alignments and gaps.

Although quantitative, semi-quantitative, and qualitative assessment methods are applied in both grey literature and academic studies, they differ significantly in how often these methods are used and the way they are carried out. Academic studies maintain a more balanced distribution across these three approaches, whereas the prevalence of quantitative and semi-quantitative methods in practice and policy suggests a focus on measurability, as shown in Fig. 1a. Semi-quantitative methods are rarely replicable in academic studies, which is largely due to a lack of consensus on indicator selection and ambiguities in scoring scales. By contrast, semi-quantitative indicators identified in grey literature, such as those within the Level(s) framework [14], the New European Bauhaus [15], and various GBRS, are developed with well-defined scoring criteria and documented with detailed methodological guidance. This transparency facilitates more consistent application, making them comparatively more replicable in practice. A similar trend is observed for qualitative methods. While an extensive number of qualitative indicators have been identified in academic studies, their practical applicability remains limited compared to those in grey literature. This suggests a clear trajectory for future research, emphasizing the further development of semi-quantitative and qualitative methods to improve their transparency and applicability in real-world contexts.

The focus on different spatial scales is consistent across policy, practice, and academic approaches, as shown in Fig. 1b. The majority of identified indicators are at the building level, while the city and beyond scales and the intermediate neighborhood level remain comparatively less-investigated. Nevertheless, recent policy suggests expanding the focus to larger spatial scales. For instance, within the policy-driven New European Bauhaus initiative [15], half of the indicators collected extend beyond the building level.

Indicators such as the "Share of renewables" are defined and assessed using scale-specific formulations, varying according to whether they are applied at the building, neighborhood, or larger urban scales. In line with this trend, future research should move beyond individual buildings, proposing scalability approaches for existing circularity indicators.

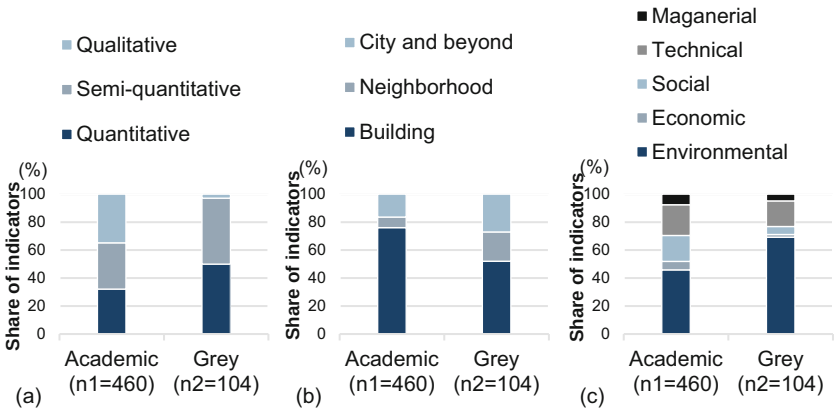

Fig. 1. Comparative analysis of indicators from academic studies and grey literature by share of: (a) assessment method, (b) application scale, and (c) circularity dimensions. n_1 and n_2 represent the total number of indicators identified in academic and grey literature sources, respectively.

Circularity assessment is recognized in both grey literature and academic studies as a multi-criteria problem, covering environmental, economic, social, technical, and managerial dimensions, as shown in Fig. 1c. While the dimensions and aspects identified in academic and grey literature are consistent, the specific methods used to assess the same dimensions or aspects still remain fragmented. For example, to assess the aspect of design for adaptability, the Level(s) framework [14] uses a semi-quantitative "Design for adaptability and renovation" indicator, while researchers tend to apply qualitative methods [7], such as the qualitative "Increased the building's future flexibility and adaptability" indicator. This methodological fragmentation suggests the need for a standardized set of indicators to ensure that circularity performance is assessed and compared consistently by researchers, practitioners, and policymakers.

4 Conclusion

This study reviewed grey literature on circularity assessment in the built environment, complementing a former systematic review of academic studies. Specifically, this included a review of standards, policy frameworks, GBRS, and specialist toolkits, and a comparative analysis to identify alignment and gaps with academic approaches.

A total of fourteen sources were reviewed, yielding 104 circularity assessment indicators that were subsequently analyzed. Results revealed considerable variation in assessment methods, including quantitative, semi-quantitative and qualitative indicators for five key circularity dimensions. While building-level assessment remains dominant in

both grey literature and academic studies, the recent policy-oriented framework suggests a growing shift toward larger spatial scales.

Methodological fragmentation indicates that future research should prioritize further refinement and alignment of existing circularity assessment methods to facilitate standardization. In particular, research should move beyond individual buildings to address larger spatial scales, such as neighborhoods and cities. Greater emphasis should also be placed on improving methodological transparency, documentation, and replicability, particularly for academic semi-quantitative and qualitative indicators, to enhance practical applicability. In this regard, indicators from grey literature may serve as useful reference examples. Finally, efforts are needed to identify and consolidate a core set of indicators that could serve as a common reference framework for researchers, practitioners, and policymakers.

A few limitations of this study can be highlighted. First, the scope of reviewed sources is largely limited to the European context. This geographical focus was chosen in line with the bibliographic analysis by Khadim et al. [8], which shows that Europe is at the forefront in this field. Although internationally recognized frameworks such as LEED [17–19] and WELL [21] were included, the primary focus on European policy initiatives and standards may limit the applicability of the findings to other regions. Second, it is possible that not all relevant grey literature was captured. Unlike academic publications, grey literature is not comprehensively indexed. As a result, some frameworks or tools may not have been identified.

Abstract. This article investigates the integration of sustainable and circular design principles in contemporary Polish architecture, focusing on completed buildings, projects currently under construction, and recent architectural competition proposals. The study examines 25 projects that reflect the growing national shift toward environmentally responsible construction, which include early CLT implementations (e.g., the Library in Białołęka by Ambient and the Office Building in Wiele by APA Wojciechowski) and competition-winning schemes that incorporate circular strategies (e.g., the Museum of Architecture in Wrocław by TŁO and the Academy of Fine Arts in Katowice by BDR Architects).To enable a systematic and technically robust assessment, the article introduces a dedicated evaluation framework based on 9R classification that consolidates criteria related to the design stage and the application of sustainable and circular strategies. This framework constitutes the core original contribution of the study: it operationalizes circularity assessment for architectural practice by translating broad circular-economy principles into a structured, practice-oriented analytical tool. Its formulation advances existing evaluation approaches by enabling consistent cross-case comparison and by offering a methodology that can be transferred to other national contexts undergoing similar transitions toward circular construction. The results indicate that the current level of sustainable development within the Polish construction sector is still emerging and at an early stage of development. Identified systemic limitations and underdeveloped areas include the narrow range of applied strategies and the limited number of initiatives addressing repair-related approaches. The main challenges associated with implementing circular principles in architectural practice is its predominance in public buildings and high-budget projects. The study concludes by indicating priority directions for improvement and by demonstrating how the proposed framework can support more coherent progress toward resource-efficient, low-impact architectural development in Poland and beyond.

Keywords: Circularity · Construction sector · Sustainability · Carbon footprint

1 Introduction

The European Union has established an ambitious policy framework to promote the transition toward a circular economy (CE). Strategic initiatives such as the European Green Deal [1] promote circularity, resource efficiency, and decarbonization objectives.

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 304–312, 2026.
https://doi.org/10.1007/978-3-032-34930-9_36

The construction sector is widely recognized as a priority area due to its high levels of material consumption, waste generation, and greenhouse gas emissions across its life cycle [2]. However, progress among Member States remains uneven. Comparative assessments of CE indicators reveal significant disparities in performance across countries [3]. Moreover, the effectiveness of CE policies varies considerably between regional contexts [4].

One of the main challenges is the lack of a universally accepted CE definition, which leads to uncertainty on how circular principles can be effectively implemented within the building industry [5]. Among the identified concepts are strategies such as design for adaptability and disassembly, material recycling, prolonging the lifecycles, and broader systemic transformation [6].

One of the widely recognized frameworks for understanding circularity is based on the R-strategies, commonly associated with the reduce, reuse, and recycle [7]. For example, the 3R framework has been used to analyze challenges related to construction and demolition waste management in China [8]. In studies focusing on the adaptation of post-industrial buildings in Poland, this approach has been extended to a 4R model, with additional recovery [9]. Such frameworks enable a relatively clear and systematic interpretation of circular solutions and facilitate their comparative analysis.

Relatively few studies address manufacturing processes or spatial planning at larger scales, such as districts or cities, while the majority focus on the material scale, particularly during manufacturing and construction stages [10]. At the same time, there is an increasing need for research focusing on real-life projects [11]. Investigating such cases can contribute to a better understanding of how circular principles are applied in practice and help identify emerging best practices. Although CE concepts are widely discussed in academic literature, their practical implementation remains relatively limited [12].

To address these gaps, the study aims to evaluate the present level of circularity integration in Polish architecture. The research comparatively examines completed and planned architectural projects in Poland that incorporate circular economy principles. To ensure methodological transparency, the study employs a structured qualitative and quantitative framework that allows for cross-case evaluation.

2 Methodology

2.1 Data Sources and Inclusion Criteria

The study employed a multi-source data collection approach combining scientific literature, professional architectural publications, and publicly accessible competition records. The process was designed to ensure that the selected cases represent verifiable, documented examples of circular practices in both completed and planned buildings.

The initial identification of academic references was conducted through Scopus using the query: ("Polish" OR "Poland") AND ("circular" OR "reuse") AND ("building" OR "architecture"). This search returned 113 publications. After title, abstract, and full-text screening, 3 publications were found to contain directly relevant case descriptions, yielding 8 buildings suitable for inclusion.

Professional architectural journals were used to identify completed projects implementing circular strategies in practice. Articles published in Architektura-Murator [13]

and Sztuka-Architektury [14] were systematically reviewed. From these sources, 10 completed buildings were selected. The presence of each R-strategy was verified using the same approach for each case study. We searched for explicit evidence—such as design descriptions, implementation details, technical documentation, jury reports, or professional publications—indicating that a given strategy was intentionally applied. Only strategies supported by verifiable statements or demonstrable design features were recorded. To address the risk of incomplete or promotional information, we applied two safeguards:

- Triangulation of sources: each project was assessed using at least two independent materials whenever available
- Conservative coding: in cases where information was ambiguous, overly promotional, or insufficiently detailed, the strategy was *not* marked as present.

Third, to ensure consistency across cases, all projects were verified using the same protocol. The process was performed by two researchers, who compared interpretations and resolved discrepancies through discussion. This procedure helped maintain uniform criteria and reduce subjective bias.

To identify planned projects, public architectural competitions were reviewed using Archikonkurs [15], a platform aggregating Polish architectural competitions, and the website of Association of Polish Architects SARP [16], a frequent co-organizer. Only first-place winning entries were included, as these represent projects confirmed for construction and therefore constitute reliable indicators of future implementation. This process resulted in the selection of 7 planned buildings incorporating circular strategies. In total, 25 completed and planned buildings met the inclusion criteria and were selected for analysis.

2.2 The Circular Economy Strategies in Architecture and the Form of the Framework

For this study, the classification of circular solutions had to be systematic rather than purely descriptive, to allow the results to be translated into numerical values and a comparable indicator. To determine the scope of circular practices, a classification based on R-strategies was therefore adopted [7]. However, unlike previous studies that relied on simplified 3R or 4R frameworks [8, 9], this research applies an expanded 9R classification, enabling a more detailed differentiation. The extended 9R framework includes Refuse (R0), Rethink (R1), Reduce (R2), Reuse (R3), Repair (R4), Refurbish (R5), Remanufacture (R6), Repurpose (R7), Recycle (R8), and Recover (R9). In architectural practice, these strategies translate into: R0 - refraining from constructing a new building or its parts when existing structures can meet the demand; R1 - designing multi-functional spaces that serve different purposes over time or introducing modularity; R2 - optimization to minimize material and energy use; R3 – adaptive reuse, reuse of materials or design for disassembly; R4 – repairing instead of replacing or designing buildings with accessible components; R5 - upgrading existing buildings to improve performance while retaining most of the structure; R6 - using building components that are disassembled and restored; R7 - Using building elements or structures for a different function; R8 – recycling materials to create new building materials; R9 - recovering energy or materials

from waste that cannot be reused or recycled. The study first identified which circular strategies were implemented in each analyzed project and then assigned a numerical value corresponding to the number of applied strategies within the 9R framework. If a project incorporated only one of these strategies, it was assigned a value of 1; if two strategies were implemented, the value was 2, and so on, up to a maximum of 10.

To estimate the stage of implementation of circular solutions in the analyzed projects, a simple scoring system termed circularity points was developed. This system considers both the number of applied 9R strategies and the project's stage of development. Each project received a score from 1 to 10 based on the number of strategies included. Additionally, weighting coefficients were introduced to reflect the stage of implementation: 0.5 for the design phase, 0.75 for the construction phase, and 1.0 for completed projects. These coefficients allow for a more balanced evaluation of projects that have not been realized and their effectiveness cannot be fully verified.

This method enables an approximate estimation of the level of circular economy implementation across the examined projects. Lower scores indicate fewer realized projects and less implemented circular strategies, whereas higher scores reflect more strategies implemented and completed in practice.

In summary, the circularity score is calculated as shown in Eq. (1).

$$\begin{aligned} &\textit{number of implemented circular strategies } (1-10) \times \textit{weighting factor} \\ &\quad \textit{based on the project stage } (0,5{-}1) \\ &\quad = \textit{circularity points } (0,5{-}10) \end{aligned} \tag{1}$$

Overall, the research framework comprises six main steps: (i) identification of circular strategies applied in each project using the 9R classification, (ii) assessment of the project stage (design, construction, or completed), (iii) quantification of the number of implemented strategies, (iv) application of a weighting factor reflecting the project stage, (v) calculation of a circularity score for each project, and (vi) evaluation of the results to determine the overall level of circular economy implementation across the sample.

3 Results

The identified cases represent a variety of functions, ranging from public buildings such as university facilities, libraries, and museums, to public spaces, to commercial buildings, including hotels and mixed-use complexes. The majority of identified cases date from the last ten years, with more examples appearing in the most recent years.

Among the analyzed buildings and designs, no project implemented more than five strategies. The most frequently adopted strategies were R3 – Reuse and R7 – Repurpose, while R9 – Recover and R4 – Repair were the least common. The mean calculated circularity points across all projects was 2.54, rising to 3.69 for completed buildings. Table 1 presents the results of the research framework

4 Discussion

The findings of this study provide important insight into the current state of circular economy integration in architectural practice in Poland.

4.1 Circular Economy Theory Versus Architectural Practice

The observed dominance of adaptive reuse and preservation-oriented strategies suggests that circularity in Polish architecture is currently driven primarily by resource retention rather than by fully systemic design approaches.

The limited application of repair-oriented strategies (R4) is particularly noteworthy. It suggests that architectural practice still tends to prioritize initial construction and adaptation phases, while long-term maintenance, repairability, and operational flexibility remain insufficiently integrated into design decision-making.

4.2 Fragmentation of Circular Strategies and the Absence of Systemic Design

A key observation is that none of the analyzed projects implemented more than five circular strategies simultaneously. This reinforces the conclusion that circularity is currently introduced through isolated design decisions rather than through comprehensive circular design frameworks.

4.3 Policy and Regulatory Implications

The underrepresentation of residential projects, public procurement, and lower-budget developments reveals a critical policy gap. The results suggest that existing policy instruments may not sufficiently support the integration of circular strategies beyond flagship or high-profile projects. In particular, the limited visibility of circular solutions in public tenders raises questions about how circular economy objectives are operationalized within procurement procedures.

The research framework proposed in this study directly addresses this challenge by offering a simplified yet structured indicator of circularity that could be adopted

or adapted by policy-makers. Competition organizers could require explicit material indicators, documentation of reuse potential, and evidence-based environmental strategies as part of the evaluation framework. Public clients could incorporate R-strategies into tender specifications and feasibility studies, ensuring that circular principles are considered from the outset. In this sense, the framework has clear potential to support evidence-based policy development.

4.4 The Limitations of the Study

The limitations of the method primarily stem from the characteristics of the data sources. Press releases and professional journal publications tend to highlight high-visibility projects, which may lead to the omission of work by smaller or niche architectural studios, privately funded developments, and small-scale interventions that are less frequently documented.

A further limitation relates to the reliance on publicly available information. The analysis may not capture the complete range of strategies considered, discarded, or modified during project development.

Another limitation is the equal weighting of all nine 9R strategies, although their impacts on a project are not necessarily comparable. Future research could address this limitation by introducing an additional weighting factor for the scale and overall impact of implemented circular solutions.

5 Conclusion

This study set out to evaluate the current level of circular economy integration in architectural practice in Poland through the analysis of 25 realized buildings and design proposals. The results demonstrate that, while interest in circular principles is clearly emerging, their implementation remains limited in scope, fragmented in nature, and concentrated around a narrow set of strategies—most notably adaptive reuse and the preservation of existing building resources.

The key contribution of this paper lies not only in documenting these limitations, but in how they are identified and assessed. The study introduces and applies a dedicated, practice-oriented evaluation framework that operationalizes circular economy theory for architectural analysis. By combining the identification of R-strategies with project-stage weighting and a synthetic circularity score, the method enables consistent cross-case comparison and reveals patterns that are difficult to capture through qualitative description alone.

The findings also carry important implications for policy and practice. The underrepresentation of residential development, public procurement, and lower-budget projects highlights structural barriers that cannot be addressed through design innovation alone.

Abstract. Circularity in the building sector is tightly connected to the recovery of materials and components for reuse and recycling, and to buildings' adaptability, facilitated by design for disassembly and deconstruction. To enable these strategies, effective deconstruction considerations must be embedded from the early design stages onwards. Accordingly, multiple circularity frameworks regard design for de-construction as essential, proposing diverse metrics and criteria for its evaluation. This study investigates how deconstruction potential is addressed within Level(s), a common European framework for assessing sustainability and circularity performance, through Indicator 2.4: Design for deconstruction. The adopted methodology is structured in five steps: (i) analysis of Indicator 2.4, including its scope, criteria/metrics, and integration into Macro Objective (MO) 2: Resource efficient and circular material life cycle; (ii) identification and synthesis of key disassembly requirements based on established frameworks; (iii) evaluation of the coverage of these requirements within Level(s); (iv) comparative assessment of methodological characteristics against selected frameworks to determine strengths and weaknesses in the Level(s) approach and highlight opportunities for alignment (v) formulation of improvement directions, including proposals for additions or modifications to different elements of the assessment. The study aims to clarify where the current approach performs well and where refinement is needed. Enhancement opportunities are detected at various levels of the framework, including refining Tier terminology, improving the inclusiveness of technical and process aspects, reconsidering criteria weights, and understanding interactions with other circularity indicators in MO2 to broaden the calculation of overall circularity score based on multiple MO2 indicators.

1 Introduction

The transition to a circular economy (CE) in the construction sector requires integrating circular design principles from the earliest stages of planning. Circular construction promotes the prolonged use of materials, components, and systems by enabling reuse, recovery, and recycling across multiple life cycle stages, thereby preserving material value and reducing the need for new resource extraction. In this context, Design for Disassembly (DfD)—also referred to as Design for Deconstruction—emerges as a key strategy for enabling circular construction.

Since the early discussions of DfD in the 1990s [1], its principles and implementation approaches have been widely explored [2]. The international standard ISO 20887:2020 [3] "Sustainability in buildings and civil engineering works—Design for disassembly and adaptability" provides a structured framework for these principles. Numerous studies highlight the importance of embedding DfD considerations from the early design stages to maximise material recovery and overcome challenges such as information gaps, regulatory constraints, and market uncertainties that often arise later in the construction process [4]. As a result, DfD principles continue to evolve through the development of new frameworks and assessment indicators.

At the policy level, the European Union has introduced the Level(s) framework as a common methodology for assessing the sustainability of buildings throughout their life cycle [5]. Level(s) consists of six macro-objectives and sixteen performance indicators. Within this framework, Macro Objective 2 (MO2): Resource efficient and circular material life cycle focuses on circularity-related aspects of buildings. In particular, **Indicator 2.4: Design for deconstruction** aims at assessing how design decisions enable the future recovery and reuse of building materials and components.

The Level(s) framework has attracted growing research interest regarding the translation of its theoretical concepts into real-life applications and national policies. Studies applying Level(s) in pilot projects highlight both its potential and the challenges of implementation, including data availability, alignment with existing standards, and integration with digital product information systems [6]. Other research has examined its integration with green building certification schemes [7], its alignment with circularity strategies such as the 10-R Framework [8], and the implementation of adaptability requirements within Indicator 2.3 (design for adaptability) [9]. Additional work has explored its compatibility with established circularity indicators such as the Material Circularity indicator (MCI) in projects designed for dismantling [10], the use of Digital Product Passports (DPPs), to support circularity-related indicators [11].

In this context and considering that limited research has critically examined how DfD principles are operationalised within the Level(s) framework, this study addresses this gap by analysing Indicator 2.4 within the context of MO2. The study evaluates how comprehensively the indicator reflects key requirements derived from established DfD frameworks, conducts a comparative assessment with selected frameworks to identify strengths and limitations, and proposes targeted improvements to enhance the implementation of DfD within Level(s).

2 Materials and Methods

This study adopts a structured analytical approach to evaluate how Design for Deconstruction (DfD) is operationalised within the Level(s) framework, focusing on Indicator 2.4. The methodology comprises five main steps. First, Indicator 2.4 is analysed in terms of its scope, criteria, tier structure, and integration within Macro Objective 2 (MO2). Second, established DfD assessment approaches—including the Disassembly Determining Factors (DDF), ISO 20887, and the CIRLAB model—are reviewed to identify key disassembly requirements and methodological characteristics. Third, a set of core disassembly requirements is synthesised and used to assess the coverage of Indicator 2.4. Fourth, a comparative analysis is conducted to evaluate methodological aspects such as level of analysis, assessment structure, technical depth, and integration with circularity strategies. Finally, based on the identified gaps and limitations, targeted improvement directions are proposed.

3 Results and Discussion

3.1 Analysis of Indicator 2.4: Design for Deconstruction

The assessment of a building's disassembly performance is essential due to the major environmental impact of building elements and the multiple renovation cycles of different scales expected throughout a building's lifecycle. These cycles involve maintenance, repair, and replacement processes, which generate material flows that can either be recovered or lost. In this context, Indicator 2.4 aims to promote design features that facilitate future disassembly and, enhance the reuse and recycling potential of materials, components, and systems. However, disassembly remains challenged by technical, procedural, logistical and market-based barriers.

Indicator 2.4. is structured across three assessment levels, each adopting a different approach while emphasizing the involvement of project teams and stakeholders. A three-tier hierarchical classification of building elements is established throughout the indicator (Tier 1: building layers such as shell, core, and external works.; Tier 2: systems such as foundations, loadbearing structural frame, and facades; Tier 3: building elements such as piles and shallow foundations).

At Level 1 (Conceptual Design), the assessment is based on a qualitative checklist structured into three criteria (design aspects) groups. The first group (*Ease of disassembly)* addresses independence and separability of elements, as well as connection characteristics, including type, accessibility, and reversibility, and the number and complexity of disassembly steps. The second group (*Ease for reuse*) focuses on standardisation, modularity, and adaptability to future functions. The third group (*Ease for recycling*), the analysis shifts to material-level aspects, including surface treatments, homogeneity, separability, and the availability of recycling pathways.

At Level 2 (Detailed Design and Construction), the assessment becomes semi-quantitative. Evaluation occurs at Tier 3 (with optional extension to a fourth tier covering components, parts, and materials). Each element is assessed based on its best practical circularity outcome, ranging from direct reuse (coefficient 1.0) to hazardous waste (coefficient 0.0), with six intermediate options. Results are normalised by mass, with optional

value (price)-based normalisation. The resulting circularity score ranges from 0% to 100% and follows a logic comparable to the approach adopted in DGNB sustainability assessment method.

At Level 3 (As-Built and In-Use), the assessment verifies performance and the implementation of the planned design strategies by comparing the structured building with the detailed design. The same layout and templates as Level 2 are applied.

3.2 Disassembly Requirements

DfD aims to ensure that buildings and their components can be dismantled in a controlled, non-destructive manner, enabling the recovery of materials for reuse, recycling, or other circular pathways. Achieving this requires the consideration of specific technical and process-related conditions during design. These conditions, often formalised as criteria or indicators in the literature, can be collectively defined as disassembly requirements, representing the design features that enable effective deconstruction.

Among the most established approaches, the Disassembly Determining Factors (DDFs) developed by Durmisevic [2] structure the evaluation of disassembly potential through 17 parameters grouped into seven aspects: functional decomposition, lifecycle coordination, relational pattern, systematisation, assembly, geometry, and connections. These parameters are assessed using fuzzy variables (0–1) and aggregated hierarchically to evaluate three configuration indicators (transformation, independence, and exchangeability) defining the overall building's transformation capacity.

With the increasing emphasis on the CE assessment, DfD has been widely integrated into broader circularity models. Many of these approaches build on the DDFs framework and combine it with material flow indicators to form the **Building Circularity Indicator (BCI)** and its variations. Subsequent BCI developments refined the selection of DDF parameters, while later studies integrated environmental indicators (e.g., embodied carbon and energy) and adaptability metrics, expanding the scope of circularity assessment [12].

Beyond BCI-based approaches, other models further develop disassembly assessment by combining DDF principles with additional criteria. For example, the CIRLAB model [12] proposes six disassembly indicators derived from both DDF and ISO 20887, applying a decision-tree logic to guide the assessment and account for limiting conditions such as inaccessibility of components. These indicators are integrated with adaptability, resource longevity, and material flow metrics to evaluate overall building circularity.

While the DDF framework remains one of the most comprehensive approaches, many studies adopt simplified criteria focusing on key aspects such as connection reversibility, accessibility, modularity, and standardisation. Although these approaches capture core DfD principles, they often lack the detailed analysis of component relationships and assembly logic provided by DDF.

A complementary reference is ISO 20887:2020, which defines general design principles for disassembly and adaptability. The standard emphasises accessibility of components, separation of building layers, use of reversible connections, minimisation of destructive techniques, and proper identification and documentation of materials. It provides a conceptual framework supporting the integration of DfD across design and lifecycle stages.

Overall, the integration of disassembly within circularity assessment models reflects its strong interconnection with other strategies such as adaptability, modular construction, and lifecycle extension. Based on the synthesis of DDF, CIRLAB, and ISO 20887, six key disassembly requirements were identified: accessibility, connection reversibility, independence of systems, assembly logic, standardisation/modularity, and lifecycle coordination. These represent the core technical conditions enabling effective disassembly and material recovery.

3.3 Comparative Analysis

Coverage of Disassembly Requirements in Level(s). This subsection evaluates how Level(s) Indicator 2.4 addresses the key disassembly requirements identified in Section 3.2. As summarised in Table 1, the analysis examines the extent to which the indicator considers the main technical conditions that enable effective disassembly.

Table 1. Assessment of the coverage of key DfD requirements within Level(s) Indicator 2.4.

Disassembly Requirement	How Level(s) addresses it
Accessibility of elements and connections	At Level 1, accessibility of connections is explicitly addressed within the *Ease of disassembly* criteria group. The accessibility of elements is not explicitly mentioned. At Levels 2–3, these aspects are not explicitly included in the logic diagram but are implicitly relevant for circularity.
Reversibility of connections	At Level 1, reversibility and sequential reversibility of connections are explicitly addressed within the *Ease of disassembly* criteria. The same considerations should be assumed when estimating the best circularity outcome for Levels 2–3 although they are not explicitly included.
Independence / layer separation	At Level 1, independence and separability of elements are addressed under *Ease of disassembly*, while material separability is considered within the *Ease of recycling* criteria group. For Levels 2–3, separability of materials and hazardous substances is explicitly included in the logic diagram for determining the best circularity outcome, while the independence of layers is implied through the tier structure. The indicator classifies elements under systems and systems under broader groups that can be interpreted as layers (shell, core, and external works).
Assembly / disassembly logic	Sequential reversibility of connections and the number and complexity of disassembly steps are addressed within *Ease of disassembly*. These aspects are not explicitly included in the Levels 2–3 logic diagram but are implicitly relevant for determining the best circularity outcome.
Standardisation / modularity	These factors are extensively examined within the *Ease of reuse* group. Although not explicitly referenced in the Levels 2–3 logic diagram, they are expected to influence the estimation of the best circularity outcome.

(*continued*)

Table 1. (*continued*)

Disassembly Requirement	How Level(s) addresses it
Lifecycle coordination / reuse enablement	Reuse enablement is addressed across all criteria within the *Ease of reuse group* at Level 1. For Levels 2–3, reusability is further examined, including the presence and separability of hazardous substances. No explicit reference to lifecycle coordination is provided.

Comparison of Assessment Characteristics. This subsection compares the main methodological characteristics of Level(s), the DDFs framework, ISO 20887, and the CIRLAB model. As summarised in Table 2, the comparison focuses on key aspects of the assessment approaches, including the level of analysis, structure of the evaluation method, technical depth of disassembly assessment, integration with lifecycle and circularity strategies, and consideration of process and implementation aspects.

Table 2. Comparison of methodological characteristics of Level(s), DDF, ISO 20887, and CIRLAB.

Assessment Dimension	Level(s)	DDFs	ISO 20887	CIRLAB
Level of analysis	Conceptual (Level 1) and element-level (Levels 2–3), aggregated to building level	Component, assembly, and connection levels	Conceptual principles applied to components, systems, and connections (generally collective)	Component and connection level with aggregation to building level
Structure of assessment method	Qualitative checklist (Level 1); tier-based semi-quantitative scoring (Levels 2–3) using mass/value weighting and end-of-life outcomes	Fuzzy scoring with hierarchical aggregation	Principle-based guidance with optional semi-quantitative scoring (0–5, yes/no, percentages)	Composite indicator with semi-quantitative criteria using linguistic scales and score functions, normalised by component change frequency

(*continued*)

Table 2. (*continued*)

Assessment Dimension	Level(s)	DDFs	ISO 20887	CIRLAB
Technical depth of disassembly assessment	10 qualitative design aspects (Level 1); applied to end-of-life evaluation via logic diagram (Levels 2–3)	17 detailed technical parameters and relationships grouped into multiple aspects	7 conceptual design principles with recommendations for designers	6 structured indicators derived from DDF and ISO following a decision-tree logic
Lifecycle and circularity integration	Integrated within MO2 and linked to other lifecycle indicators	Limited integration with broader circularity strategies, mainly linked to adaptability	Conceptual lifecycle linkage (adaptability, durability, standardisation, modularity)	Strong integration with adaptability, longevity, material flows, and embodied impacts for energy and carbon
Process and implementation considerations	Includes documentation, planning aspects, and stakeholder roles	Limited consideration of implementation processes	Addresses safety, handling, operational considerations, and stakeholder roles across lifecycle	Moderate consideration through assessment logic and decision rules

3.4 Improvement Directions

The analysis presented in Tables 1 and 2 highlights several limitations in how Level(s) operationalises design for deconstruction. Based on these observations, several improvement directions can be identified.

First, refinement of the tier structure and terminology is needed to better reflect disassembly logic. Although the existing three-tier hierarchy provides a useful framework, relationships between building layers, systems, and elements remain implicit. A clearer alignment with layer-based design approaches and system independence principles would strengthen the assessment. In addition, a unified layer structure across all MO2 indicators should be established. For example, Indicator 2.3 refers to structure, façade, space plan, and services, while others use shell, core, and external elements. A consistent classification—starting from the bill of quantities and applied across indicators—would support coherent evaluation, enable trade-offs, and clarify each layer's contribution.

Second, the expansion and clarification of technical criteria is required. While Level 1 addresses key aspects such as reversibility, accessibility, and modularity, important requirements—such as assembly sequence logic, lifecycle coordination, and detailed component relationships—remain partially covered or implicit. Incorporating more

explicit criteria informed by frameworks such as DDF and ISO 20887 would enhance technical depth.

Third, process and implementation aspects should be more explicitly integrated. Current guidance gives limited attention to stakeholder roles and documentation. Including deconstruction planning, material passports, and digital tools (e.g., BIM and Digital Product Passports) would improve applicability across the building lifecycle.

Fourth, the assessment methodology should be refined to improve consistency. The shift from qualitative assessment at Level 1 to semi-quantitative scoring at Levels 2–3 creates discontinuities. Introducing semi-quantitative or weighted criteria at early design stages would enable more consistent and comparable results.

Finally, the integration of Indicator 2.4 within MO2 should be strengthened. Currently, Indicator 2.4 is the only MO2 indicator providing a quantified score, limiting its interaction with other circularity indicators. The development of a composite circularity index integrating all MO2 indicators would enable more balanced trade-offs (e.g., between design for adaptability and design for disassembly), support benchmarking across projects, and improve alignment with broader sustainability indicators (e.g., lifecycle impacts in MO1 and MO6). Such an approach would provide a more comprehensive evaluation of circularity and support informed decision-making.

Building Passport-Based Circular Housing Transformation in Turkey: An Assemblage Perspective

Abstract. Urban transformation in Turkey has accelerated through legal reforms intended to renew earthquake-vulnerable building stock. In practice, however, this process has largely been reduced to parcel-based demolition and reconstruction, shaped by fragmented decision-making, short-term profitability, and limited life-cycle thinking. This paper argues that urban transformation should be understood not only as a physical rebuilding process but also as a socio-material assemblage formed by actors, regulations, material flows, and data infrastructures. Within this framework, assemblage theory is used as a diagnostic lens and building passports are examined as informational interventions capable of reconnecting fragmented relations between actors, materials, data, and decisions. The Turkish context is characterized by fragmented datasets, weak institutional coordination, and information asymmetries that hinder adaptive reuse, material recovery, and long-term planning. In response, the paper proposes an assemblage-informed diagnostic matrix structured around four critical relations: building-data, building-component, actor-data-decision, and material-future-use. The matrix identifies where these relations are disrupted, what building passport information is required, and which circular transformation decisions this information can support. The study concludes that building passports should be understood not only as technical repositories but as governance infrastructures through which fragmented socio-material relations can be made visible and potentially reorganized.

Keywords: Building Passport · Circular Housing Transformation · Assemblage Theory · Socio-material Dynamics · Urban Regeneration

1 Introduction

Urban transformation in Turkey gained momentum after the enactment of Law No. 6306 in 2012, which aimed to renew unsafe building stock under disaster risk [1]. More recent amendments under Law No. 7471 and the establishment of the Urban Transformation Presidency further strengthened the institutional and legal framework [2]. Despite these changes, implementation has remained limited in scope. Rather than enabling comprehensive urban regeneration, transformation has often been reduced to the demolition of existing buildings and the construction of new ones on a parcel basis [2, 3].

This prevailing model is strongly shaped by contractor-led development and short-term financial priorities [2]. Developers tend to focus on centrally located and profitable sites, while broader concerns such as infrastructure capacity, environmental performance, and long-term social impacts remain secondary [3]. As a result, conventional demolition methods are preferred, and the recovery potential of existing materials is largely ignored [4]. This pattern reproduces a linear building logic in which buildings are treated as disposable products rather than long-term resource systems.

From a sustainability perspective, this approach creates major limitations. The lack of reliable data on material composition, structural condition, and end-of-life potential prevents the integration of life-cycle thinking into urban transformation [4, 5]. Without such information, it is difficult to evaluate reuse, selective dismantling, adaptive renovation, or environmental performance. This is precisely why building passports and related digital tools have become increasingly important in recent literature: they offer a way to document buildings as material, technical, and informational entities throughout their life cycle [5, 12, 14]. However, the problem is not limited to missing technical information. Building data, material flows, regulatory requirements, and decisions are distributed among multiple actors and institutions that operate without a shared information environment. From an assemblage perspective, this fragmentation weakens the relations through which existing buildings could be evaluated as long-term material and spatial resources.

Building passports provide a potential response by making these dispersed socio-material conditions visible and accessible throughout the building life cycle [5, 12, 14]. Accordingly, this paper asks: How can an assemblage perspective inform the use of building passports to identify and address the socio-material barriers to circular housing transformation in Turkey? To answer this question, the study first interprets the current Turkish transformation model through assemblage theory and then develops an assemblage-informed diagnostic matrix linking identified disruptions to the building passport information required for circular transformation decisions.

2 Assemblage Theory, Circular Housing, and Building Passports

Assemblage theory understands social and spatial phenomena not as fixed totalities but as temporary and dynamic alignments of heterogeneous components [6]. In this view, actors, materials, rules, infrastructures, and discourses do not disappear into a single whole; they remain relatively autonomous and can be detached, reconnected, and reconfigured in new ways [6, 7]. This perspective is useful for urban transformation because it moves beyond linear explanations and highlights how urban outcomes emerge through unstable relations among multiple elements [8–10].

Applied to urban transformation, assemblage theory reframes housing as more than a physical object. A dwelling becomes a socio-material formation shaped by public institutions, private developers, property owners, legal codes, building components, financial pressures, and data systems [8, 10]. Transformation therefore involves not only physical replacement but also the reorganization of these relations (Fig. 1).

Processes such as demolition, displacement, regulatory change, and reconstruction can be interpreted as phases of deterritorialisation and reterritorialisation, through which an existing urban configuration is dissolved and a new one is stabilized [6–8].

Fig. 1. Assemblage dynamics in urban transformation: deterritorialisation and reterritorialisation.

This theoretical perspective connects closely with circular housing. Circular housing aims to extend building life, reduce virgin material use, enable repair and reuse, and maintain the value of components through design for disassembly, modularity, and life-cycle assessment [11–13, 17]. In this model, buildings are treated as dynamic material banks rather than single-use products. Such a shift, however, depends on reliable data. Without information on material origin, condition, toxicity, maintenance history, and recovery potential, circular design principles cannot be implemented effectively [12, 13].

Building passports respond to this need by functioning as structured digital repositories of building life-cycle information [14, 15]. Integrated with BIM and related digital tools, they can record material inventories, technical properties, maintenance history, environmental indicators, and end-of-life scenarios [12, 16, 18]. From an assemblage perspective, however, their relevance extends beyond data storage. Urban transformation depends on relations between buildings, materials, property owners, public institutions, contractors, regulations, and decision processes. When information is missing or inaccessible, these relations become fragmented and circular alternatives such as adaptation, selective dismantling, and reuse become difficult to evaluate. Building passports can intervene in this condition by making material and technical information traceable across actors and decision stages. In this study, assemblage theory is therefore used as a diagnostic lens, while the building passport is examined as an informational intervention capable of reconnecting fragmented relations between actors, materials, data, and decisions (Fig. 2).

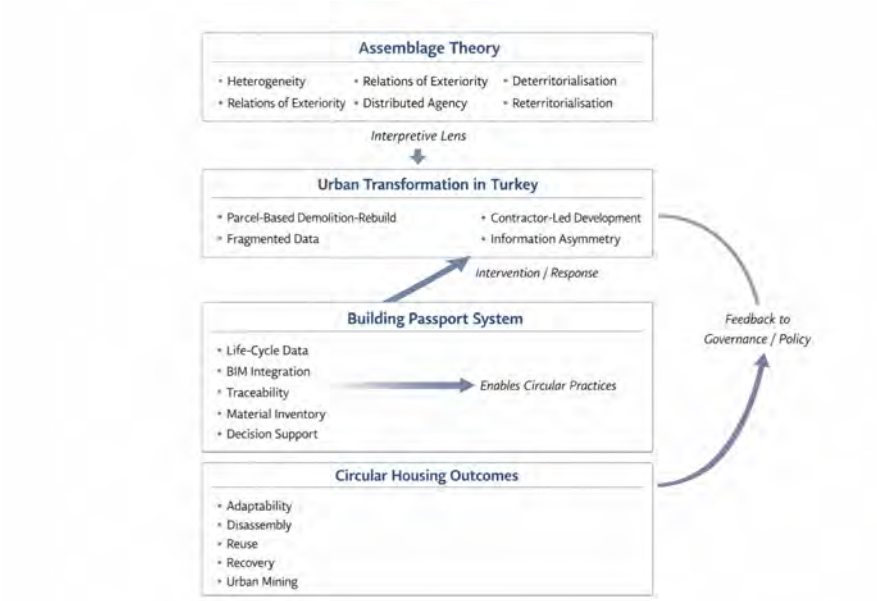

Fig. 2. Conceptual relationship between assemblage theory, circular housing, building passports, and urban transformation in Turkey.

3 The Turkish Context: Fragmented Data and Multi-Actor Decision-Making

In Turkey, one of the main obstacles to circular urban transformation is the fragmented nature of building data [1, 5]. Information about existing building stock is not gathered within a unified and continuously updated system; instead, it is dispersed across local authorities, project documents, and disconnected institutional records [1]. This fragmentation limits access to reliable knowledge about structural condition, material composition, and environmental performance [5].

The problem is intensified by the multi-actor nature of urban transformation. Central government, municipalities, contractors, consultants, demolition firms, and property owners all participate in the process, but they do not operate through a shared data environment [2, 19, 20]. As a result, decision-making is characterized by information asymmetry, coordination problems, and unequal access to technical knowledge [19] (Fig. 3).

Under these conditions, short-term economic logic tends to dominate, while long-term environmental performance and reuse potential remain poorly integrated into practice [4, 5].

This is why building passport systems are particularly relevant in the Turkish context. By centralizing life-cycle data and making it accessible to multiple stakeholders, they can reduce uncertainty and support more transparent decision-making [14, 16, 20]. They also create the informational basis required for selective demolition, repair, adaptation,

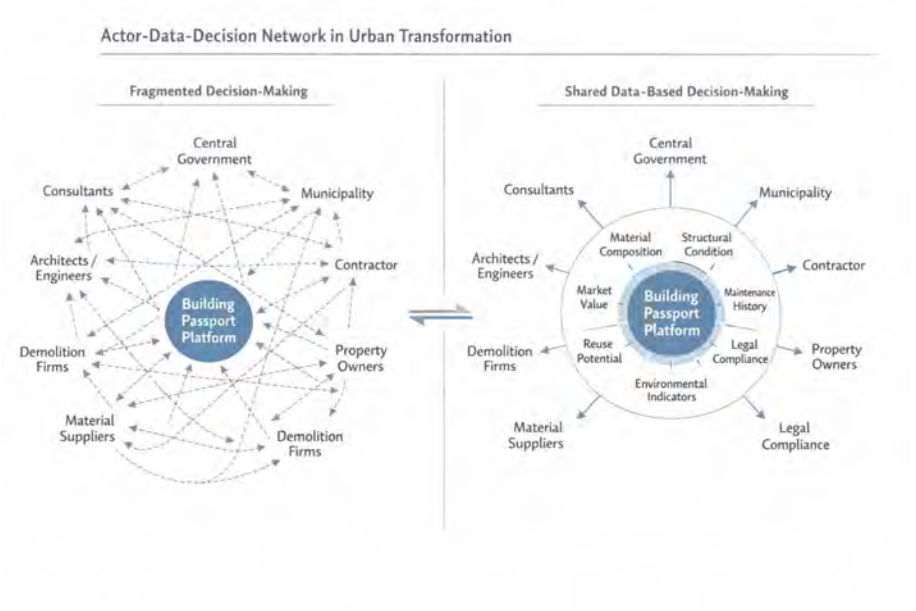

Fig. 3. Fragmented versus shared data flows among stakeholders in urban transformation.

and material recovery, all of which are essential for a circular transformation model [12, 17, 18].

Viewed through this framework, the Turkish case can be understood as a fragmented urban transformation assemblage. The central problem is not the absence of individual actors, regulations, or technical knowledge, but the weak connections between them. Material information is disconnected from demolition decisions, building performance data from redevelopment choices, and stakeholders from a common decision environment. These disruptions limit the capacity of the existing building stock to be evaluated for adaptation, reuse, selective dismantling, or material recovery.

The following section therefore translates these assemblage-level disruptions into a diagnostic matrix. Rather than scoring buildings, the matrix asks where a critical socio-material relation is disrupted, what information is missing, and what building passport information could support a circular transformation decision.

4 Results: An Assemblage-Informed Building Passport Diagnostic Matrix

To operationalize the theoretical argument, the study proposes an assemblage-informed diagnostic matrix for circular housing transformation in Turkey. The matrix does not evaluate circularity through a numerical score. Instead, it identifies critical disruptions between the actors, materials, information, and decisions that constitute the urban transformation assemblage and connects these disruptions with the information that a building passport should provide.

The matrix was developed through a conceptual synthesis of the two bodies of literature discussed in the previous sections. Building passport studies were reviewed to identify recurring information requirements, including material inventories, structural and maintenance records, life-cycle indicators, traceability, adaptability, disassembly, and recovery potential [12, 14–18, 21, 22]. These information requirements were interpreted through assemblage concepts concerning heterogeneous actors and material components, relations of exteriority, and processes of deterritorialisation and reterritorialisation [6–10]. The resulting matrix connects four recurrent problems identified in the Turkish context—fragmented building information, irreversible physical configurations, fragmented actor-decision relations, and disconnected material flows—to corresponding building passport information and circular transformation decisions [1–5, 19, 20]. Assemblage theory identifies the relations that constitute the urban transformation process; the matrix diagnoses where these relations are disrupted; and the building passport defines the information required to reconnect them (Table 1).

Table 1. Assemblage-informed building passport diagnostic matrix for circular urban transformation

Assemblage relation	Identified disruption	Building passport information required	Supported transformation decision
Building-data relation	Material, structural, maintenance, and environmental information is incomplete or dispersed across different records.	Material inventory; structural condition; maintenance history; LCA indicators; component traceability.	Determines whether adaptation, renovation, selective dismantling, or replacement can be evaluated on reliable evidence.
Building-component relation	Components and connections may prevent adaptation or non-destructive dismantling.	Component type; connection method; modularity; adaptability; disassembly and deconstructability information.	Identifies whether components can remain in use, be adapted, dismantled, or directly reused.
Actor-data-decision relation	Stakeholders operate with unequal access to information and decisions are poorly traceable across the transformation process.	Data ownership and accessibility; stakeholder access; decision records; communication protocols; shared platform information.	Creates a common information basis for negotiation and makes transformation decisions more transparent and traceable.
Material-future-use relation	Demolition decisions are disconnected from information about recovery, reuse, and secondary material flows.	Reuse/recycling potential; recovery quantity; component condition; second-hand value; selective dismantling requirements.	Connects pre-demolition decisions with reuse, recovery, urban mining, and secondary material markets.

The matrix changes the role of the building passport from a passive repository of building information into a diagnostic decision-support infrastructure. Each row begins with a relation within the urban transformation assemblage and identifies what prevents that relation from supporting circular transformation. The corresponding passport information then provides the informational basis required to reconsider the transformation decision.

For example, before the redevelopment of an apartment building, missing material and structural information would first appear as a disruption in the building-data relation. The passport would indicate the need for additional survey and documentation before demolition or renovation is selected. If information exists but components cannot be separated without destructive loss, the problem shifts to the building-component relation. Similarly, if reusable components are identified but this information does not reach demolition firms or potential secondary users, the material-future-use relation remains disrupted.

From an assemblage perspective, these distinctions are important because circular transformation cannot be achieved by accumulating building data alone. What matters is whether information changes the relations through which actors evaluate buildings and materials. The matrix therefore identifies where intervention is required before the existing assemblage is replaced through conventional demolition and indicates how building passport information can support its reconfiguration toward adaptation, reuse, recovery, and more informed redevelopment.

5 Discussion and Conclusion

This study asked how an assemblage perspective can inform the use of building passports to identify and address socio-material barriers to circular housing transformation in Turkey. The analysis shows that the central problem is not simply a lack of building information. Rather, the current transformation model is characterized by fragmented relations between building data, material components, actors, and decisions. Under these conditions, demolition and reconstruction become the dominant response because alternative futures for existing buildings and materials remain difficult to identify and coordinate.

Assemblage theory changes how this problem is understood. Instead of treating the building as an isolated physical object, it directs attention to the relations through which its future is decided. Material condition, regulatory requirements, ownership, technical knowledge, economic priorities, demolition practices, and available data operate together as a socio-material configuration. Circular transformation therefore requires intervention not only in the physical building but also in these relations.

The building passport provides such an intervention by creating a shared informational layer between the building, its components, stakeholders, and future material flows. The proposed matrix operationalizes this argument by identifying four critical relations: building-data, building-component, actor-data-decision, and material-future-use relations. For each relation, it identifies a potential disruption, the building passport information needed to make that disruption visible, and the transformation decision that this information can support.

The contribution of the matrix is therefore diagnostic rather than predictive. It does not calculate a circularity score or prescribe a single transformation outcome. Instead, it provides a structured way to ask what is currently disconnected before a decision to renovate, dismantle, recover, or replace a building is made. In this sense, the building passport becomes more than a digital repository: it becomes an infrastructure through which fragmented socio-material relations can be made visible and potentially reorganized.

For the Turkish context, this reframes circular urban transformation from a question of what information should be stored to a question of what relations that information should enable. Future empirical studies can test the proposed matrix through building-scale cases and stakeholder applications and examine whether these informational connections alter actual renovation, demolition, and material-recovery decisions. The conceptual contribution of this study is to establish this missing link between assemblage theory and building passport implementation, positioning data as an active component in the reconfiguration of urban transformation toward more circular outcomes.

Design for Disassembly Performance of Inter-Modular Connections in Modular Steel Buildings

Farhan Ahmed, Michaela Gkantou(✉), and Ana Bras

BEST Research Institute, School of Engineering and Built Environment, Liverpool John Moores University, Liverpool, UK
m.gkantou@ljmu.ac.uk

Abstract. Design for Disassembly (DfD) is a fundamental enabler of circularity in modular steel buildings (MSBs), as the long-term reuse of modules depends directly on the reversibility and mechanical separability of inter-modular connections (IMCs). This paper presents a comparative technical assessment of four primary IMC typologies—bolted, post-tensioned tie-rod, self-locking, and grouted systems. Relevant international standards are reviewed to identify requirements governing reversible assembly, structural integrity during repeated cycles, and material traceability. Using a Multi-Criteria Decision-Making (MCDM) framework, each connection type is evaluated across five performance vectors: operational accessibility, modular independence, reversibility, structural integrity, and post-disassembly recertification. Quantitative analysis shows that bolted connections achieve the highest DfD Performance Index (PI) at 91%, offering high demountability despite susceptibility to slip. Post-tensioned tie-rod systems follow with a PI of 87%, providing rigid behaviour, but requiring specialised hydraulic equipment for safe release. Self-locking mechanisms attain an average PI of 80%, constrained by limited visibility of internal elements. Grouted connections score the lowest PI at 40%; although they can provide full-strength capacity, their permanent bonding necessitates destructive removal. Overall, the study demonstrates that circularity in MSBs is governed by a trade-off between structural performance and disassemblable integrity, with bolted and post-tensioned tie-rod systems identified as the most effective solutions for achieving reversible, multi-cycle modular construction.

1 Introduction and Relevant DfD Standards

The construction industry is shifting toward environmentally driven, resource-efficient practices. Modular steel buildings (MSBs) [1] offer rapid, high-quality solutions for applications, such as disaster response and fast-track healthcare [2], but sustaining long-term value requires reuse pathways that enable component recovery and multi-cycle

deployment. Deconstruction, the selective disassembly of building components is central to circular-economy practice because it preserves structural integrity and supports repeated reuse [3].

In MSBs, reversibility depends on inter-modular connections (IMCs), making Design for Disassembly (DfD) the key framework governing separability, accessibility, and damage-free extraction. Reversible systems also require coordinated disassembly planning, traceable material data, and value-retention processes. Building Information Modelling (BIM) supports this by embedding material and connection metadata for disassembly simulation and reuse assessment [4]. While traditional codes emphasise safety and structural performance, construction standards increasingly mandate reversibility, traceability, and controlled dismantling, criteria critical for certifying IMCs across multiple life cycles. Table 1 summarises the main standards for reusable IMC design.

Table 1. Relevant DfD standards and codes.

Standard	Scope & Technical Relevance	IMC Specific Justification
ISO 20887 [5]	Requirements for reversible and accessible joints, and disassembly sequencing.	Establishes principles for non-destructive, demountable joints to facilitate modular recovery.
BS EN 15978 [6]	Defines life-cycle assessment modules (A–D).	Essential for evaluating end of life and reuse benefits for recovered joints.
BS EN 15804 [7]	Product-level EPD rules for circularity and reuse potential.	Standardises recoverability claims for MSBs and their constituent fasteners.
EN 1993-1-8 [8]	Eurocode 3 provisions for steel joints.	Governs mechanical behaviour and replaceability of bolted IMCs.
PAS 2080 [9]	Carbon management through value-chain collaboration.	Prioritises low-carbon procurement of reversible assemblies.
IStructE Ltd. [10]	Guidance on structural steel reuse, testing, and re-certification.	Provides protocols for validating the residual capacity of IMC bolts and plates after service.
BS EN 18239 [11]	Digital passports to trace structural properties.	Enables BIM-integrated tracking for verified reuse of modules.

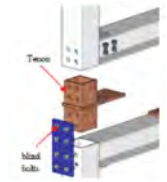
To systematically compare the circularity potential of MSBs, this study applies a Multi-Criteria Decision-Making framework (MCDM) to assess the DfD characteristics of four IMC typologies, bolted, tie-rod, self-locking, and grouted systems. A Disassembly Performance Index (PI) is then calculated to determine which IMCs are most suitable for reversible, multi-cycle MSB reuse.

2 Methodology of DfD Assessment

MCDM approach is used to systematically evaluate circularity [12]. This method enables qualitative and semi-quantitative judgments to be normalised and aggregated into a single quantitative PI, using Eq. (1):

$$PI_J = \left(\sum_{i=1}^{n} w_i r_{ij} \right) \times 100\ (\%) \tag{1}$$

where: w_i = weighting factor ($\Sigma w_i = 1$); rating $r_{ij} = s_{ij}/S_{max}$; s_{ij} = Likert score (1–5) for joint j at criterion i; $S_{max} = 5$; and n = total criteria (n = 5).



IMCs are assessed using a five-point Likert scale (C1–C5). The qualitative benchmarks and scoring logic that underpin these ratings are presented in Table 2. The assigned scores are based on qualitative interpretation of reported IMC behaviour and disassembly characteristics from the reviewed literature. Scores are derived using expert judgement to ensure consistency across IMCs. Although the MCDM framework enables systematic comparison, the semi-quantitative scoring process involves expert judgement and some inherent subjectivity.

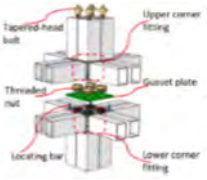


Table 2. DfD performance scoring matrix for IMCs.

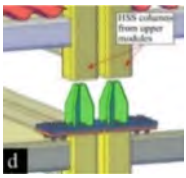
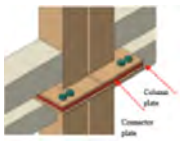


Category	Criterion	Objective	1	2	3	4	5
A: OE (30%)	C1: Accessibility	Ease to dismantle	Destructive removal	Heavy machinery	Light power tools	Two-sided, tools	One sided, tools
	C2: Disassembly sequence	Module decoupling	Partial demolition	High-interlocked	Moderate-needs bracing	Reverse order	Fully independent
B: SC (50%)	C3: Reversibility	Damage to IMC mechanism	Permanent joint	Partially destructive	Semi-reversible	Sacrificial bolts	Fully mechanical
	C4: Damage decoupling	Severity of joint deformation	Failure of primary member	Major deformation	Minor local yielding	Needs replaceable parts	Sacrificial fasteners
C: PDV (20%)	C5: Recertification index	Ease of reuse inspection	Non-rectifiable	Hidden parts	Partial access	Minor wears	NDT ready



3 Performance of IMC Typologies

IMCs, identified from the literature and illustrated in Fig. 1, are evaluated using the proposed MCDM framework. Weighting factors assign priority to structural circularity (SC) (50%), operational efficiency (OE) (30%) and post-disassembly viability (PDV) (20%) to reflect the emphasis on non-destructive recovery and reliable recertification. Greater weighting is assigned to SC because irreversible damage to primary members directly limits multi-cycle reuse potential, while OE and PDV govern the practicality of dismantling and reuse verification. Table 3 presents the resulting scores and corresponding PI values.

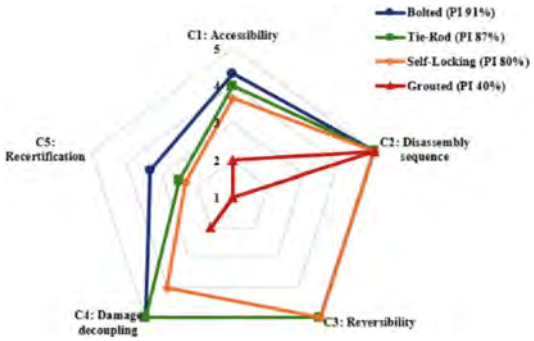

Fig. 2. Comparative PI of IMC Typologies

Quantitative results in Fig. 2 reveal performance based on connection typologies.

- *Bolted Connections (PI = 91%):* These achieve the highest PI, as damage is isolated to replaceable fasteners while the main structural components remain intact. Their full mechanical reversibility supports multi-cycle reuse. However, structural efficiency may be reduced by bolt-hole clearances and the associated risk of slip-controlled behaviour.
- *Tie-Rod Connections (PI = 87%):* Tie-rod systems score highly in reversibility but face circularity constraints due to their reliance on specialised hydraulic jacks for tension release and the difficulty of inspecting concealed internal components during recertification.
- *Self-Locking Connections (PI = 80%):* These mechanisms embed the locking interface within the joint, limiting visibility and requiring invasive intervention for safe retraction. This reduces operational efficiency during deconstruction. Additionally, their dependence on tight manufacturing tolerances may constrain geometric flexibility and affect structural performance.

- *Grouted Connections (PI = 40%):* Although grout can provide rigid, full-strength behaviour, its strong bonded interface prevents non-destructive removal. Deconstruction typically results in section loss at column ends, requiring substantial refurbishment prior to any potential reuse.

4 Conclusions

This study demonstrates that the disassembly performance of modular steel buildings is governed primarily by the reversibility and inspection accessibility of their inter-modular connections. Using an MCDM-based DfD assessment, bolted and tie-rod systems emerged as the most suitable typologies for multi-cycle reuse, offering high mechanical recoverability and manageable recertification demands. Self-locking mechanisms provide moderate performance, limited by obscured interfaces and precision-dependent manufacturing, while grouted connections remain incompatible with circularity due to their inherent destructiveness. Overall, the results highlight that circular MSBs require reversible and accessible connection systems that enable robust dismantling and reuse. Future work could include quantitative environmental indicators and life cycle assessments to strengthen the framework's practical applicability.

Building Designers' Attitudes Towards Reuse of Materials in Construction

Abstract. The construction sector's contribution to environmental degradation and global waste highlights the need for circular practices that extend the life of existing resources. By prioritizing reuse, adaptability, and longer service life over demolition and replacement, circular construction can reduce primary material extraction and construction waste across scales of the built environment. Yet its uptake depends not only on technical solutions but also on the values, emotions, and tacit knowledge guiding designers' decisions. This study examines how these determinants of behavior shape building designers' attitudes towards material reuse within the Belgian construction context, where policy ambitions coexist with market barriers, and how they influence the effectiveness of emerging digital tools such as digital building logbooks, material passports, and reuse marketplaces. An interactive workshop with Belgium-based building designers used generative collages to access unconscious associations and bypass social desirability biases. The analysis of collages and descriptive narratives considered affective, behavioral, cognitive and values components. Findings show that designers' attitudes toward reuse are primarily rooted in biospheric and altruistic values, with hedonic values playing a consistent and influential role. Participants expressed optimism, framing reuse as transformation and value creation rather than simple substitution, while also reporting apprehension regarding uncertainty, limited trust in reused materials, and a perceived external locus of control. The study highlights that strengthening re-use through digital tools requires aligning information with designers' value structures, lowering cognitive effort through defaults and streamlined processes, and reinforcing collective and past positive actions through feedback, demonstrating how behaviorally informed tool design can support circular construction in practice.

Keywords: material reuse · designers' attitudes · decision-making digital building logbooks · circular construction

1 Introduction

The construction sector is highly material-intensive and generates substantial waste, making circular strategies such as reuse, adaptability, and extended service life central to reducing primary material extraction and construction waste. European policies

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 340–347, 2026.

increasingly emphasize digitalization as a lever for advancing circularity in the built environment [1, 2]. Digital Building Logbooks (DBLs), material passports, and linked reuse marketplaces are expected to improve traceability, information exchange, and lifecycle management, thereby enabling more efficient reuse of materials [3, 4].

However, the availability of digital tools alone does not guarantee adoption. Studies in the Architecture, Engineering, and Construction sector indicate that technological maturity is not the main barrier; rather, behavioral, organizational, and market-related factors constrain implementation [5, 6]. In Belgium, institutional and market challenges are identified as more significant obstacles to circular transition than technical indicators [7], and previous research shows that architects rely primarily on experience and client demands rather than decision-support tools in their design processes [8, 9]. Tools are adopted when they improve design quality and reduce complexity by solving problems existing practices cannot address, rather than by providing added information.

These findings from previous studies suggest that advancing circular design and construction requires understanding how designers perceive reuse, how they evaluate its risks and opportunities, and how digital infrastructures can align with professional values and decision-making practices. Building on this insight, the current research investigates how tacit knowledge shapes building designers' attitudes towards material reuse in the Belgian context, and how these attitudes influence the potential adoption of digital tools intended to support circular construction.

2 Theoretical Framework and Methodology

Understanding why technically feasible reuse strategies are not systematically adopted requires attention to the behavioral determinants shaping professional decision-making. The Theory of Planned Behavior (TPB) posits that behavior is guided by intentions, which depend on attitudes, perceived social expectations, and perceived behavioral control, that is, whether individuals feel they have the capability, resources, and opportunity to act [10]. When perceived behavioral control is low, positive intentions may not translate into implementation. This is particularly relevant in professional contexts, where time constraints, risk, and responsibility influence decisions. Internally motivated intentions are also more likely to be enacted than those driven primarily by external pressures [11]. The TPB has been applied to designers' decisions in sustainable material specification, waste minimization, and heritage conservation, highlighting the importance of attitudes and perceived control in professional practice [12–15].

To analyze attitudes more closely, this study adopts the ABC model, which distinguishes affective (emotions), behavioral (intentions and action tendencies), and cognitive (beliefs, perceived barriers, and enabling conditions) components [16]. Emotions influence how situations are evaluated and whether action feels attractive or risky and have been shown to shape environmental decision-making and technology acceptance [17, 18]. Attitudes are grounded in relatively stable value orientations that guide what individuals consider important [19]. In environmental contexts, biospheric values (concern for nature and ecosystems) and altruistic values (concern for others and society) are often associated with pro-environmental behavior, whereas hedonic values (seeking pleasure, comfort, and aesthetic satisfaction) and egoistic values (seeking status,

power, or personal gain) may inhibit action when the behavior is perceived as costly in terms of effort, time, or comfort [20, 21]. This connects to the "hassle factor", whereby anticipated complexity and cognitive burden discourage sustainable behavior despite favorable attitudes [22]. Together, these concepts provide the analytical lens to examine how designers interpret reuse, how they emotionally and cognitively evaluate it, and why positive orientations may or may not translate into practice.

An interactive focus group with 11 architecture professionals was conducted in Brussels in October 2023. Participants engaged in a generative collage exercise exploring tacit meanings associated with material reuse, followed by recorded group discussions. The dataset consisted of visual materials and transcribed narratives, analyzed using the ABC framework and four value orientations [20] through qualitative content and thematic coding.

3 Results

Participants described reuse of materials using both positive and ambivalent terms, from opportunity and value to uncertainty and disruption. Across collages and narratives, recurring patterns converged around three central beliefs: reuse is (or should be) beautiful; it requires collaboration; and it is urgent.

At the level of values, biospheric orientations are most frequently expressed, followed by hedonic and altruistic values. References to nature, including landscapes, trees, ecosystems, and sustainability, appear consistently across images and narratives. However, climate change is rarely mentioned explicitly, suggesting that environmental concern is not primarily framed in carbon or emission terms. As one participant noted, climate action "it is more of a way of life, reducing global warming is not just about materials". Altruistic values are expressed through emphasis on collaboration and inclusivity, for instance in statements such as "everyone needs to be included" and in images depicting collective action. Hedonic values play a central role in how reuse is perceived. Beauty, charm, and poetry are repeatedly associated with reused materials, often framed as opportunities for reinterpretation rather than compromise. The image of a kintsugi-repaired plate, described as "seeing the beauty of the imperfect", illustrates how repair and reuse are linked to aesthetic appreciation and value creation (Fig. 1). Egoistic values appear less frequently and are primarily described as external barriers, for example through criticism of consumption-driven preferences for novelty and short lifecycles.

Emotionally, reuse is largely framed in positive terms. Following Plutchik's classification [17], joy is the most frequently identified emotion, followed by anticipation. Participants describe hope, curiosity, and willingness to experiment, often combined with urgency, as reflected in the statement "we need to do it now and don't push it any further". At the same time, apprehension emerges in relation to uncertainty and lack of trust, particularly regarding material quality and unclear processes. In one instance, frustration with the pace of change was expressed physically when a participant tore apart the collage support, stating "we need a second world before 2030 because that's already in seven years and we are not doing enough yet". This episode reflects a tension between aspirational commitment to reuse and perceived systemic inertia.

Fig. 1. Collage illustrating the aesthetic reframing of repair and reuse exemplifying the role of hedonic values in shaping attitudes toward reused materials.

From a behavioral perspective, reuse is understood as an active and deliberate design choice rather than a simple substitution of materials. Participants describe it through verbs associated with creativity and experimentation, such as create, reinterpret, and transform. Demolition is framed as the opposite of this approach and, as one participant stated, "demolition is design failure". Reuse is associated with intentional decision-making and responsibility, requiring designers to "try and see what can work". Perceived material value influences these choices, as illustrated by references to marble as desirable for reuse and glass as more readily discarded. Beyond material selection, participants address reuse across multiple scales of the built environment, including landscape, buildings, structures, and space. Reuse is linked to limiting expansion into the landscape and to reinterpreting existing spaces, suggesting that it is conceived not only as material recovery but as spatial and structural continuity over time.

At the cognitive level, participants articulate both barriers and enabling conditions. Barriers include lack of knowledge, uncertainty, complexity, financial and time constraints, prevailing market mindsets, and inaction. Designers question "how are we dealing with these uncertainties?" and observe that "new sells better", indicating the influence of market logics. Reuse is sometimes perceived as slower and more demanding, requiring shifts in expectations regarding value and durability. At the same time, enabling conditions are strongly emphasized. Participants refer to valuing materials differently, improving affordability, strengthening collaboration, and accelerating policy support. Data, transparency, marketplaces, and technology are repeatedly mentioned as critical infrastructures to reduce uncertainty and increase trust, for example through labelling, measuring, and tracking materials. Technology is not described as lacking, but as insufficiently integrated into existing workflows.

Overall, designers appear solution-oriented: 79% of coded references relate to enablers, while 21% refer to barriers (Fig. 2). Data is the most frequently cited enabler,

followed by policy intervention. However, despite identifying multiple solutions, participants display a pronounced external locus of control [23]. Only 19% of references to enabling actions are attributed to architects' own decisions, with most responsibility assigned to policy frameworks, market structures, and broader institutional and supply-chain constraints (Fig. 3). This gap between positive orientation and perceived behavioral control frames the conditions under which reuse can be scaled in practice.

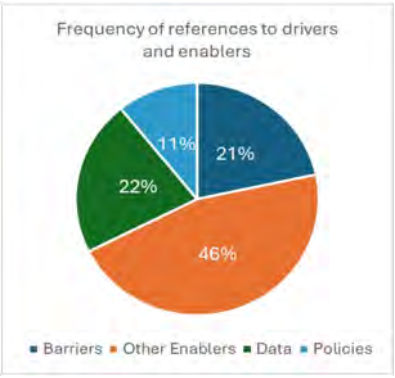

Fig. 2. Frequency of references to barriers and enablers.

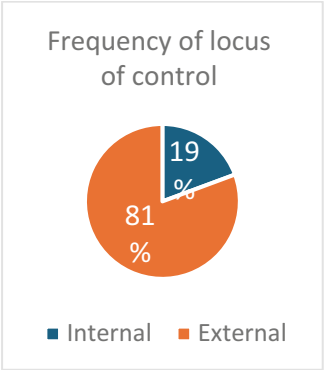

Fig. 3. Frequency of locus of control of enablers.

4 Discussion and Implications

The results show that designers generally view reuse positively, associating it with environmental concern, collaboration, and creative opportunity. At the same time, this optimism coexists with uncertainty and limited trust in reused materials. Together, these findings reveal a gap between positive attitudes towards reuse and the perceived ability to implement it in practice, highlighting the importance of considering behavioral determinants when designing digital tools to support reuse.

Behavioral change interventions do not directly alter behavior but instead act on its underlying determinants [24]. Values, which are relatively stable over time, therefore represent a crucial entry point for transformation. While pro-environmental action is commonly associated with biospheric and altruistic orientations [20], the present findings show that these values coexist with hedonic motivations. Designers repeatedly frame reuse not only as environmentally responsible but as aesthetically rewarding and creatively stimulating. As Steg [20] notes, even individuals with strong hedonic values engage in pro-environmental behavior when it becomes the most pleasurable option. Reinforcing positive actions already in place, such as the adaptive reuse of existing buildings (historic feedback), or providing information about the story, history, and heritage value of reused materials (information provision), may therefore contribute to emission reductions by activating value orientations other than carbon awareness. Increasing circularity is not primarily about strengthening environmental messaging, but about aligning reuse practices with designers' existing professional and aesthetic values.

The results also highlight a gap between motivation and perceived behavioral control. In line with Bouman et al. [21], participants identify strongly with biospheric and altruistic values, yet frequently attribute egoistic motivations to others, particularly market actors. Enabling conditions such as regulation, data availability, and market demand are perceived as decisive, but largely external to the designer's own influence. Whether designers in practice have greater actual behavioral control and can act as change agents in the construction sector than they themselves perceive remains an open question. Nevertheless, this limited perceived behavioral control may reduce the likelihood that positive intentions translate into action. Interventions that make collective progress visible may help address this gap. In the context of digital reuse platforms, this could include accounting for CO_2 saved together through platform use (group-based feedback) or benchmarking a designer's reuse material score against peers in the same geographical area (social comparison feedback).

Emotional dynamics further clarify these mechanisms. Participants oscillate between optimism and apprehension, reflecting commitment to reuse alongside concerns about uncertainty and reliability. Emotions shape decision-making by amplifying perceived risks or rewards [18]. Trust-building measures, transparency, and credible performance data are therefore central to strengthening perceived behavioral control. At the same time, anticipated hassle and cognitive burden may inhibit action, consistent with the "hassle factor" described by de Vries et al. [22]. Designers expressed concern that reuse introduces additional complexity into already constrained workflows. Reducing cognitive effort, simplifying procedures, and embedding reuse as a default option within digital tools may thus be more effective than providing additional technical solutions alone.

5 Conclusion

In conclusion, the findings indicate that advancing reuse in the built environment requires more than technical optimization or one-to-one material substitution. Designers already hold value orientations compatible with circularity and often approach reuse as a creative opportunity. The main challenge lies in strengthening perceived behavioral control and reducing cognitive friction while reinforcing collective momentum. Digital tools such as DBLs and marketplaces can support this transition when designed as behaviorally informed instruments aligned with professional values and decision-making practices.

Abstract. This paper presents a multi-stakeholder Living Lab addressing construction waste reduction through the redesign and adoption of recyclable, bio-based underfloor heating systems. Through stakeholder mapping workshops and semi-structured interviews with municipalities, material producers, construction companies, waste managers, and policy actors, we identify systemic barriers to circular material adoption: procurement frameworks prioritising lowest cost over lifecycle impact, resistance to innovation among practitioners, lack of material standardisation for reuse, and absence of mandatory material registries. After alignment workshops, the redesigned bio-based underfloor prototype was produced and installed in a university room and a kindergarten for validation, where material performance and user satisfaction are measured, providing empirical evidence for bio-based technology viability in real-world conditions. Our contribution lies in documenting the co-design process that shapes circular innovation pathways in the built environment, suggesting scalable strategies for bio-based material integration and addressing the gap between circular economy ambitions and construction sector realities.

Keywords: Construction Waste · Circular Economy · Bio-based Materials · Multi-stakeholder Collaboration · Living Labs

1 Introduction

The construction and demolition sector is one of the largest contributors to waste generation in Europe, accounting for approximately 37% of total waste produced across EU member states [1]. Within this context, heating infrastructure represents a particular challenge in terms of both energy cost and problematic waste streams: conventional systems require high-temperature water (>60 °C) and rely on mineral-based materials that

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 348–356, 2026.
https://doi.org/10.1007/978-3-032-34930-9_41

are difficult to separate, recycle, or reintroduce into productive cycles at end-of-life. As the European Union accelerates its circular economy transition through the European Green Deal and associated regulatory frameworks, the built environment has come under renewed scrutiny as both a source of systemic inefficiency and a domain of significant transformation potential [2].

Circular economy (CE) principles offer a compelling reorientation of how buildings are designed, constructed, and ultimately deconstructed. Rather than following a linear take-make-dispose model, circularity demands that materials retain value across multiple lifecycles, that waste is designed out, and that buildings function as material banks rather than material sinks [3]. Bio-based materials—derived from renewable biological sources—are particularly promising candidates, combining lower embodied carbon, biodegradability or recyclability, and the potential for closed-loop material management. However, even after technical solutions have been developed, widespread industry adoption remains constrained by a complex web of regulatory, economic, behavioural, and knowledge-related barriers.

This paper presents a work-in-progress project employing a Living Lab methodology to investigate the development, implementation, and adoption of bio-based, recyclable underfloor heating systems as a circular alternative in existing buildings. Two real-world installation sites in Sweden—a university building and a nursery school—serve as experimental environments in which technical performance, user acceptance, and stakeholder dynamics are simultaneously evaluated. The project is explicitly co-designed: citizens, construction companies, municipalities, and policy actors collaborate closely with researchers, material producers and waste managers to redesign the products, adapt the processes, and develop the new prototypes—co-developing the conditions under which circular transitions become feasible.

2 Circular Economy in the Built Environment

Although societies have always recycled materials (stone, wood, bricks, metals, paper) out of scarcity and economic necessity, the CE concept gained global prominence in the 2010s as a model designed to minimize waste by keeping products, materials, and systems in use for as long as possible, moving from niche academic discourse to mainstream policy driven by recognition that resource consumption is structurally unsustainable at current demands.

The construction sector is resource-intensive and lifecycle thinking has become a priority. CE principles have been applied through concepts such as design for disassembly, material passports, urban mining, and reversible buildings [3, 4]. The Ellen MacArthur Foundation's framework of inner loops—reuse and repair over recycling and recovery—has been particularly influential in the built environment [5]. In 2015, the sector was included in the first EU Circular Economy Action Plan, and buildings have since been considered "materials banks". Despite this conceptual richness, empirical evidence on CE adoption in construction practice remains sparse. The sector is characterized by long asset lifetimes, fragmented value chains, project-based procurement, and a risk-averse innovation culture [6]—structural features creating path dependencies that reproduce conventional material choices even when circular alternatives are technically and economically viable. A recurring finding is that barriers to circularity are not

primarily technical but institutional and behavioural: procurement frameworks, upfront cost, lack of trusted data on material quality and provenance, and absence of incentive alignment across actors [7].

Bio-based materials occupy an important but contested position within circular construction. They offer genuine environmental advantages—lower embodied carbon, renewable feedstocks, and closed-loop recyclability at end of life—yet face significant market acceptance challenges related to perceived durability, fire and moisture performance, unfamiliarity among specifiers and contractors, and a regulatory framework calibrated to mineral-based products [8]. Bio-based underfloor heating systems illustrate these tensions: while technical performance can be demonstrated, adoption requires overcoming institutional inertia across the value chain.

3 Multidisciplinary Collaboration as a Precondition for Systemic Change

The systemic nature of CE transitions implies that no single actor or discipline possesses the knowledge or leverage to drive change unilaterally. Municipalities set procurement standards and zoning; material producers determine what enters the market; construction companies mediate between design intent and physical reality; waste managers define what happens at end of life; and end users shape demand [10]. This interdependence reflects a socio-technical system in which technological change is inseparable from institutional arrangements, market structures, cultural practices, and governance dynamics: transformations emerge not from isolated innovations, but from coordinated changes across multiple system dimensions simultaneously [9].

Multidisciplinary collaboration in this context means more than assembling diverse stakeholders: it requires structured knowledge translation across disciplinary and sectoral boundaries, mechanisms for negotiating conflicting interests, and shared frameworks for evaluating success. Recent CE research indicates that collaboration failures often stem not from technological limitations, but from fragmented information flows, asymmetries in decision-making power, and the absence of common performance metrics across the building lifecycle [20]. In this project, stakeholder mapping workshops were used as an initial instrument to identify the full ecology of actors implicated in the adoption of bio-based heating systems, and to map the collaborative and antagonistic relationships between them. Such participatory approaches are increasingly indicated in transition management and Living Labs as essential for identifying leverage points, institutional lock-ins, and opportunities for coordinated intervention, with well-demonstrated potential to drive sustainable development, particularly in the bioeconomy sector [20].

Semi-structured interviews with municipalities, construction firms, material producers, waste managers, and policy actors revealed a consistent pattern of systemic misalignment: each actor acknowledged the desirability of circular transitions, yet located barriers primarily in the behaviour of other actors—absent standardized material data, client risk aversion, lowest-cost procurement frameworks, and missing material registries. This mutual attribution is diagnostic of a collective action problem that cannot be resolved unilaterally.

A further challenge concerns the temporal mismatch between economic incentives and environmental benefits: many construction actors operate within short investment cycles that prioritize immediate cost minimization over lifecycle performance, systematically disadvantaging reusable, adaptable, and bio-based materials despite their long-term value [11]. CE transitions therefore require institutional mechanisms aligning financial incentives with long-term sustainability objectives.

The research project described here explicitly addresses this collective action dimension: bringing multiple stakeholder categories into a shared Living Lab environment creates conditions for mutual learning, joint problem-framing, and collaborative solution development, and generates evidence—on material performance, user acceptance, and process effectiveness—that can build the trust needed to shift procurement practices and professional norms.

3.1 The Living Lab Framework and Its Application in This Project

Living Labs are open innovation environments in which products and systems are developed, tested, and refined in real-world settings with the active participation of end users and other stakeholders [11]: unlike controlled laboratory experiments, they operate in the complexity of actual social and physical environments, and unlike purely consultative processes, they generate empirical data alongside stakeholder engagement. In circular construction, Living Labs have been used to test material innovations, evaluate retrofit strategies, and explore new business models for resource recovery [12]. Because multiple stakeholders participate in defining questions and interpreting results, they accelerate the social learning that underpins systemic change.

This project operates in one Living Lab where prototypes were co-designed, tested and validated at two Swedish locations: a renovated meeting room in a university building and a nursery school classroom. These sites were deliberately selected for their distinct user profiles (academic staff and students; teachers and young children), organizational contexts, and patterns of floor use that may differentially stress the material's thermal and mechanical performance. At the university, conventional radiators were replaced by recyclable underfloor heating; at the planned nursery, recyclable floors were considered as part of the municipality's requirements.

The Living Lab process encompasses three phases: first, stakeholder mapping and semi-structured interviews characterized the barrier landscape; second, the installations are presented for stakeholder approval; third, the bio-based underfloor heating system is installed and its technical performance, energy savings and end-user satisfaction are quantified. Material performance is compared with traditional heating floors based on expanded polystyrene foam, and energy savings with respect to traditional radiator systems. Finally, user perceptions are captured through structured surveys covering functional, emotional, and experiential dimensions, drawing on prior research on indoor environmental quality, material experience, and public acceptance of sustainable technologies [13, 14]. Functional perception captures attributes such as thermal comfort, noise, slipperiness, and cleanability; emotional perception covers affective responses such as comfort and pleasantness; experiential perception evaluates tactile qualities (temperature, smoothness, resistance) through direct interaction with the floor surface;

an additional module assesses attitudes toward circular materials relative to conventional alternatives.

4 Results

Stakeholder engagement in the first project phase identified three categories of systemic barrier to bio-based circular material adoption.

First, procurement frameworks in both the public and private sectors remain strongly oriented toward upfront cost minimization, with limited capacity to incorporate lifecycle cost or environmental impact assessments—a structural disadvantage for bio-based alternatives whose lifecycle advantages are not captured in conventional metrics. Moreover, through substitution of fossil-based alternatives, forest-sector products reduce fossil CO_2 emissions by over 200 million tons annually in the Nordic-Baltic region alone [15].

Second, resistance to innovation among construction practitioners was identified as a significant barrier, rooted in risk aversion, unfamiliarity with the new bio-based 3D-paper composite materials, and negative beliefs about their moisture performance.

Third, EU countries differ in how they follow the "waste ladder" of EU Directive 2008/98/EC on waste [21], whose intentions this project follows: in Sweden, zero organic waste goes to landfill, compared with more than 100 Mt./y in the rest of the EU. Bio-based heated underfloors consist of 82% paper (FSC-certified mechanical, semichemical, chemical and/or recycled pulp-based liner, fluting and inner liner) and 18% aluminium, with water pipes inserted within this matrix. When dismantled, the materials are easily separated for traditional recycling cycles. Strength results of hot-pressed papers show that conventional fossil-based EPS foam could be replaced without problems, except that the bio-based paper composite is more expensive.

For use in wet areas, however, the wet strength and moisture resistance of the "heat-board" must be further improved, which can be achieved with a new hot-pressing technology for the paper materials in the 3D-composite board. With hot-pressed paper from chemithermomechanical pulp (28% lignin content if made from spruce), dry tensile strength increases by 50–150%, depending on whether the starting material is a semi-chemical pulp such as NSSC (high starting value) or a low-energy chemithermomechanical pulp such as HTCTMP (low starting value). Laboratory sheets and industrially produced paper were hot-pressed in lab- and pilot-scale machines; example dry-strength results (tensile index) are shown in Fig. 1, partly based on research published by Joelsson et al. [16–18].

In addition, this combination of elevated temperature and pressing conditions significantly improves wet strength, retaining 20–35% of the dry tensile index, depending on the hot-press conditions, while untreated materials exhibit no measurable wet strength, examples are shown in Fig. 1.

More fundamental studies indicate that hot-pressing of paper materials consisting of lignin-rich fibers recreates fiber–fiber bonds close to those in native wood, which means that paper with both high dry and high wet strength is achieved. Experimental results show a pronounced increase in wet strength above 175 °C, which correlates with lignin softening and enhanced fiber–fiber bonding in the simulation studies [19]. These findings highlight the ability of molecular simulations to elucidate the mechanisms of

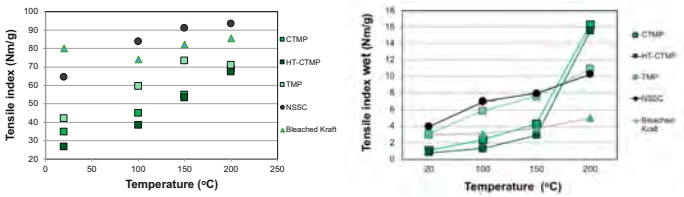

Fig. 1. Dry (left) and wet (right) tensile index as a function of hot-pressing temperature of paper made from high yield pulps (TMP, CTMP and HTCTMP), semichemical pulp (NSSC) and bleached kraft pulp.

lignin-driven bonding and provide a foundation for optimizing the use of lignin-rich materials in various applications; see Fig. 2.

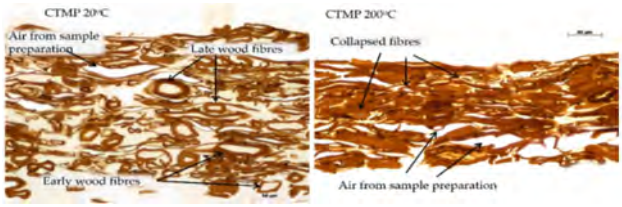

Fig. 2. SEM images of paper sheet cross sections: (a) reference sample, (b) 180 °C moist, (c) 260 °C dry, and (d) 260 °C moist. Red and blue markings show areas where the interface (at 260 °C) between neighboring fibers becomes invisible under moist but not dry conditions.

The implementation of the bio-based 3D-paper composite heating floor yielded several empirical results: installation was completed in two working days without major disruption to the building; the new system adapted perfectly to the existing water heating circuit, confirming compatibility with traditional systems; and the room was furnished (carpet, two large meeting tables, twenty chairs with wheels) without any technical problem, confirming in use the resilience demonstrated in the laboratory.

Regarding user perception, preliminary data suggest broadly positive acceptance of the bio-based floor, with functional ratings comparable to conventional alternatives and emotional perception scores above neutral, consistent with prior research on user acceptance of sustainable building materials [15].

5 Toward a Theory of Change for Circular Construction

The Living Lab methodology and multi-stakeholder engagement process described here are oriented toward developing not only practical implementation strategies but also a theory of change: an account of the causal mechanisms through which circular transition in construction can be achieved, and of the interventions most likely to activate them.

Based on the empirical findings, a nascent theory of change can be articulated around three interlocking mechanisms. The first is evidence-based legitimation: the generation

of credible performance data, both technical and experiential, that enables decision-makers to justify circular procurement choices against the dominant cost-minimisation logic; the Living Lab is the primary instrument for generating this evidence in real-world conditions. The second is stakeholder alignment: the structured engagement of actors across the value chain to surface misalignments, build mutual understanding, and develop shared frameworks for assessing value, initiated through the mapping workshops and interviews and to be consolidated in the third-phase co-design workshops. The third is institutional embedding: the translation of project learnings into procurement frameworks, professional standards, and regulatory instruments that normalise circular material choices.

Together, these mechanisms constitute a theory of change that is neither purely top-down (regulatory mandates) nor purely bottom-up (individual innovation), but systemic: it operates simultaneously at the levels of evidence, relationships, and institutions, coordinating action across multiple leverage points [9].

6 Conclusions

This paper has presented a Living Lab project investigating the redesign and adoption of bio-based, recyclable underfloor heating systems as a contribution to circular economy transitions in the built environment. Its principal methodological contribution is the integration, within a single Living Lab framework, of multi-stakeholder co-design, technical performance measurement, and user perception research—reflecting the core argument that circular transitions in construction are inherently socio-technical.

The findings confirm the systemic character of the barrier landscape: procurement frameworks oriented toward upfront cost minimization, practitioner resistance rooted in risk aversion and unfamiliarity with bio-based materials, and considerable differences in the implementation of EU waste-hierarchy regulations across member states. The Living Lab implementation confirms the feasibility of the innovative material, its energy-saving efficiency, user acceptance, and end-of-life recyclability advantages.

Design for Deconstruction: Closing the Material Loop in Malta's Construction Industry

Abstract. The construction industry is frequently criticized for its contribution to global resource depletion, particularly through the disposal of materials from end-of-life buildings. Closing the material loop by transforming waste into a resource is essential for achieving a more sustainable and circular built environment. Design for Deconstruction (DfD), also referred to as Design for Disassembly, is a waste minimization strategy that enables buildings to be dismantled at the end of their service life, allowing components and materials to be reused or recycled rather than landfilled. This study investigates the potential for implementing DfD within the Maltese construction industry, where construction and demolition waste remains a significant environmental concern. A quantitative research approach was adopted through the distribution of a survey among key industry stakeholders to assess current practices, levels of awareness, perceived barriers, and potential drivers for adoption. The findings indicate that time and cost constraints, limited education and training, entrenched industry culture, and existing policies and regulations represent major obstacles to DfD implementation. However, financial incentives, strengthened regulatory frameworks, and enhanced professional training emerged as key enablers that could facilitate wider adoption. Although carried out within the Maltese context, the results reflect broader challenges faced by small islands and resource-constrained regions, highlighting DfD's wider applicability as a systemic strategy for promoting circular construction and reducing waste in the built environment.

Keywords: End-of-life · Design for Deconstruction · Material Reuse · Barriers · Strategies

1 Introduction

The construction industry is among the most resource-intensive sectors globally, significantly contributing to material consumption, energy use and waste generation [1]. A substantial portion of this impact occurs at the end-of-life stage of buildings, where demolition remains the dominant practice, leading to the loss of valuable materials that could otherwise be recovered and reused [2]. This linear '*take-make-dispose*' model

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 357–364, 2026.
https://doi.org/10.1007/978-3-032-34930-9_42

intensifies energy consumption, greenhouse gas emissions, natural resource depletion and landfill pressure. In response, circular economy principles promoting reuse, recycling and regeneration have gained prominence [3, 4]. Design for Deconstruction (DfD) represents a key waste minimization strategy, enabling buildings to be dismantled rather than demolished. By integrating de-constructability into the design phase, DfD facilitates material recovery and reuse, reduces waste generation, enhances resource efficiency and supports long-term environmental sustainability [5, 6].

The Maltese Islands present a critical context due to high population density, limited land availability and intense construction activity. Construction and Demolition Waste (CDW) constitutes a significant share of the national waste stream, with landfilling and quarry backfilling remaining the predominant disposal methods [7]. Such practices are unsustainable in the long term and misaligned with the EU's circular economy goals [8]. This paper explores the potential of implementing DfD in Malta to reduce construction waste and simultaneously promote material reuse through sustainable design. It assesses stakeholder awareness, current practices, and barriers to adoption, while identifying strategies to support integration. Although centered on Malta, the findings are relevant to other regions facing similar environmental challenges.

2 Literature Review

2.1 Construction Waste and Circular Economy

The construction industry plays a vital role in national economies, as it shapes the built environment and by being an important economic driver [8]. However, this sector is among one of the most resource-intensive sectors [9], driven by urban redevelopment, building obsolescence, and short design lifespans [10, 11]. Unsustainable construction practices often prioritize disposal rather than value retention, leading to the loss of embodied energy and materials, intensifying resource scarcity, and contributing to climate change [2]. Circular economy challenges this, as it turns waste into a resource by closing the material loop [3, 4].

Circular strategies in the built environment include material reuse, recycling, adaptive reuse and life-cycle-based design. DfD aligns well with these circular principles by enabling high-quality material recovery for reuse, which generally provides greater environmental benefits than recycling [5, 12, 13].

2.2 Design for Deconstruction (DfD)

DfD is an approach in which buildings are intentionally designed for disassembly at the end of their service life, enabling the reuse and recycling of recovered materials [13]. It requires strategic consideration of material selection, structural systems, accessibility and documentation. By promoting resource efficiency DfD delivers environmental and economic benefits, including embodied carbon preservation, waste reduction, job creation and the growth of secondary material markets [2, 14–16].

Theoretical models such as Brand's shearing layers conceptualize buildings as dynamic systems composed of components with varying lifespans [17]. Designing these layers for easy separation facilitates effective deconstruction [18].

2.3 Barriers to DfD Adoption

Despite its recognized benefits, DfD remains underutilized in the construction industry with several recurring aspects being identified in literature as potential barriers, including higher perceived upfront costs, lack of regulatory incentives, fragmented industry structure, limited market demand for reused materials, limited education and training among built environment professionals and cultural perceptions regarding the quality and reliability of reused materials [13–16]. These barriers are especially evident in contexts where demolition has been normalized and where policy frameworks do not promote circular strategies [2].

2.4 The Maltese Context

Over the years, CDW management in Malta has relied heavily on landfilling and quarry backfilling. Recycling practices such as the reuse of stone and the crushing of concrete for aggregate, are currently in place; however, more sustainable long-term strategies need to be implemented [8, 19]. The Maltese context is characterized by a strong demolition culture, constrained land availability, and a regulatory framework which has not incentivized circular construction strategies. These conditions make Malta a particularly relevant case for investigating the feasibility and challenges of implementing DfD.

3 Methodology

3.1 Research Design

The study adopts a quantitative research approach by developing a structured 18 question survey, consisting of 11 closed 'Yes' or 'No' questions and 7 Likert scale structured questions, allowing for both quantifiable responses and additional open-ended comments. This was done to best capture stakeholder perspective on end-of-life practices, awareness of DfD, perceived barriers, and potential drivers [20].

The survey targeted key stakeholders within the Maltese construction industry including warranted architects and engineers, contractors, developers and clients. To encourage truthful reporting, data was collected anonymously. Although the Maltese market size is small a total of 125 respondents participated in this study, 38 of which were clients, 13 were contractors and 74 were warranted architects and engineers, referred to locally as 'Perit'. Even though the sample size was considered acceptable to produce statistically meaningful and reliable results, the contractor participation remained relatively low compared to other stakeholder groups. This potentially may have affected the representativeness of contractor perspectives.

3.2 Data Analysis

Quantitative data was analyzed through the use of the Chi-Square and the Kruskal-Wallis tests, where the relationship between the respondent characteristics, such as professional role, age, and their attitude towards deconstruction, material reuse and end-of-life, was examined [20].

4 Results

4.1 Current Practices and Respondents Awareness

Although this is not yet reflected in current industry practice, overall results show that a vast majority of the respondents recognize deconstruction as a preferable end-of-life strategy, as shown in Fig. 1. A clear gap therefore exists between theoretical acceptance and practical implementation within the Maltese construction industry.

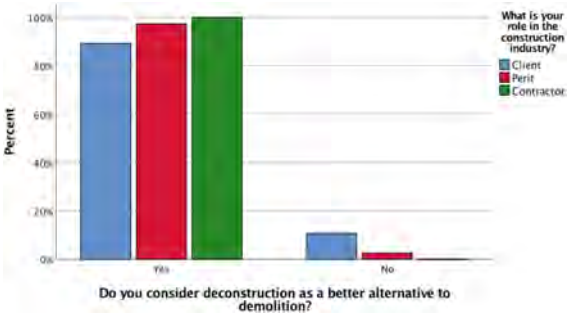

Fig. 1. Respondents choice between choosing deconstruction as an alternative to demolition, sub-divided by role.

When asked if they use recycled or reused material/products in their projects (Fig. 2) or if they think on what will happen to the materials after a building end-of-life (Fig. 3), the results however show a different picture altogether, as only a minority of respondents reported considering end-of-life outcomes to buildings, especially during the design stage. Some participants argued that buildings are intended to last for a considerable number of years, rendering such considerations unnecessary. As a result, design decisions continue to be dominated by cost, aesthetics, and regulatory compliance, reinforcing a linear '*take-make-dispose*' building model, further highlighting the gap between sustainability and everyday design practice.

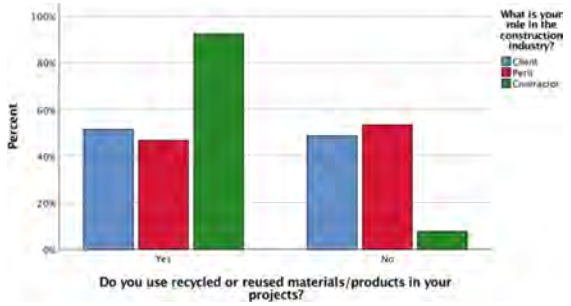

Fig. 2. Respondents use of recycled or reused material/products in their projects, sub-divided by role.

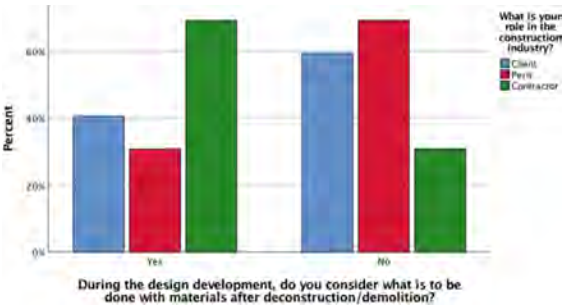

Fig. 3. Respondents consideration of what will happen to the materials after a building end-of-life, sub-divided by role.

Although some respondents reported the use of recycled or reused materials, such practices are mainly used in conservation projects, where materials such as traditional stone components are reintegrated into the development. Other recycled materials are typically down cycled and utilized for backfilling operations. This suggests that these practices are not primarily driven by sustainability objectives.

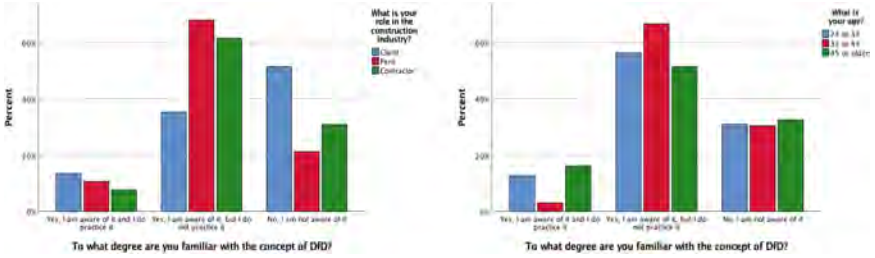

Fig. 4. Degree of familiarity of the concept of DfD sub-divided by (*left*) the role of the respondents, and (*right*) by age of the respondent.

Awareness of DfD varied significantly among stakeholder groups. Figure 4 *left* shows how professionals demonstrated higher familiarity with this concept compared to developers and contractors. This generational shift was particularly evident in younger professionals, as shown in Fig. 4 *right*.

4.2 Barriers to Implementation

Several key barriers to the adoption of DfD were identified and rated across the three main stakeholders' groups as shown in Fig. 5. While these barriers are consistent with previous international research, the findings demonstrate how they collectively reinforce demolition-oriented practices within the Maltese construction industry.

– **Time and cost constraints:** Respondents earmarked this as a major concern, with DfD perceived as more expensive and time-consuming than conventional demolition.

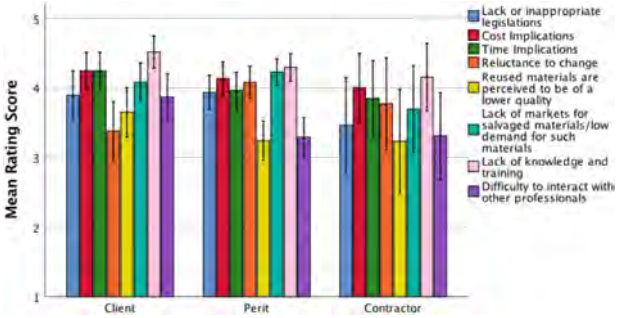

Fig. 5. Respondents rating of potential barriers to DfD.

Open-ended responses, revealed that the long standing perception is that developers prioritized short-term financial returns over long-term environmental benefits, reflecting the importance of immediate financial returns over long-term environmental value identified in existing literature [14].

- **Limited education and training:** Respondents are conscious of the insufficient knowledge and practical experience related to deconstruction principles. The absence of skilled expertise increases uncertainty and risk aversion within the sector, consistent with prior research on successful DfD adoption [21].
- **Policy and regulation:** Existing regulatory frameworks neither incentivize deconstruction nor discourage waste-intensive demolition practices. Aligning with existing literature indicating that DfD adoption is more likely when supported by policy incentives [14], respondents argued that without appropriate legislation, the implementation of DfD would remain unrealistic.
- **Industry culture:** A strong demolition culture is present, reinforced by risk aversion and skepticism towards reused materials. Respondents reported negative client perceptions of reused materials and reluctance to change. Previous research indicate that reused materials are often perceived as inferior in terms of safety and aesthetics to first time use materials [21]. Such perceptions reveal that barriers to DfD are not only technical or economic, but also cultural and behavioral.

4.3 Drivers and Enablers

To overcome barriers in adopting DfD principles, several measures were proposed as shown in Fig. 6. These include implementing new policies and stricter regulations (such as tighter landfill rules), offering financial incentives to reduce cost concerns, developing clear technical guidelines, improving education and training, integrating digital tools like BIM, involving demolition and deconstruction professionals early in the design stage, and providing adequate storage facilities for reclaimed materials. Among these, financial incentives were ranked by stakeholders as the most influential in promoting DfD adoption, consistent with previous research [21]. The findings therefore indicate that transitioning toward circular construction will require not only greater awareness, but also broader systemic support.

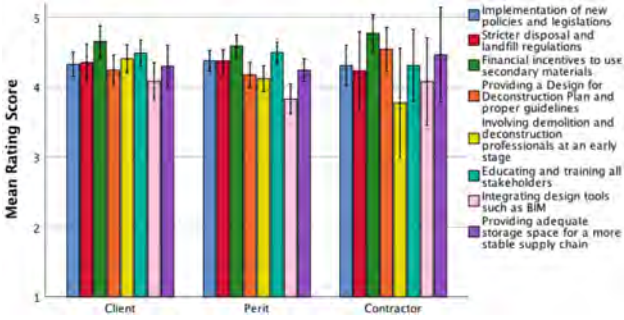

Fig. 6. Respondents rating of potential drivers to DfD.

5 Conclusion

The continued use of linear construction practices is becoming unsustainable, particularly in areas where rapid growth is increasing pressure on land, resources, and waste systems. A shift toward circular lifecycle thinking is needed, with greater emphasis on material recovery and reducing reliance on virgin resources.

The research identifies Design for Deconstruction (DfD) as a practical strategy to reduce construction and demolition waste but highlights a gap between theoretical support for circularity and its real-world application. Major barriers include cost and time pressures, lack of expertise, weak regulatory frameworks, and a demolition-focused industry culture.

Awareness alone is insufficient to drive systematic change. To enable transition, the study recommends financial incentives, stronger policies, technical guidelines, education and training, digital tools, specialist involvement, and improved infrastructure for reclaimed materials. Although focused on Malta, the findings are relevant to other resource-constrained regions. Future research should use life cycle assessment, whole-life costing, and pilot projects to validate the environmental and economic benefits of DfD and support systemic industry reform.

Abstract. Despite the ecological and economic benefits of reusing construction components, widespread market acceptance remains limited. This study investigates the factors driving and hindering the adoption of salvaged materials to develop a strategy for integrating reused components into mainstream renovation and conversion projects. The research involved a systematic analysis of current market acceptance levels and a comprehensive identification of core barriers. By evaluating the role of component and scrap exchanges, the study mapped the landscape of material reuse—from historic quality and aesthetic value to logistical and perception-based hurdles. The primary outcome is towards a Comprehensive Action Plan structured around three interconnected elements. It identifies that while salvaged materials often surpass new products in quality, market growth it currently hindered by logistical uncertainty and perception gaps. The interviews with ten Swiss key stakeholders provide insights into specific interventions for stakeholders and policymakers to bridge these gaps, transitioning component reuse from a niche concept to a mainstream industrial practice. The study concludes that the transition to a circular construction industry requires a collaborative, strategic roadmap to overcome market barriers identified in a first series of interviews. Implementing the proposed Action Plan requires more work to unlock the full ecological potential of building component reuse, and providing a clear path forward for both component exchanges and the broader construction sector.

Keywords: Circular · Reuse · Renovation · Market Acceptance

1 Introduction

As one of the most resource-intensive sectors of the economy, the construction and real estate sector makes a significant contribution to global environmental pollution. In the European Union, it is responsible for around 50% of total raw material extraction and 37.5% of total waste generation [1]. Globally, construction activities account for about 30% of total annual waste, with these figures expected to continue to rise due to population growth and infrastructure needs [2]. In addition, the construction sector is a

https://doi.org/10.1007/978-3-032-34930-9_43

major driver of the climate crisis, as it is responsible for 37% of global greenhouse gas emissions as well as 50% of total material consumption [3]. As a systemic response to this practice, the circular economy is establishing itself as a necessary paradigm shift. Their goal is to minimize resource consumption by keeping materials and products in a closed loop for as long as possible [4].

From an environmental point of view, reuse is clearly superior to recycling, as it avoids the emissions-intensive production phases. Current LCA studies quantify this advantage precisely: Compared to new material inflows, a 75% reduction in greenhouse gas emissions in manufacturing (phases A1–A4) was found. If reused components are compared directly at the component level with new equivalents, the reduction in manufacturing emissions is even up to 90% [5].

Despite these significant environmental benefits, recycling or even landfilling is still the predominant practice in many countries [2]. In reality, prioritizing reuse over recycling often fails due to a crucial hurdle: the lack of reliable data. A comprehensive information deficit is often cited in the literature as the main cause of ineffective recovery and reintroduction of components into the cycle [6]. Senarathne et al. (2025) confirm that the lack of comprehensive material information remains a significant barrier [7]. In contrast to recycling, to reuse a component directly, precise data on condition and properties are necessary, which are often not currently available in existing buildings. This underlines the need for new digital methods to rapidly improve the circularity of the entire sector [3].

Despite the ecological and economic benefits of reusing construction components, widespread market acceptance remains limited. This study investigates the factors driving and hindering the adoption of salvaged materials to develop a strategy for integrating reused components into mainstream renovation and conversion projects.

2 Methodology

The research design of this work is designed as a qualitative, exploratory study (Döring & Bortz, 2016) [8]. This approach was chosen because the design of digital marketplaces in the context of the circular economy is a complex and dynamic field in which subjective perspectives, patterns of action and specific requirements of the actors are in the foreground. Methodologically, the thesis follows a two-stage approach that combines theoretical and empirical findings:

1. In a first step, the theoretical frame of reference was developed through a comprehensive literature and document analysis. This served to record and critically classify the current state of the art, regulatory framework and systematic analysis of current market acceptance levels.
2. Based on this, a qualitative interview study was carried out in the second step. The aim was to mirror the concepts identified in theory with practical experience, to concretize information needs and to identify gaps.

This structure ensures that the design principles developed a comprehensive action plan are not only theoretically sound, but also practically anchored.

2.1 Procedure for Literature Review

The theoretical foundation of the work was based on a systematic literature and documentary analysis. Since the field of investigation of the digital circular economy is characterized by a high level of dynamism and technological innovation, a triangulation of different types of sources was undertaken.

Search strategy and sources: The research was carried out in the period from September to November 2025. To reflect both the state of scientific research and the current market reality, three main categories of sources were used:

Scientific literature: Use of meta-databases (e.g. Google Scholar, ResearchGate) and publishing portals (e.g. ScienceDirect, MDPI) to identify peer-reviewed papers.

Grey literature and standards: Analysis of industry reports, white papers and technical documentation from relevant stakeholders. In addition, specific Swiss standards (SIA 2032, SIA 390/1) and European regulations (ESPR, newCPR) are used as a normative basis.

Practical sources: Direct research on the websites of the analysed platform operators to verify functionalities and business models.

2.2 Sampling (Selection of Examination Units)

The interview partners were selected according to the principle of purpose-led sampling (targeted selection) according to Döring and Bortz (2023) [8]. In this procedure, the study units are not selected at random, but on the basis of defined characteristics that were of central importance for answering the research question.

The aim of the sampling was to depict a maximum variation of perspectives along the entire value chain of construction. Therefore, it was necessary to include experts from all relevant phases.

A total of ten experts were interviewed. The identification and approach of the people was carried out via existing professional networks, targeted research on LinkedIn and Google, and through the supportive identification of relevant professionals. The selection criteria included:

1. Technical expertise: Several years of experience in a specific role in the Swiss construction and real estate sector.
2. Specific reference: Direct points of contact with topics of the circular economy (reuse, recycling), digitization (BIM, data management) or material testing.
3. Role representation: Coverage of the entire process chain (customer, planner, operator, recycler).

The data collection took place in the period from October to November 2025 and was carried out via Microsoft Teams due to the geographical distribution of the participants. All interviews were audio-visually recorded with the consent of the respondents to enable detailed transcription. The atmosphere of the discussions was characterised by openness, with the digital implementation via MS Teams enabling the efficient integration of experts spread throughout Switzerland.

3 Results

The results are based on the qualitative evaluation of a total of 1028 coded text segments. To focus on the central findings, the synthesised core statements are presented in the following sections. Due to its scope, the complete data basis, including all detailed subcodes and assignments, is stored as a separate digital document (Codesys-tem_BA_Graf.xlsx) and serves as an evidence basis for the deductions made here.

The analysis shows that the theoretical role model is often expanded in practice by pragmatic adjustments and new responsibilities.

3.1 Strategic Aspiration and Operational Reality

Especially in the case of public building owners, a gap between aspiration and reality is revealed. While she sees herself strategically as an "enabler" who would have to initiate reuse concepts in early phases such as the preliminary study (Interview E, item 39), operational implementation often depends on the initiative of individual project managers. Binding instructions are often lacking, and processes are not yet established across the board (Interview E, pos. 20, 41–46). In addition, there is an expectation on the part of the building owner that specialist planners and contractors should proactively introduce CE concepts, but this often fails due to their lack of experience (Interview E, items 44–49).

3.2 The New Role of the "Component Hunter"

Between the static existing building and the dynamic new building, a new functional role has emerged with the specialized specialist planner for reuse (often referred to as the "component hunter"). These actors act as translators between the vague data of the existing building and the precise requirements of planning (Interview D, pos. 6–10). Its activities are divided into two directions:

In the case of the source object (dismantling): Here they act as "screeners" who carry out inventories and assess the potential of the existing building.

At the target object (new building): Here, as "hunters", they look for specific components that fit the design (Interview D, pos. 3–4).

3.3 Structural Design Between Safety and Innovation

For engineers, reuse is not an aesthetic end in itself, but a technical challenge. Its role is primarily defined by ensuring its load-bearing capacity and durability (Interview J, item 6). The experts emphasise that reuse (e.g. of steel girders) must not be treated as a "nice-to-have" item but must be ordered by the client as a "mandatory part of the project" (Interview F, item 57). Without this explicit order and the willingness to reward additional expenses, reuse remains a niche in structural engineering (Interview F, item 49).

3.4 Forgotten Facility Managers

A critical process gap is evident in the transition to operation. Facility managers (FM) are often involved too late in defining data requirements. As a result, BIM models or digital twins become "data cemeteries" that contain design data but provide irrelevant or outdated information for operations (Interview A, pos. 4–6). FM often mistakenly sees itself in the role of passive data receiver instead of actively defining requirements for maintenance (e.g. maintenance cycles, warranties) (Interview A, pos. 6, 39; Interview B, item 4).

3.5 Timely Need for Information

Timely availability emerged as critical factor with regard to information requirements. For almost all stakeholders, timing—specifically "time-to-market"—serves as the primary decision criterion. "If the date doesn't work, there's no point in looking any further to see if the quantities match" (Interview D, Pos. 19). Synchronizing the source and target objects constitutes the greatest logistical hurdle, as intermediate storage is to be avoided for cost reasons (in line with "Just-in-Time" principles). Without a guarantee of availability at the required time, effective planning is virtually impossible for engineers and architects (Interview F, Pos. 36; Interview J, pos. 20–22).

3.6 Acquisition for Geometry and State

The requirements for geometric precision are not static, but develop in the course of the project:

(1) Rough survey (screening): Initially, a rough recording (e.g. "40 washbasins", standard dimensions for radiators) is sufficient, as a detailed recording would be too resource intensive if no buyer has been determined (Interview D, pos. 3–8, 10).
(2) Detailed survey: Only if there is a concrete interest in placement is a precise recording made. In this context, purely digital methods reach their limits: The physical condition (e.g. jammed window handles, dismantling) often must be verified by an on-site inspection, as photos alone are not sufficient (Interview D, pos. 27–30, 49–50).

3.7 Pollutants as Knock-Out Criteria

A key obstacle is the data gap on pollutants. Freedom from harmful substances is considered an absolute basic requirement ("As a matter of principle, we do not release anything that we do not know to be free of harmful substances" – Interview D, item 39). Existing dismantling reports are often too inaccurate for a reuse assessment. In addition, experts from industry warn of new risks such as PFAS, which could contaminate entire material flows in the future (Interview C, pos. 35–40; Interview I, pos. 9–16). In the case of supporting structures (steel/concrete), a lack of material documentation (e.g. unknown steel grade or carbonation depth) means that safety factors must be increased, which often nullifies the economic efficiency of reuse (Interview F, items 6–8; Interview J, Pos. 19).

4 Discussion

The roles and demands of the actors were examined. This is where the greatest conflict between the theoretical ideal of the "material bank" and physical reality becomes apparent. The chosen research design of a qualitative, exploratory study with ten expert interviews proved to be expedient in shedding light on the complex, often informal processes of reuse practice. Through the deliberate selection of a heterogeneous sample from component hunters to public builders to industrial recyclers, it was possible to draw a multi-layered picture of the conflicting interests. However, it should be noted that the semi-structured character of the interviews led to thematic digressions in places. Since the interviewees had very different backgrounds, the discussions sometimes digressed into specific specialist areas such as chemical details of pollutants or legal subtleties in liability. This made it difficult to directly compare individual answers in the coding process, but at the same time brought unexpected insights to light, such as the psychological hurdle of cultural scepticism. In addition, the sample shows a certain bias, as most of the experts already had a positive attitude towards circular economy. The perspective of the broad mass of conventionally working architects, who categorically reject reuse due to traditions, was only indirectly recorded.

4.1 Timely Availability

While the theory postulates that buildings act as dynamic material banks and resources circulate through closed loops, practice identifies temporal synchronization as the biggest obstacle [9]. The results show that it is not the material itself that is missing, but the right time window. Without a physical interim storage facility ("buffer"), digital mediation often fails, as a direct "just-in-time" delivery from demolition to new construction is hardly logistically feasible. Experts confirm that components often "silt up" if they cannot be conveyed exactly at the time of dismantling (Interview D, item 67). This puts the theorical assumption into perspective that digital marketplaces alone can solve the problem; rather, it requires concepts that actively address time management.

4.2 Economics of Values

Theoretically, the circular economy transforms the building from a cost factor into a valuable warehouse whose residual value is intended to cover the dismantling costs. Practice often refutes this calculation: the high Swiss labour costs for selective dismantling and processing often exceed the material value of virgin material. A reused steel beam can be up to twice as expensive as a new one due to the testing and logistics costs (Interview C, item 63). In addition, storage costs are identified as a "massive cost driver" that can quickly neutralize ecological advantages (Interview A, item 85). This leads to the realization that Reuse often does not scale in a purely market economy without external regulators or idealistic builders.

4.3 Trust

Another contrast emerges when it comes to trust. While theory relies on technological solutions such as blockchain or the Digital Product Passport (DPP) to guarantee a

seamless "Chain of Custody" [10], practice relies on analogue mechanisms. The trust is primarily based on the physical "building materials report in hand" (Interview G, item 32) and the personal inspection. Trust is therefore not (yet) fully digitizable, since haptic testing ("stuck-the grip") is considered the last instance (Interview D, item 50).

5 Conclusions

This work analysed stakeholders' views on reused materials and components for the circular economy from a role-based perspective.

The research involved a systematic analysis of current market acceptance levels and a comprehensive identification of core barriers. By evaluating the role of component and scrap exchanges, the study mapped the landscape of material reuse—from historic quality and aesthetic value to logistical and perception-based hurdles.

The primary outcome is structured around three interconnected elements. It identifies that while salvaged materials often surpass new products in quality, market growth it currently hindered by logistical uncertainty and perception gaps. The interviews with ten Swiss key stakeholders provide insights into specific interventions for stakeholders and policymakers to bridge these gaps, transitioning component reuse from a niche concept to a mainstream industrial practice.

This outcome can feed into a Comprehensive Action Plan structured around seven interconnected components. For this, more work is needed and will be done in the coming months.

The study demonstrates that the transition to a circular construction industry requires a collaborative, strategic roadmap to overcome market barriers. The interviews with ten Swiss key stakeholders provide insights into specific interventions for stakeholders and policymakers to bridge these gaps, transitioning component reuse from a niche concept to a mainstream industrial practice. Implementing the proposed Action Plan requires more work to unlock the full ecological potential of building component reuse, and to provide a clear path forward for both component exchanges and the broader construction sector.

Abstract. Achieving European climate-neutrality goals requires adopting circular strategies that regenerate the life cycles of building materials. Within this framework, Environmental Design provides the conceptual and methodological foundation for integrating circularity into the early stages of architectural and technological design. According to this perspective, the contribution discusses a Cradle-Based approach (CBa) which, supported by Material and Product Passports, directs the design process towards the cradle of the next use cycle, thus overcoming a perspective limited solely to end-of-life considerations.

The theoretical and legislative framework analysis (European regulatory requirements for eco-friendly design, construction products, waste management, the principles of design for disassembly, LCA, Level(s)) is needed to guide the discussion about the CBa through a new cradle scenario-based analysis and scenario life cycle indicators of disassembly, recovery, durability, circularity, and environmental impact, made operational and traceable through Material and Product Passports. By embedding circular criteria and Material and Product Passports into Environmental Design processes, the method enables anticipation of material flow regeneration and guides informed design choices that reduce waste and emissions while supporting the transition towards more sustainable, adaptive and regenerative built environments.

Keywords: Cradle to Cradle · Circular Approach · Material and Product Passport · Circular Design · Environmental Design

1 Introduction

The transition of the European construction sector towards climate neutrality has become a central objective of the European Union's climate strategy. The built environment is a critical domain for achieving long term decarbonisation targets, in fact, the construction and operation of buildings account for approximately 37% of global energy-related CO_2 emissions and more than 1/3 of global material consumption [1]. These figures highlight the need to reconsider how buildings are designed, constructed, used, and ultimately dismantled.

L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 374–382, 2026.
https://doi.org/10.1007/978-3-032-34930-9_44

The construction sector traditionally follows a linear model in which the environmental strategies largely target end-of-life (EoL) stages. While these efforts reduce landfill waste, they are reactive and limit material preservation, hindering climate-neutrality and resource-efficiency goals [2].

The circular economy has become central in research and policy on the built environment. Circular construction focuses on keeping materials in productive cycles through design strategies for reversibility, adaptability, and recovery [3]. Buildings-as-material banks view buildings as temporary repositories of recoverable, reusable materials. Digital information systems play a crucial role in enabling this transition. In particular, Material and Product Passports (MPPs) have been proposed as documenting tools for improving traceability and transparency of information, to support circularity [4]. European initiatives promoted by the European Commission, including research programmes such as Buildings As Material Banks [5], have explored the role of material passports in supporting circular construction practices.

Despite these developments, most existing frameworks continue to treat the EoL stage primarily as a waste management issue rather than a design opportunity. Consequently, a gap remains between circular economy principles and the decision-making processes that shape building design [6]. To address this limitation, recent research has begun to explore a shift from EoL approaches towards a cradle-based perspective, in which the end of one lifecycle is conceived as the cradle of the next.

MPP supports scenario-based design to anticipate future material flows like reuse, refurbishment, remanufacturing, or recycling. Including these at the design stage helps create regenerative material cycles and increases long-term resource value.

This article explores the integration of a Cradle-Based approach (CBa) in architectural and engineering design, with a focus on the role of Material and Product Passports in supporting cradle-to-cradle transitions operations. This approach guides the design process toward the next material cycle, aiding the transition from linear to regenerative, circular building systems.

2 Methodology

This research adopts a design-oriented approach to develop and operationalise a CBa for circular transitions in the built environment. The proposed framework reframes the building as a dynamic material system, shifting the focus from conventional EoL management towards cradle-of-the-next-use-cycle thinking. Through scenario construction, the methodology explores regeneration pathways that extend material value across successive use cycles. European circular economy principles provide contextual boundary conditions, while MPPs are enabling tools for traceability, monitoring, and lifecycle continuity. The outcome is a conceptual methodological framework that translates circularity principles into a project-oriented design strategy for environmental design process.

Methodologically, the study follows a qualitative framework-analysis approach in two stages: **(1) regulatory and theoretical framework analysis**, identifying conceptual foundations and operational limitations of cradle-based lifecycle perspective, supporting the definition of key indicators to guide life cycles management; **(2) scenario-based analysis** in which potential scenarios and indicators are framed, combining disassemblability, recovery potential, durability, circularity performance, and environmental

impact metrics, into multicriteria scenario-based matrices, supported by MPPs, to ensure lifecycle traceability and monitoring (Fig. 1).

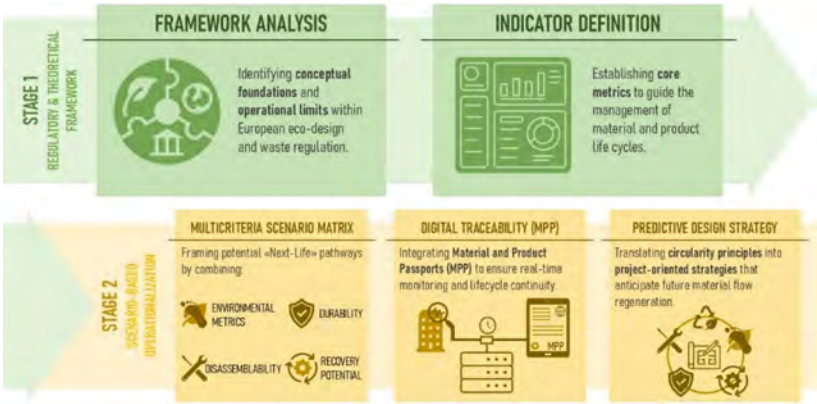

Fig. 1. The Cradle-based approach: a methodology for regenerative technological design

2.1 Research Design and Framework Development Approach

This study proposes a design framework to address the lack of operational models for regenerative lifecycle transitions in the built environment. The Cradle-Based Approach combines circular economy, lifecycle assessment, and circular design strategies to evaluate future material cycles early in the design phase. The framework is oriented towards the conceptualisation of indicators according to Design for Disassembly and Design for Recovery strategies, assessed through Life Cycle Assessment (LCA), which facilitate the future extraction and reintegration of materials into subsequent use cycles [7]. The development is guided by key European regulations and policies promoting circularity and digital traceability in construction, as Regulation (EU) 2024/1781 on Ecodesign, Regulation (EU) 2024/3110 on Construction Products, and Directive 2008/98/EC on waste. Additional guidance comes from the EU Construction and Demolition Waste Protocol and the Level(s) framework, which support lifecycle thinking and environmental assessments in building design.

The study's theoretical and regulatory framework was conducted through a structured review of key European legislative instruments and peer-reviewed literature (databases: Web of Science, Scopus), focusing on the last decade's research on lifecycle management, circular design strategies, and digital traceability in construction. Conceived as a conceptual framework analysis, it aimed at identifying recurring principles, operational variables and methodological gaps related to cradle-based circular design. The variables/criteria set (Sect. 2.2) was developed by mapping literature-derived variables against the functional requirements of each strategy within the 10Rs priority hierarchy [8]. This process was designed to be replicable: any research team can (1) identify applicable regulatory boundary conditions, (2) map material/component characteristics

against the 10Rs hierarchy, and (3) translating these into measurable indicators traceable via MPP data flows. While this work focuses on the conceptual operationalisation, its transferability across building typologies and regulatory contexts remains a priority for future empirical validation. Material and Product Passports act as digital infrastructures for data management, traceability, and lifecycle monitoring, documenting material traits, performance, and recovery potential, to support regeneration assessment and cradle-to-grave lifecycle thinking.

2.2 Scenario-Based Analysis

The cradle-based approach to the built environment's life cycle redefines the "End of Life" as "Next Life", by closing the cycle. The Design phase should adopt a predictive approach using scenario-based analysis to forecast the 'future lives" of elements, supported by tools like multi-criteria matrices and MPP, guiding lifecycle management toward predicted scenarios. The next "cradles" have been identified in the circular economy strategic framework, namely among the 10Rs of circularity, which focuses on "extending useful life": Reuse, Repair, Refurbish, Remanufacture, Repurpose, and finally High-quality Recycling.

Table 1. The fundamental variables that describe the potential access to new life scenarios.

Category	Variables/criteria	Description
Design and Assembly	Disassembly	Non-destructive disassembly level for recovery without physical damage [9].
	Connection Types	Mechanical connections or chemical bonds determine the separation difficulty and the element possible damage [9].
	Standardization	Reduced number of types of components to minimize the procedures risks [9].
	Accessibility	Ease access for maintenance or replacement without damaging surrounding elements [11].
Physical and Technical	Durability	Resist deterioration over time and wear and tear [11].
	Structural and mechanical integrity	Preservation level of the original properties (e.g., compressive strength or tensile strength) [14].

(*continued*)

Table 1. (*continued*)

Category	Variables/criteria	Description
	Maintainability and repairability	Components that can be maintained, repaired, or refurbished are more likely to extend their life cycle [13].
Chemical and Safety	Presence of toxic substances or contaminants	The presence of hazardous substances or chemical finishes can prevent their safe reuse or contaminate recycling streams [15].
	Material complexity and purity	For recycling, single-material solutions are preferable to complex composites, as separating different materials is often difficult and costly. Material purity is key to avoiding downcycling [16].

The order in which the scenarios are mentioned also represents, as stated by the scientific literature, a ranking according to their environmental impact in terms of emissions, energy and resource consumption [8], and this has also been taken as the order of priority of the 'new lives'. However, numerous variables determine an element's suitability for a given scenario. These must be translated into indicators describing the element's condition, enabling prediction of its potential future life. Table 1 summarises the identified variables.

Translating variables/criteria into measurable indicators enables creating scenario-based multi-criteria matrices to identify optimal new life scenarios. Indicator combinations define scenario access requirements, guiding design/management, while MPP data flows supports real-time, accurate access scenario updates [12].

3 Discussion

The proposed CBa aims to orient design frameworks towards predictive perspectives that outline next-use-cycle scenarios in advance, enabling proactive life-cycle management for closed-loop circularity. The shift from a reactive to a predictive design paradigm is fundamental, moving from damage management to value creation and regeneration, going beyond minimum cost/performance requirements and waste management, toward operational circularity integration with a regenerative purpose [10]. Table 2 compares the two paradigms.

The CBa offers unique contributions at the design methodology and lifecycle management interface compared to conventional methods. While existing LCA frameworks robustly quantify environmental impacts, they are generally used retrospectively as assessment tools rather than proactive tools for early-stage design decisions. Design for

Disassembly approaches address technical reversibility at component level but do not systematically link disassembly indicators to prospective use-cycle planning supported by dynamic digital tools [7]. The CBa integrates these complementary methodologies into a coherent, predictive design framework, shifting lifecycle thinking from retrospective evaluation to prospective generation, enabling design decisions that actively regenerate material value rather than merely minimising environmental losses. The goal is therefore to provide an approach based on Design for Disassembly and Design for Adaptability principles [11], orienting preliminary design towards strategies for reintroducing components into circular supply chains at the end of their life cycle, while broadening its scope by considering multiple possibilities to minimise unexpected events.

A scenario-based operational matrix is proposed as a support combining indicators with MPP data to predict the best life scenario at any stage. These matrices aid preliminary design and management by integrating environmental, technical, economic, and social factors. However, they need reliable data and high system interoperability (LCA-Digital Passports-BIM) to work effectively at scale [11].

MPPs are crucial for tracking the details and evolution of building components through dynamic indicators. However, barriers to adopting this predictive Cradle-Based approach include standardisation, digital interoperability, data access, and stakeholder participation [17]. The shift to this predictive CBa presents several notable operational challenges. The lack of standardised indicator protocols hinders cross-project comparisons and the adoption of multi-criteria matrices. Achieving digital interoperability between BIM, LCA tools, and MPP systems is complex and depends on developing sector-wide data standards. The framework is conceptual and its practical reliability needs to be tested using real case studies, which is a current limitation. Furthermore, engaging stakeholders across the supply chain is essential for data flows, yet coordination mechanisms for multi-actor lifecycle management are not well established.

Table 2. Comparison between reactive and predictive paradigms.

	Reactive	Predictive
Main goal	Meeting project brief, cost, performance and regulatory requirements, with possible "burden shifting" effects.	Maximise circularity and value retention across multiple use cycles; resource regeneration.
Life Cycle boundary	Often limited to partial lifecycle boundaries (e.g. Cradle to Gate or simplified Cradle-to-Grave approaches)	Cradle to Cradle
Circularity	Implemented as "beyond system boundary".	Central in lifecycle design and management.
Flux focus	Operational energy use and, in some cases, "upfront embodied carbon" assessment, limited material flux management.	Embodied and operational energy and carbon evaluation and management; material flux management.

(*continued*)

Table 2. (*continued*)

	Reactive	Predictive
MPP	Static approach and unclear data management.	Central use: complete data availability managed and updated dynamically during the lifecycle, supporting decision making.
Stakeholders	Gaps in stakeholders' communication during the life cycle, because of lack of clear and complete data and purposes.	Full cooperation thanks to completeness and interoperability of dynamically updated data and clear goals.
Design stage	Options chosen mainly on cost/performance; no life cycle planning.	Options selected on next-life scenario-based analysis and life cycle planning.
Operational stage	Static approach focused on energy use and basic reactive maintenance to manage the damage.	Dynamic approach focused on performance monitoring for efficiency and lifecycle management for circularity.
End of Life stage	Demolition and reactive waste management; low quality circular strategies implemented, decided during EoL stage.	No EoL, but New Life. Pre-planned strategies for no waste production, supported by lifecycle management through MPP.

4 Conclusions

The transition to climate-neutral, resource-efficient built environments demands shifting from linear to circular systems. This study proposes a CBa that treats the end of one material's use as the start of the next. By incorporating prediction into design, it aims to go beyond waste management, fostering material regeneration across use cycles. The proposed framework highlights the role of Environmental Design as a strategic entry point for integrating circularity at the early stages of architectural and technological design. Within this perspective, MPPs emerge as a key enabling infrastructure, supporting lifecycle continuity through improved data traceability, transparency and information sharing. By linking material characteristics, technical performance and environmental indicators to scenario-based design logic, these digital tools can contribute to more informed decision making and to the anticipation of potential future material trajectories such as reuse, refurbishment, remanufacturing or high-quality recycling. The study also introduces the conceptual structure of scenario-based multi criteria matrices that combine indicators related to disassembly potential, durability, recovery pathways, circularity performance and environmental impact. Although the present work focuses on the conceptual and methodological architecture of this framework, the proposed indicators and variables represent a first step towards operationalising predictive lifecycle management in the built environment. The originality of the approach lies in integrating circularity principles and MPPs into the environmental design process, reinterpreting MPPs as predictive

informational infrastructures supporting the anticipation of future 'next-life' scenarios during the early design stages. From this perspective, lifecycle information becomes an active driver of regenerative decision-making, rather than being limited to passive documentation for end-of-life management. Future research should focus on developing the multi-criteria matrices and defining measurable indicators for scenario evaluation in real design contexts. It should also explore integrating the framework with digital tools like BIM-based life cycle assessment systems and Material and Product Passport platforms. Applying the approach to real case studies is essential to test its feasibility and value for circular design and regenerative built environments.

Abstract. Construction and Demolition Waste (CDW) represents a key barrier and opportunity in advancing circularity within the built environment, as countries intensify efforts to reduce waste and recover resources more effectively. Its valorisation increasingly relies on the combined influence of technological capabilities, economic feasibility and social acceptance. This study brings together national data from eight countries: Cyprus, Estonia, Greece, Latvia, Romania, Slovenia, Switzerland, and Türkiye to explore how economic, technological and social perceptions shape the potential of CDW in circular construction. The analysis examines the main economic opportunities and challenges in CDW recycling, including national market gaps and the availability of certified CDW-based products. It also highlights the growing role of digital tools, such as material-tracking systems,

https://doi.org/10.1007/978-3-032-34930-9_45

which support more reliable and transparent reuse pathways. From a social perspective, public perceptions and user preferences regarding recycled materials are analysed, along with stakeholder roles across the CDW value chain and the social implications of waste management. The study shows that an integrated approach that combines economic incentives, digital technologies, and stakeholder and community participation can effectively transform CDW into a valuable secondary raw material. It aims to guide policymakers, local governments, and industry professionals in creating diverse, practical initiatives from a comprehensive perspective, while also helping establish a strategic waste management framework.

Keywords: Construction and Demolition Waste (CDW) · Circular Construction · Secondary Raw Materials · CDW Valorisation · Digitalisation in Construction

1 Introduction

Construction and Demolition Waste (CDW) is one of the key material streams in the global transition toward a circular economy. With urbanisation, infrastructure development, and growth in the building stock, the amount of waste generated by construction activities will also increase. Therefore, this situation is transforming into a large consumption sector that uses primary raw materials [1]. In total waste statistics at the European Union, more than a third comes from CDW -over about 925 million tons per year- highly heterogeneous both in mineral and non-mineral content: concrete, bricks, metals, wood, glass, plastics [2]. Consequently, the management of CDW is of strategic importance due to its scale, material density, and environmental footprint. CDW is now increasingly conceptualised as a secondary raw material within broader systems of circular construction. The shift is associated with the transformation of linear "take–make–dispose" models into more resource-efficient modes that include waste prevention, reuse, and high-quality recycling, parallel to the gradual mainstreaming of circular economy discourse [3]. Despite increasing awareness of the problems related to CDW, fragmented policies, technological limitations, economic deterrents, and societal acceptance barriers remain a challenge for countries.

Most existing studies on CDW management evaluate single dimensions, predominantly emphasising technological and economic analyses [4, 5]. Increasing evidence in recent years shows that economic conditions - infrastructure, both digital and physical, and societal-level governance models and behavioural norms - play a key role in enabling or constraining technological readiness and cost-competitiveness pathways to successful CDW valorisation. This paper is therefore framed within an integrated, cross-country perspective, evaluating the economic, technological, and social dimensions and interactions that drive or hamper the valorisation of CDW. Eight countries (Cyprus, Estonia, Greece, Latvia, Romania, Slovenia, Switzerland, and Türkiye) from dıverse geographical contexts, with emerging to mature markets and under different governance structures, were selected. The study will evaluate national experiences to capture common and shared trends, enabling factors, and obstacles in transforming CDW from an assumed problem into a secondary raw material.

This study aims to address gaps in the literature by expanding the limited economic and technological perspectives on CDW through social and stakeholder engagement and by conducting an international synthesis. In line with this objective, the main research question guiding the evaluation is: How do economic and technological conditions, along with social acceptance and stakeholder perceptions, shape CDW valorisation within the circular construction context? By addressing this question, the paper contributes to a growing body of literature advocating multidimensional, governance-oriented approaches to implementing the circular economy in the built environment.

2 Method

The study uses a multi-country research design to analyse the economic, technological, and social aspects of CDW valorisation in circular construction systems. Eight countries - Cyprus, Estonia, Greece, Latvia, Romania, Slovenia, Switzerland, and Türkiye - were selected to represent diverse geographical regions and various levels of economic development, with different governance structures, spanning emerging to fully developed waste management and recycling markets. Such diversity allows both an analysis of how very different institutional/regulatory/market environments shape paths for CDW valorisation and the discovery of common challenges across national contexts, as well as potentially transferable practices.

Data were collected by systematically reviewing national statistics and official policy documents, strategic plans, regulatory frameworks, and publicly available reports on CDW management and circular economy implementation in construction practices. The resource selection focuses on documents that address direct CDW, recycling, digitalization, and circular construction practices. To ensure data consistency, the data collected using the same thematic coding structure were evaluated: economic conditions, technological/digital enablers, and social perceptions. The evaluation incorporated stakeholders' roles within a cross-country comparative synthesis, aiming to identify emerging common themes and structural gaps across enabling factors, while retaining sensitivity to country-specific contexts. The thematic comparative approach (inductive) allows for the discovery of both widespread regularities and context-dependent dynamics (interaction effects), thus providing a strong intellectual footing for developing fine-grained yet practically relevant (hence evidence-based) recommendations. The study is limited by the fact that CDW levels vary across countries and are based on national data sources. Therefore, the findings should be interpreted as a comparative thematic synthesis rather than a statistically definitive assessment.

3 Economic Perspectives on CDW Valorisation

The reuse of CDW as a secondary raw material brings wide economic benefits, particularly within circular construction systems. National strategies, policy assessments, and market analyses demonstrate that, in addition to reducing waste, the recovery of CDW creates jobs in the country's labour market, develops local markets, and improves resource-use efficiency in construction value chains. Enterprise support schemes further

illustrate the effects of incipient market formation: national circular economy de minimis programs have financed dozens of projects and created new jobs, thus registering growing economic activity related to CDW valorisation [6, 7].

Evidence from each country shows distinct yet parallel benefits. In relatively advanced CDW markets such as Romania, Greece, and Slovenia, government programs, circular economy plans, and green public procurement practices play a significant role in both supplying and using CDW [8–11]. These measures facilitate greater use of recycled materials in construction and expand recycling systems [12, 13]. On the other hand, in growing markets such as Türkiye, Cyprus, Estonia, and Latvia, using CDW mainly creates jobs in areas including landfill management, road construction, landscaping, infrastructure development, and local recycling businesses [14–17]. Despite differences in scale and implementation difficulty, the basic economic reasoning remains strong: using CDW reduces dependence on imported materials, supports local supply chains, and adds value by keeping resources within national and regional economies.

Data from each country shows similar gaps and shared challenges. In Romania and Greece, even though governments set rules and technical standards, the use of recycled materials remains low. This can be attributed to several factors, including lower costs of new construction materials, limited high-quality data, uncertainties about implementing such changes, and persistent concerns about the quality of recycled products [18–20]. In Türkiye, Cyprus, Slovenia, and Latvia, the main challenges are associated with certification procedures for materials, difficulties in recruiting skilled labour, the high costs of processing and transporting materials, and insufficient demand or support from businesses purchasing these materials [15, 21–23]. Unless there is a cohesive economic strategy that integrates the establishment of common standards, improvements in certification processes, financial incentives, and the enhancement of trust within the market, recycling of CDW is likely to remain economically unviable and inefficient, even with current technological capabilities.

4 Technological Perspectives on CDW Valorisation

Even though the level of development and use of digital tools (DT) varies from country to country, they are becoming essential in circular CDW management. Tools like Building Information Modelling (BIM), artificial intelligence (AI), material passports, and digital tracking systems help make better decisions, identify which parts to remove, recover materials, and recycle them properly [24, 25]. Common trends in the countries studied show a preference for DT in the processing and CDW.

In Romania, progress is reflected in increased institutional attention to digitalisation, including the development of a national BIM roadmap and initiatives to strengthen digital skills in the construction sector. Implementations at the project level include Scan-to-BIM workflows using laser scanning and photogrammetry as well as pilot initiatives exploring AI- and sensor-assisted CDW sorting, such as Robot Efficient Cdw Intelligent Classifier for Automatic Recycling Management (RECICLARM) [26, 27]. Slovenia's CINDERELA project presents a digitally integrated circular business model for a one-stop-shop platform marketplace for stakeholders in the waste-to-resource value chain. Latvia LIFE "Waste to Resources" provides easily accessible information and an

actual citizen engagement platform that supports circular economy practices through digital dissemination and the development of local repair and recycling infrastructure. Switzerland has developed digital solutions such as "Madaster" and "buildingSMART", both with a strong focus on technology [28]. Greece is a participant in the RECONMATIC project, which will develop automated, digital, and robotic solutions to support collaboration among construction industry stakeholders and improve waste traceability [29].

Digitalisation efforts in Türkiye and Cyprus are shaped more by governance structures and regulatory practices than by advanced automation. Cyprus provides a notable example of operational digital traceability through its mandatory collective systems and the Electronic Waste Recording System [30]. In Türkiye, digitalisation efforts primarily focus on electronic monitoring and reporting mechanisms, exemplified by systems such as the Electronic Concrete Monitoring System (ECMS). In parallel, the emerging consideration of AI-based tools for post-disaster damage assessment indicates a growing potential to support future evaluation and management of CDW [31, 32]. Although digital CDW technologies are not yet mature, their broad use is considered essential.

5 Social Perspective, Public Perceptions, and Stakeholder Roles on CDW Valorisation

A comparative social perspective on CDW valorisation indicates that, across countries, public acceptance and stakeholder engagement are influenced less by general environmental awareness than by tangible institutional, economic, and regulatory frameworks. Despite variations in governance structures and market maturity, the evidence consistently suggests that trust in certified quality standards, affordability, and clearly defined stakeholder responsibilities plays a decisive role in normalising reused and recycled construction materials within mainstream construction practices.

In Romania, consumer and stakeholder perceptions are strongly influenced by price- and quality-considerations; surveys indicate a cautiously positive yet conditional acceptance of reused and recycled materials, with 73% of buyers favouring certified "green" products, while demonstrating limited willingness to pay a premium [33, 34]. Evidence from the RECONMATIC Project suggests that technical familiarity and workflow reliability dominate decision-making over sustainability motivations, positioning Greece at an early stage in the social normalisation of CDW valorisation [35]. In Slovenia, while environmental awareness is increasing, scepticism about the quality and safety of recycled construction materials persists, but awareness is being raised through EU-funded projects [36].

In Cyprus, stakeholder surveys conducted under the Build CIRCULAR Up project show that 65% of construction actors actively separate CDW and derive economic benefits from selling recycled materials, despite gaps in standards, infrastructure, and cross–supply-chain collaboration [37]. In Türkiye, academic and stakeholder studies report broadly positive attitudes among users, designers, and professionals toward recycled and reusable materials, particularly regarding environmental benefits and design potential [38]. Public perception in Estonia (as well as in the Nordics) is mixed and largely characterised by a lack of awareness [39]. Similarly, in Latvia, the public lacks sufficient

knowledge of circular construction principles, identifying insufficient information and awareness as a primary societal barrier to the adoption of circularity [40]. Collectively, these cases demonstrate that while social receptivity exists across contexts, its consolidation depends on aligning awareness with enforceable regulations, credible quality assurance systems, and tangible economic benefits.

6 Conclusions and Recommendations

This study demonstrates that utilising CDW as a secondary raw material is a multidimensional process shaped not only by economic and technological capacity but also by re gulatory alignment and societal dynamics. Evidence from eight countries highlights the significant potential to increase recycling capacity through technological innovation, particularly through improved sorting, monitoring, and material recovery systems. Economic instruments (especially green public procurement, certification schemes, and incentives) play a decisive role in shaping viable markets for CDW-derived products. The finding further confirms that social acceptance is influenced not solely by environmental awareness but by pricing structures, regulatory clarity, and clearly defined stakeholder responsibilities (Table 1).

Table 1. Comparative Patterns in CDW Valorisation Across Countries

Country	Economic	Digitalisation	Social	Main Barrier	Key Enabler
Romania	◆◆◆◆◇	◆◆◆◇◇	◆◆◆◇◇	Market trust	Green procurement
Greece	◆◆◆◆◇	◆◆◆◇◇	◆◆◆◇◇	Cost competition	Policy frameworks
Slovenia	◆◆◆◆◆	◆◆◆◆◆	◆◆◆◇◇	Quality perception	Circular platforms
Türkiye	◆◆◇◇◇	◆◆◇◇◇	◆◆◆◇◇	Digital gaps	Regulatory transition
Latvia	◆◆◇◇◇	◆◆◇◇◇	◆◆◇◇◇	Knowledge gaps	EU initiatives
Cyprus	◆◆◇◇◇	◆◆◆◇◇	◆◆◆◇◇	Infrastructure	Digital traceability
Estonia	◆◆◆◇◇	◆◆◆◇◇	◆◆◇◇◇	Public engagement	Digital governance
Switzerland	◆◆◆◆◆	◆◆◆◆◆	◆◆◆◇◇	Public engagement	Advanced digital systems

Comparative findings indicate that a successful CDW evaluation depends on the alignment of the following three dimensions: (i) economic incentives and market stability, (ii) digital and technological traceability systems, and (iii) social trust supported by regulatory legitimacy and stakeholder coordination. Based on these findings, the study

recommends adopting a multi-faceted approach that simultaneously addresses economic, technological, and social dimensions through coordinated policy action. Finally, future research should expand this cross-country synthesis by incorporating empirical data and long-term assessments to better analyse the impacts of governance reforms and digital innovation on circular construction systems.

Integrating Circular Objectives into Performance-Based Façade Technical Specifications: A Conceptual Framework

Marie Belle Georges(✉) and Issam Srour

Department of Civil and Environmental Engineering, American University of Beirut, Beirut, Lebanon
msg20@mail.aub.edu

Abstract. Façade systems are typically designed using performance-based criteria such as structural capacity, weather protection, thermal performance and energy efficiency. These documents are conventionally used by façade stakeholders to define how façade systems are designed and delivered. Circular considerations, however, are rarely written as explicit façade requirements. Reuse and design for disassembly are often discussed during design but are not al-ways translated into specification clauses. This paper explores how circular objectives could be incorporated into façade delivery through performance-based specifications. Circular economy frameworks and façade literature were reviewed, together with the structure commonly used in façade technical specifications. The review highlighted several circular objectives relevant to façade systems. These include design for disassembly, reuse potential and maintainability. Other aspects such as adaptability, service life alignment and material traceability were also identified. The study then explores how these ideas could be reflected in façade specifications. In a project specification, they would appear in different sections of the document. Some relate to material information submitted by the contractor, while others concern design details that allow components to be disassembled or maintained. Compliance could be checked through design submissions, contractor submittals or inspection during installation. If circular provisions are written into façade specifications, they become part of the project requirements rather than general sustainability intentions. Contractors and designers would then need to address these objectives during façade design and construction.

Keywords: Façade engineering · Circular economy · Performance-based specifications · Building envelopes · Circular construction

1 Introduction

Façade systems are essential in the performance of buildings [1, 2]. They are the interface between the interior and exterior environment [1]. The façade design is dictated by performance-based technical specifications that establish requirements for structural behavior, thermal performance, watertightness, airtightness, fire safety and acoustic performance [2, 3]. The specifications define the façade requirements, how compliance is verified, and the responsibilities of project stakeholders [3].

Circularity has become commonly discussed in the built environment sector [4, 5]. Concepts such as design for disassembly, material traceability and service life extension are now conferred more frequently in relation to building components [6, 7]. However, these ideas are typically addressed at building assessment level rather than within the technical structure of façade specifications.

Despite the growing attention to circularity, it is not consistently and commonly expressed within façade technical specifications. In many projects, circularity is addressed through certification systems or sustainability reporting rather than through façade specifications' clauses. This study explores where circular objectives could be placed within façade performance-based specifications.

2 Literature Review

2.1 Circularity in the Built Environment

The built environment sector is a major consumer of materials and a significant source of construction waste. In response, circular economy principles have been increasingly discussed as a way to address these challenges [4, 5, 8, 9]. Circularity in construction encompasses several approaches, from the reuse of construction materials to the recycling of construction and demolition waste (CDW) [4, 5]. These approaches also include extending the life of materials and designing buildings so that components can be reused later [4, 6]. Buildings contain large quantities of materials. For this reason, building components play an important role in enabling circularity.

2.2 Circularity in Façade Systems

Building façades represent a significant part of a building. They also contain large quantities of different materials such as glass, aluminium, steel, gaskets and sealants [2]. Façade systems may be replaced or refurbished during the life of a building, often before the service life of the main structure [7, 10]. This creates opportunities to consider circular strategies at the façade level. Many of these materials eventually become construction waste. For this reason, façades are relevant when discussing circularity in the built environment. Several studies have examined circular approaches for building façades. Commonly discussed ideas include design for disassembly, reuse of façade components, material traceability or material passports, and service life considerations [6, 7, 10–12]. However, these ideas are usually discussed at the building level rather than within façade specifications documents.

2.3 Performance-Based Façade Specifications

The façade technical specifications sets out the performance criteria that the façade system must comply with [2, 3]. These requirements typically include structural performance, watertightness, airtightness, thermal performance, acoustic performance, fire resistance and durability. These specifications define compliance requirements, guide design development, allocate responsibilities between stakeholders and define what contractors must deliver.

2.4 Research Gap

Circular strategies for buildings and façade systems have been widely discussed. However, their integration into façade technical specifications has received limited attention. Circular ideas are not widely structured in façade technical specifications as performance criteria comparable to other façade requirements. This gap is noticeable. The paper considers how circular objectives could be incorporated into façade performance-based specifications.

3 Methodology

The methodology builds on reviewing three relevant frameworks related to circularity, examining the typical structure of façade technical specifications and analyzing literature review on circularity in façades. The proposed positioning was discussed informally with experienced façade professionals to assess practical relevance. The study adopts a qualitative and exploratory conceptual approach.

ISO 59020:2024 "Circular economy - Measuring and Assessing Circularity Performance" was reviewed due to its importance in providing a structured approach for measuring and assessing circularity performance across systems [13]. This international standard translates circular economy principles into defined indicators, lifecycle boundaries, measurement logic and performance evaluation structure. Since façade specifications are based on measurable performance requirements, ISO 59020 helps show that circularity can also be framed in measurable terms.

Level(s) - A Common EU Framework of Core Sustainability Indicators of Office and Residential Buildings (2021) was analysed because it shows how circularity is structured at the building assessment level [14]. Hence, in order to position circular provisions in façade technical specifications, it is important to understand how they are already structured elsewhere at the building level. This framework explicitly references adaptability and design for deconstruction. It frames circularity in terms of lifecycle performance, not just environmental intention. Circularity is not just a concept. It can be broken into structured requirements. Its relevance is in demonstrating how circular requirements could be organized and categorized systematically.

BREEAM New Construction Version 7 was also reviewed. This widely recognized sustainability certification system used to evaluate the environmental performance of buildings gives credits for lifecycle assessment, material documentation, and waste reduction [15]. This means circularity is already influencing how buildings are designed and evaluated. But these requirements usually sit in sustainability assessment systems. They are not always written directly into façade technical specifications.

Façade technical specifications follow a structured format. Similar to the general construction specification practice. The commonly used three-part structure; General Requirements, Products and Execution was examined to understand how these documents are organized. As well as the type of information typically belongs in each section. This was necessary in order to determine where circular provisions could realistically be placed.

The circularity objectives themselves were identified from recurring themes across the reviewed frameworks and literature. Only those considered relevant to façade specifications practice were retained. The positioning was then carried out against the three-part structure that underpins most façade technical documentations.

The proposed placement was also discussed informally with senior façade practitioners to see if it aligns with current practice. These were informal conversations rather than structured interviews. The paper is conceptual in nature and does not analyze data from specific projects.

4 Conceptual Framework

Performance-based façade specifications encompass the criteria required to design and deliver a façade system. In practice, façade specifications normally address issues such as structural capacity, thermal performance, resistance to water and air penetration, acoustic control, fire safety and durability. In practice, such requirements are not left at a conceptual level. They are translated into performance measurement criteria that can be tested, certified or verified through documentation.

From this perspective, circularity should be treated similarly. It does not always have to be addressed as an independent sustainability aspiration. Instead, circularity could be specified as other performance expectation. In terms of positioning, circularity requirements can potentially be placed in the same specifications' logic as structural capacity or thermal performance.

Figure 1 illustrates the conceptual relationship between circular objectives and the structure of façade technical specifications. Table 1 then shows where these objectives could be placed within the specification structure. The idea is not to propose a new specifications format. The intention is to demonstrate that circularity provisions could be incorporated into the typical façade performance-based technical specifications. Whether they follow a standard format or are written specifically for a project. By placing circularity within the façade technical specifications, it becomes part of the contractual performance requirements instead of remaining a separate sustainability target.

The wording in Table 1 simply shows where circular objectives could be placed in façade specifications. In practice these requirements would be reflected in different parts of the document. Some relate to material information submitted by the contractor. While others relate to design details that allow components to be disassembled or maintained. Compliance could then be checked through typical project practices such as design documentation, contractor submittals and site inspection.

Table 1. Conceptual positioning of circularity objectives within façade specifications' structure.

Circularity objective	Lifecycle phase	Specifications section	Possible specifications provision	Example
Design for disassembly	Design/End-of-life	Part 1 – Performance requirements	Allow disassembly of primary façade components without irreversible damage	Curtain wall panels fixed with bolted connections
Material traceability	Across lifecycle stages	Part 1 – Submittals	Documentation of material composition, origin and environmental data	EPDs and aluminium alloy information
Maintainability	Operation/service life	Part 3 – Execution	Components expected to require replacement remain accessible for maintenance	Glass units replaced without removing mullions
Reuse potential	Design/post-disassembly	Part 2 – Products	Preserve structural and functional integrity of reusable components	Standardized façade modules sized for reuse
Adaptability	Design/mid-life modification	Part 2 – Products	Allow future upgrade or modification of façade components	Glazing upgraded without replacing the frame
Service life alignment	Design stage	Part 1 – Performance requirements	Allow elements with different lifespans to be replaced independently	Gaskets replaced without removing framing

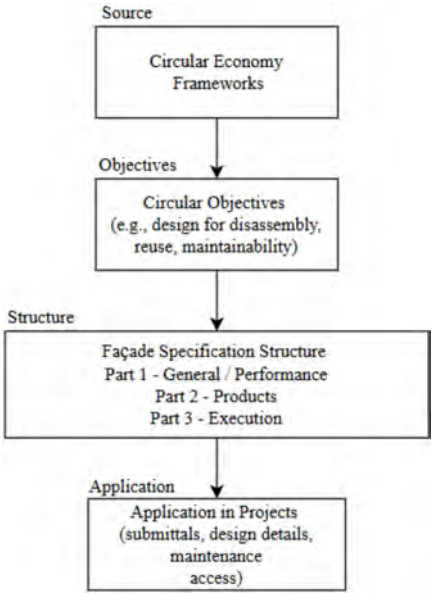

Fig. 1. Conceptual framework linking circular economy objectives with façade specification structure

5 Illustrative Application of the Framework

Table 2 presents examples of incorporating circularity objectives into performance-based façade technical specifications using conventional requirements typically found in façade projects. The examples show how circularity considerations can be included within current specification practices while maintaining the existing performance-based approach used in the façade industry.

Table 2. Examples of Integrating Circular Objectives into Performance-Based Façade Specifications.

Specification requirement	Circular objective	Example specification clause
Thermal performance requirements	Adaptability over service life	The façade system shall permit future replacement or upgrading of insulated glazing units without replacement of the primary framing system
Structural performance requirements	Design for disassembly	Mechanical fixings shall be utilized for primary facade components where possible to support future disassembly and material recovery

(*continued*)

Table 2. (*continued*)

Specification requirement	Circular objective	Example specification clause
Material selection requirements	Material traceability	To support future recovery and reuse, aluminum components shall include material identification and recycling information
Maintenance requirements	Maintainability	Damaged glazing components and gaskets shall be replaced without significant removal of adjacent façade elements

6 Discussion & Conclusion

When circular objectives are written into façade technical specifications, they become part of what must be delivered on a project. This changes their role. Specifications describe the roles of consultants, suppliers and contractors and explain how compliance is checked on a project. If circular provisions are written into these documents, they become part of what contractors must deliver. This influences material selection and procurement decisions, and it also impacts the preparation of technical submittals. Ideally, on projects the façade consultant and design team would include these requirements in the specifications. The contractors would address these requirements during tendering and construction phases. Circularity becomes part of the technical scope rather than considered only through certification schemes.

Market conditions and client priorities vary, which may limit the applicability of this approach across façade projects. Public developments could adopt such provisions more than smaller private projects. The conceptual framework presented here does not analyze real project specifications. Also, challenges such as cost implications or enforceability were not examined.

Circular objectives can be incorporated into the current structure of façade performance-based specifications. These provisions include design for disassembly and reuse potential. Other aspects relate to maintainability, adaptability, service life alignment and material traceability. The framework should therefore be viewed as an initial step rather than a complete solution. Future work could explore how similar provisions might be implemented in real project specifications.

Abstract. The construction industry is applying more circular economy principles to reduce waste, raw material extraction and support decarbonisation goals. This changing landscape has led to developers considering adaptive reuse and building retention more seriously. However, the sustainability assessment models created to assess reuse potential are underutilised in industry, and there are a lack of studies analysing and contrasting existing approaches against one another in practice or applying different models to case studies to ascertain the different assessment outcomes. This study critically analyses various models, chosen from a semi-systematic review, evaluating the parameters used within the model and the calculation methodology. Structural appraisal reports and publicly available information from a number of adaptively reused buildings were used to assess the outputs of the models, comparing the outcome to what happened in reality. The results show the need for a more comprehensive and robust model that can adapt to a range of use types. New models should: (1) be interactive tools, to allow for filtering questions for specific use types; (2) be split into technical and non-technical questions to allow them to be used by experts and non-experts; (3) assess practical adaptive reuse potential and social wants separately to prevent bias affecting the final score; and (4) provide tangible recommendations to users, to make the models more valuable to single building developers.

1 Introduction

New planning policies, such as Westminster's Retrofit First policy [1], are showing the shift towards adaptive reuse being considered more seriously in the construction industry. However, there is often reluctance to use this option due to a lack of information on the building [2], and a lack of knowledge about circularity [3]. One of the ways to mitigate this is to use assessment models that can quickly assess a building's adaptive reuse potential. Previous work comparing adaptability assessment models [4] looks only at

https://doi.org/10.1007/978-3-032-34930-9_47

how the current models are structured, rather than their usability and reliability, which is the knowledge gap that this paper fills.

1.1 Definition of Adaptive Reuse

There is a lack of consensus regarding an exact definition of *adaptive reuse*, however, for this study, it was important to define *adaptive reuse* to contextualise which models are within scope.

A small-scale review of definitions for *adaptive reuse* in literature led to the following definition, based on Schmidt III et al.'s [5] work on adaptability strategies and Brand's [6] building layers:

> Adaptive reuse refers to the infrequent, non-cyclical change to an existing building, either through change of function, which includes changes to the space, service or skin; or change of size, which includes changes to the space, service, skin or structure.

Change of function refers to the use of the building, either through change of use or to suit new requirements within an existing use. Change of size refers to the physical size of the building, achieved by providing additional floor space, either vertically or horizontally.

2 Methodology

2.1 Selection of Models

Throughout this paper, all assessment frameworks, instruments, methods, strategies and models will be referred to as assessment models. The adaptability potential assessment models were chosen through a semi-systematic review. First, Web of Science and Scopus were searched with the terms [adaptive reuse AND model AND assessment AND buildings].

A manual check of each paper was conducted to highlight only those that proposed new adaptability potential assessment models for existing buildings. This removed papers that aimed to: (1) Assess the effectiveness of past reuse schemes; (2) Focus on the delivery of reuse projects; (3) Assess the adaptability of proposed new-builds.

One model required input from several users to be used, which is beyond the scope of this study, so was removed from the analysis. This led to 6 models being identified.

From these models, references and citations were checked to identify other adaptability potential models. This led to a total of 9 models selected for this study.

2.2 Introduction of Case Studies

Each model was assessed using four UK-based case studies. The study was conducted using data from structural appraisal reports and publicly available information, in line with what would have been known prior to the reuse project occurring. Table 1 shows basic information about the existing buildings in their pre-reuse state. All four of the

case studies have recently undergone an adaptive reuse project, in line with the definition set out above, with the new and previous use type being office in all cases.

Table 1. Basic information about the case studies.

	A	B	C	D
General Location	London	London	London	Milton Keynes
Year of original construction	1840	2000	1920	1990s
Current Use Type	Office and Retail	Office	Office (Originally warehouse)	Office and Storage
Main Frame Type	Cast iron, steel and load- bearing masonry	Steel frame	Loadbearing masonry, and steel and iron columns	Concrete frame
Condition of Building (Pre-Strip Out)	No visible damage	Good	Poor condition of roof and slabs	Good
Storeys	5 (inc. basement)	6 (inc. partial basement)	2	6 (inc. basement)
Approx. floor space (m^2)	10,000	12,000	2,000	29,000

3 Critique of Approaches

This paper focuses on the different approaches the models use to calculate adaptability potential. For the individual parameters used in each model, we refer readers to the original papers. Table 2 shows the approaches each model uses.

Table 2. Approaches used by models.

	Knowledge Level	Use Type	Scoring	Output	Parameters

Total Yes (out of 9)	5	6	3	6	4

3.1 Knowledge Level of User

Some models required specialised knowledge, such as understanding the structure's condition and the impact this has on adaptability, and thus needed an expert to be used (5/9). Others only required general knowledge about the building and could be used by a non-expert (4/9). The expert models would require a design team's input, increasing costs to the owner and likely requiring a structural appraisal report, which may not be completed before the *Preparation and Briefing* stage (RIBA stage 1). The nonexpert models could be used at the *Strategic Definition* stage (RIBA stage 0) by the owner, making them more accessible. However, they did not look at the condition of the structure, whereas the expert models gave a deeper understanding of the physical building's adaptability potential.

3.2 Applicability to Different Use Types

Although most of the models applied to all current use types (6/9), a few were limited to specific uses (3/9). Non-specific models can be used for a wider range of buildings; however, they do not allow for as in-depth questions, as certain criteria would only apply to particular use types, for example, office grade would only apply to office buildings. Specific models allowed for more in-depth questions.

3.3 User or Criteria Scoring

The models used two different scoring methods: User-scored (3/9), which required the user to score how adaptable different building attributes were on a scale; and criteria-based scoring (6/9), which gave the user a set amount of options to choose from for

each parameter. Criteria-based models were quicker to use, but only when the building attribute fit into one of the pre-assigned categories, otherwise, it was challenging to assign a score. The user-based scoring was applicable to all building typologies, however, it requires the user to understand what makes a building more adaptable. It can also lead to bias if the user deems certain building attributes as more adaptable, allowing the model to be misused to fit a certain agenda.

3.4 Final Score and Output

The majority of the models (6/9) gave the user a categorical final score, such as an adaptability class, while the others' (3/9) output was purely numerical, only giving a score or percentage. While the numerical score can be used to compare several buildings, they are less useful when looking at individual buildings, as they don't translate a score into a level of adaptability. On the other hand, the categorical scores work for both individual buildings and comparing buildings; however, the classes are often split equally, which may not reflect reality, for example, the adaptability of a building may be exponentially related to the score.

3.5 Types of Parameters Included

Some models only included physical parameters (4/9), such as the structure, condition and layout of the building. Others included a wider range of parameters (5/9), for example, the social value of the building, such as user satisfaction and community support. Models that only included physical parameters were fairly objective, so there was less confusion; however, the model cannot assess if reusing the building would lead to any added value, economic or social. On the other hand, including non-physical parameters meant that the model could evaluate whether reuse has any value, but the non-physical parameters are often subjective and harder to measure; for example, user satisfaction requires interviews, which would be time-consuming to obtain.

4 Critique of Results

Although none of the models found that the buildings were not adaptable, there was variation in the magnitude of adaptability they predicted, see Fig. 1. This discrepancy may be due to the models looking at adaptability from different lenses, such as some focusing more on social wants than others. The models that only looked at physical factors scored lower than those that also considered other factors.

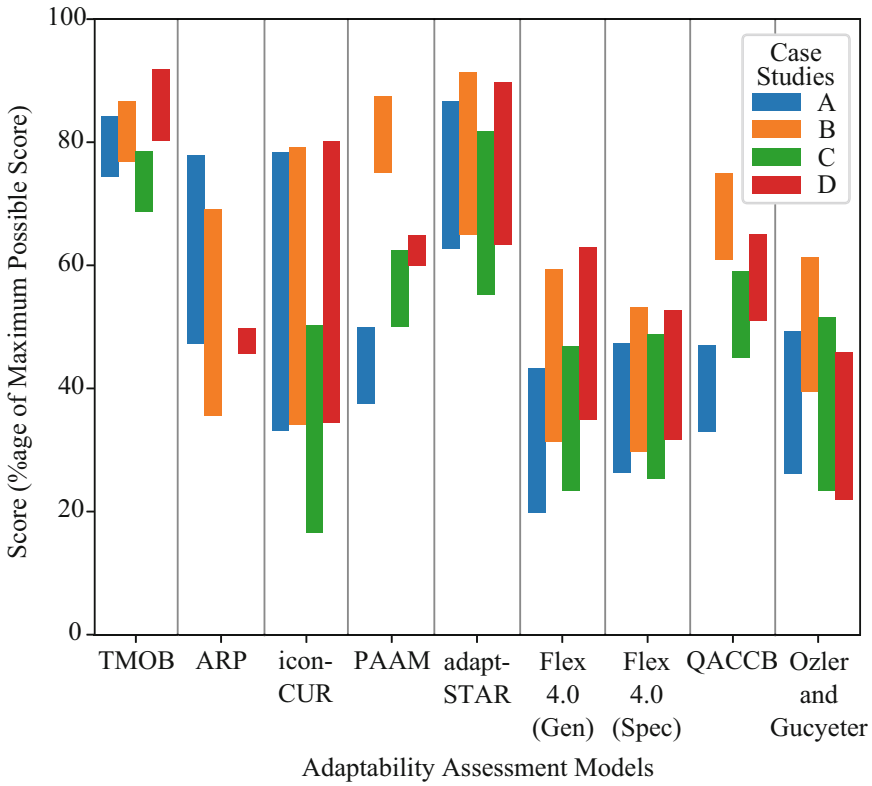

Fig. 1. A figure showing the model results for all four case studies. A higher percentage represents a more adaptable building. The coloured ranges represent the spread between the most conservative and most optimistic assumptions for unknown parameters.

The four case studies are located in authorities with policies dissuading the net loss of office space, and therefore would be considered to be in" priority area[s]" [7]. This means that they should not be changed to residential and, therefore, would fail the initial filtering criteria in the TMOB model [7]. However, the assessment was continued for full evaluation to test the validity of the model. The ARP model [8] is incompatible for buildings that are significantly older than their typical design life, which is the case for case study C, resulting in a negative percentage, and thus has been removed from Fig. 1.

Most models identified case studies B and D as the most adaptable, which was consistent with the opinions of the engineers involved in the case studies, with the order of most adaptable to least adaptable being D, B, A, C. Therefore, the models are somewhat accurate in determining the adaptability of several projects in comparison to one another. However, all of the case studies were successfully adaptively reused, despite over half of the models attributing average scores below 60%, suggesting they are less accurate when assessing individual buildings.

4.1 Overall Value of Models

From this analysis, we conclude that the main value of these models lies in their ability to help inform decisions between reusing several buildings, as understanding which is more adaptable helps developers with multiple assets to decide which building to focus on, helping to analyse adaptability at a portfolio level. However, there is less value in using the tools to assess a singular building, as most of the final outputs don't give suggestions as to what to do. While they can still potentially be used to persuade building owners to investigate adaptability, they would need to explain why the building is or is not adaptable to provide more value. As development often occurs on a building-by-building basis, these models may not be very valuable and may further suggest why they aren't being used.

5 Conclusion and Recommendations

This study assessed the approaches used by 9 adaptability assessment models, using four UK-based adaptively reused case studies, drawing conclusions about the models' usability, reliability and overall value, which has not previously been done. There are four main recommendations for future models to address the shortcomings of the current models:

1. Models should be interactive tools. This would allow for filtering, for example, if a particular use type is desired, then this can be selected, which will filter out the more irrelevant questions automatically, making it more applicable to different building types. It would also be able to automatically do post-processing, keeping a database of other adaptively reused buildings, so the user can compare their building to successful projects. There is also the scope to give the user a more in-depth answer, explaining which adaptability strategies are more relevant to that building.
2. Models should be split into several parts. A non-technical section could be used by building owners and non-experts to infer further information about the building, but with more uncertainty; the second part would ask technical questions about the building and be able to provide a more reliable adaptability assessment.
3. If social value is included, and hasn't already been considered during planning, its effect on adaptability should be calculated separately from the physical adaptability. This would mean that if there is a lot of social value in reusing the building, but it cannot safely be reused, then the social value of the reuse assessment will not affect the output for the physical adaptability potential. The social wants are also more likely to be subjective questions, so any bias in answering the questions would also not affect the physical adaptability potential score.
4. Models should provide tangible recommendations to the user, rather than just providing an adaptability score, to make the outputs more valuable to developers with a singular building, rather than just large portfolio holders. This would also give users some direction for their projects and could inspire action. These recommendations could be based on outcomes from adaptive reuse projects, allowing the user to compare their building to real examples, making the outputs more valuable to building practitioners.

Funding Declaration. This research was funded through the Doctoral Landscape Award, from the Engineering and Physical Sciences Research Council (EPSRC), and Elliott Wood Partnership.

Reuse of Post-Event Waste: A Case Study of Circular Design Involving the Academic Community

Silvia Tedesco(✉), Elena Montacchini, Nicolò Di Prima, and Angela Lacirignola

Department of Architecture and Design, Politecnico di Torino, Turin, Italy
silvia.tedesco@polito.it

Abstract. Temporary events, characterised by their brief timeframes, present considerable challenges in terms of material consumption. Often, the materials used during these events quickly become waste, even though they retain a high residual value that is not exploited for reuse. As a result, these events have a significant impact on the built environment, highlighting the need to rethink cultural, design, and organisational approaches in order to promote systemic change. This article describes a project focused on experimenting with circular design through a specific case study centred on recurring university temporary events organised at the Politecnico di Torino (Italy). This initiative was carried out by a multidisciplinary team of architecture and design students and professors, with the goal of recovering materials from events and making them accessible to the academic community for reuse. The project included an analysis of the actors involved in the process, the quantification of waste, the exploration of opportunities for material recovery, and experimental activities. This research resulted in the development of prototypes and new scenarios for reuse and sharing. The case study provides an opportunity to develop new organisational and management models aimed at extending the useful life of post-event materials, which may be applied in other contexts. Additionally, this initiative offers an educational opportunity to train future professionals through innovative teaching and research-through-design methods, focusing on crucial topics related to the ecological transition and fostering a culture that views waste as a resource.

Keywords: Circular Design · Reuse · Temporary Events · Post-Event Waste · Teaching and Research-Through-Design

1 About Temporary Events and "Cultural Waste": An Introduction

Temporary events, characterised by their brief timeframes, present considerable challenges in terms of material consumption. Often, the materials used during these events quickly become waste, even though they retain a high residual value that is not exploited for reuse [1].

In particular, materials that include graphic elements communicating a coordinated visual identity and event-specific content become obsolete as soon as the event is over.

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 409–417, 2026.
https://doi.org/10.1007/978-3-032-34930-9_48

As a result, these materials have a significant impact on the built environment [2, 3], highlighting the need to rethink cultural, design, and organisational approaches in order to promote systemic change [4, 5].

This article describes a project focused on experimenting with circular design through a specific case study centred on recurring university temporary events organised at the Politecnico di Torino (Italy) and on the "cultural waste" generated through the production, staging, communication, and use of temporary cultural activities.

This type of waste includes, among others, signage (banners, panels, totems), stage design components, exhibition and stand materials, printed items, and single-use products such as fabric bags, badges, customised lanyards, and accessories. At the end of the event, these materials are typically discarded because they are no longer communicatively relevant, cannot easily be reused, or are not convenient to store and refurbish.

To illustrate the scale of the problem, in 2024 alone the Politecnico di Torino organised 10 large exhibition installations, including 'Salone dell'Orientamento', 'A&T Automation & Testing Fair', 'Biennale Tecnologia', 'Salone Internazionale del Libro di Torino', and the initiative 'PoliTO for Peace', as well as 15 additional exhibition projects supporting promotional initiatives. These temporary and recurring events produced large quantities of roll-ups, coverings, signage, banners, totems, and other communication materials that are typically not reused.

The project described in this article involved a multidisciplinary team of architecture and design students and professors with the goal of recovering materials from events and making them accessible to the academic community for reuse. The project included: a systemic analysis of stakeholders and materials involved in the process; the exploration of opportunities for material recovery; experimental activities aimed at producing prototypes; and the development of new reuse scenarios.

The exploration of this specific case study represents an opportunity not only to propose new organisational and management approaches to extend the useful life of "cultural waste" that would otherwise be sent to landfill, but also, more broadly, to raise awareness and train future professionals on key issues related to the ecological transition.

Although focused on temporary events, the strategies explored are also relevant to broader building-sector practices, particularly in relation to interior fit-outs, exhibition systems, and temporary installations, where short life cycles and material turnover present similar challenges.

2 A University Case Study: Context, Project and Key Actors

For several years, the Politecnico di Torino has been integrating sustainability principles into its activities in teaching, research, third mission initiatives, and campus management, as explicitly stated in its University Strategic Plan, the institutional document defining the long-term vision and objectives of the university [6].

Among the priority action lines is the responsible management of resources within a circular economy perspective. Following the "reduce–reuse–recycle" approach, actions undertaken across the campus include, for example: plastic-free bars and cafeterias; distribution of reusable water bottles to new students and staff; new waste separation

stations; electronic waste (WEEE) collection; responsible procurement policies; initiatives for reusing post-consumption materials generated by the university. Campus sustainability represents the broader framework within which the project described in this article is situated.

The project investigates post-event waste related to the set-up and communication of large events organised by the Politecnico di Torino and open to the public. In particular, the project focuses on two events: i) 'Salone dell'Orientamento', an annual event designed to guide high school students in choosing their university path through informational stands on bachelor's and master's programmes, thematic meetings, open lectures, and laboratory visits; ii) 'Biennale Tecnologia', a biennial cultural event dedicated to exploring the complex relationship between technology and society and addressing the impact of innovation on the environment, democracy, health, and work through lectures, dialogues, debates, exhibitions, and performances hosted in the university's main venues.

These events, which take place regularly, generate recurring waste materials (flags, banners, panels, etc.) whose graphics make them unusable for subsequent editions. The challenge is therefore to identify ways to reuse and manage these post-event materials within the university, extending their useful life.

The project was developed through the collaboration of multiple actors within the academic community of the Politecnico di Torino. Specifically, it emerged from the collaboration between the University Sustainability Division, which promotes sustainable initiatives and practices within the campus, and students and professors from the Master's degree programmes in Architecture and Design, who developed proposals and scenarios within the course Designing and Developing the Circular Economy (academic year 2024/2025) [7].

The project also benefited from the support of the Exhibition Design, Graphics and Merchandising Office, responsible for exhibition design projects and visual identity for university initiatives, and from the LaSTIn Laboratory (Laboratorio Sistemi Tecnologici Innovativi) of the Department of Architecture and Design, which supports teaching and research activities related to technological innovation and sustainability.

3 Post-Event Materials: Analysis, Design, and Experimentation Activities

The project included field research, desk research, design activities, and laboratory experimentation aimed at giving a second life to the "cultural waste" generated by the university.

Following a teaching and research-through-design approach [8], the design and experimental practice carried out by the multidisciplinary team of students and professors served as a means of generating new knowledge. The objective was not limited to producing final artefacts, but rather to identify new potential processes, new actor networks, and new scenarios for the reuse of post-event materials.

The first phase of field research was conducted through interviews with staff from the Exhibition Design, Graphics and Merchandising Office and through on-site observations conducted at the end of Politecnico di Torino events. These activities made it possible to

analyse the organisation of university events, map and represent processes, actors, and materials, and identify inefficiencies and the main types of post-event waste materials.

Event design, organisation, and management are handled by the Exhibition Design Office, which is also responsible for drafting tender specifications and assigning the supply of materials to specialised external companies. According to these specifications, exhibition materials are generally dismantled and disposed of by the suppliers at the end of the event, with landfill as the most common end-of-life destination.

Only a small portion of materials - those considered suitable for experimental recovery projects - is kept and stored within the Politecnico di Torino. However, this practice faces difficulties due to the absence of dedicated storage spaces and the lack of systematic cataloguing, resulting in materials accumulating over time in an uncontrolled way.

Among the most frequently used and quantitatively significant materials in large university events are: 'Piuma' panels, also known as sandwich panels, consisting of a polyester core and two external PVC sheets; Forex panels, a rigid and lightweight plastic material made of expanded or semi-expanded PVC; flag fabric banners, printed on fire-retardant polyester nautical fabric; PVC banners, widely used in exhibitions due to their durability and high print quality (Fig. 1).

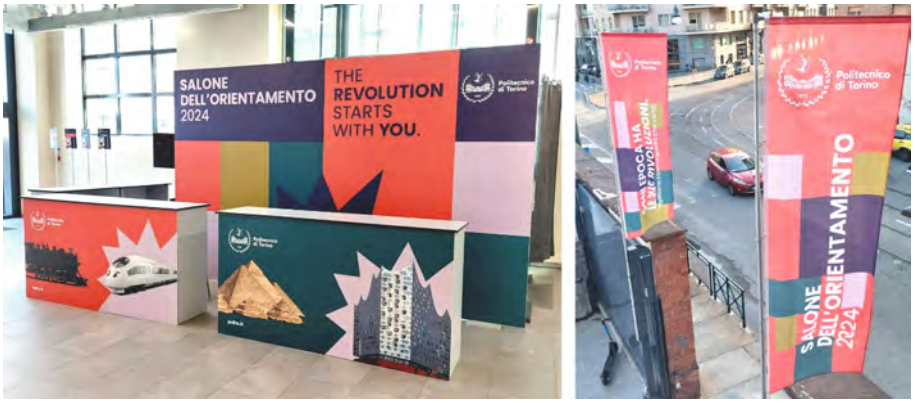

Fig. 1. Example of display materials used for the 2024 "Salone dell'Orientamento" (Careers Fair) at the Politecnico di Torino

These materials present common critical issues: their graphic customisation prevents reuse in subsequent events, and in some cases their multi-polymeric composition makes them difficult to separate and recycle at the end of life.

Although the Exhibition Design Office is working to intervene upstream in the design phase so that exhibition systems can be reused across multiple event cycles, the extreme temporariness of the materials currently used and the absence of consolidated recovery strategies still represent a significant waste of resources.

To identify alternatives to landfill disposal, the field research phase was followed by desk research exploring reuse possibilities through the analysis of international case studies and best practices. These case studies provided references not only for constructive solutions or reuse strategies but also for recovery processes activated through

the involvement of new territorial stakeholders beyond the companies responsible for producing, installing, and dismantling the materials.

In parallel, the available materials were explored through an analysis of their physical and sensory characteristics. The components are highly heterogeneous: rigid materials such as panels and soft materials such as fabrics. Within these categories, materials differ in mechanical resistance, surface treatment, durability, and semantic characteristics. Observation, study, manipulation, and experimentation through cutting, perforating, gluing, and sewing guided the development of design concepts, which were subsequently prototyped at full scale in the laboratory.

The design concepts did not focus exclusively on the development of new objects made from recovered materials but also explored systemic processes and scenarios capable of bringing materials back into circulation. Particular attention was given to identifying new actors to be involved in the process, with a focus on the academic network (students, professors, laboratories, associations, and student teams) and local small enterprises engaged in material transformation.

4 Towards a "Circular" University: Prototypes and Scenarios for the Reuse of Post-Event Materials

Focusing on the academic community - particularly students - made it possible to identify unmet needs related to everyday university life, such as temporary and informal supports for working individually or collaboratively outside classrooms (e.g., portable laptop tables, picnic blankets, desks), as well as the need for low-cost household objects such as lamps, laundry baskets, and storage containers (Fig. 2).

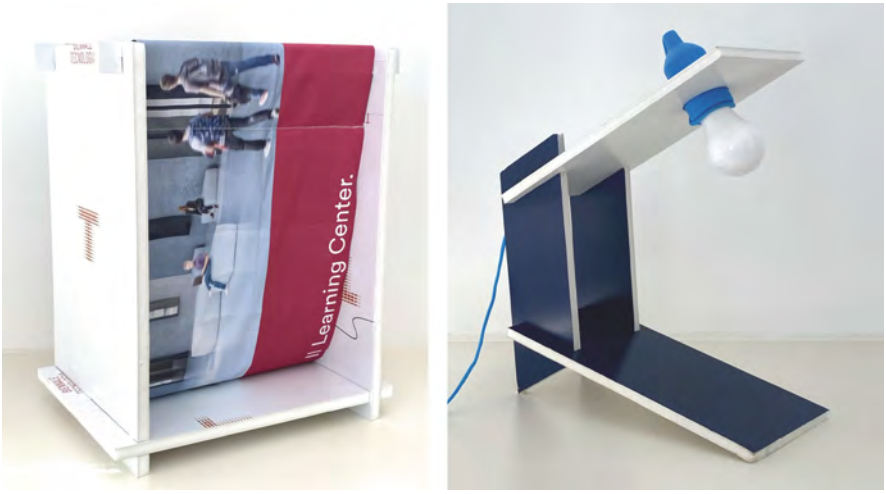

Fig. 2. Examples of prototypes made from post-event waste. On the left, a laundry basket; on the right, a table lamp. Prototypes and pictures by M.E. Cardinale, G. Gaminara, M.G. Romano, S. Rovelli, E. Scarsella, E. Vaira

This led to the development of a catalogue of objects prototyped directly by students with the support of the LaSTIn Laboratory. The prototyping phase allowed the feasibility of design hypotheses to be verified through a material-based approach that prioritised minimising processing steps and optimising the use of available materials. The goal was to avoid generating additional offcuts or waste while ensuring the most efficient possible use of resources and technologies suitable for self-construction and easy replication.

Together with the catalogue of objects, new organisational and management models for reuse were also proposed. Three main reuse modalities were identified.

The first modality involves acquiring post-event materials immediately after the event. Some materials may be booked online before the event and collected during dismantling by student teams for prototyping activities or by professors interested in using the materials in their courses. Individual students may also collect materials and receive assembly instructions to build objects from the catalogue or develop their own projects.

The second modality consists of organising educational and social activities structured as theoretical and practical workshops dedicated to reuse and circularity principles. Participating students produce objects using event materials under the guidance of professors and experienced students. Even simple objects - such as storage containers - can be produced quickly with basic tools, becoming concrete opportunities to learn and experiment with circular design principles in a collaborative environment (Fig. 3).

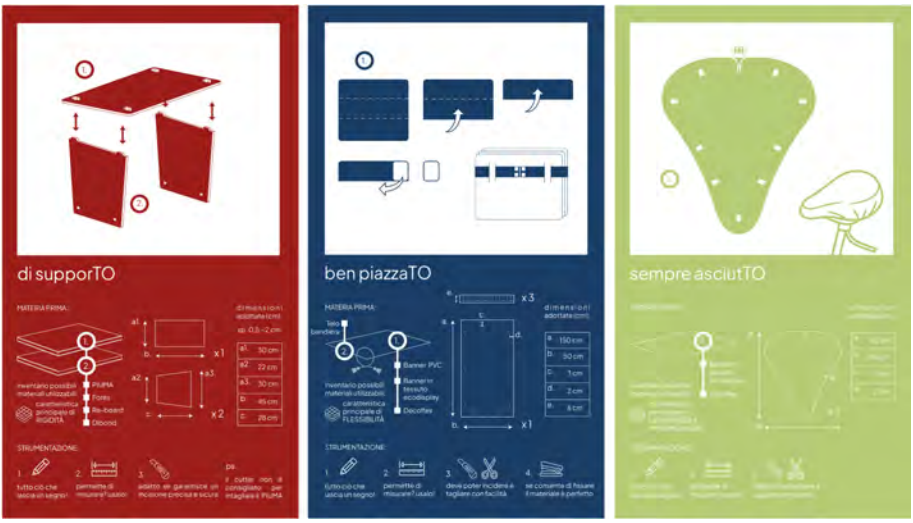

Fig. 3. Examples of assembly instructions for creating objects from post-event waste. Project by A. Cochis, G. Di Lucente, M.V. Nicastro, M. Oberto

The third modality involves the production - supported by the university - of objects useful for everyday campus life, which would then be made available to students through sharing systems. Sharing objects such as portable laptop tables or picnic blankets represents an opportunity to promote a culture of shared use and to move beyond individual

ownership. It also encourages informal moments of study and relaxation, fostering the use of open spaces and social interaction within the academic community.

Prototypes and new organisational and management scenarios were shared with the Exhibition Design, Graphics and Merchandising Office and the Sustainability Division of the Politecnico di Torino. The Sustainability Division will further develop and implement projects beyond the educational context in which they originated by launching several pilot experiments. The first experimentation, related to the reservation of post-event materials, began during the "Salone dell'Orientamento" in March 2026. More than 150 post-event materials - including forex panels, PVC panels, and flag banners - ranging in size from 1000 × 200 cm to 35 × 50 cm, were made available for reservation without usage restrictions. The materials could be reused for teaching activities, design workshops, prototypes and models, as well as personal or social initiatives. Participants were also asked to share photographs documenting the reuse of the reserved materials, which were later published on social media channels. All items were fully booked within a few hours. The success of the initiative, involving professors, students, and laboratories, led to its replication during the "Biennale Tecnologia" event in April 2026.

Additional experiments will be organized by the Sustainability Division as workshops within sustainability-focused festivals, together with the activation of pilot sharing initiatives across different campuses of the Politecnico.

5 Discussion and Conclusion

This project resulted in the development of prototypes and the definition of new scenarios for the reuse and sharing of so-called "cultural waste". The outcomes were presented to the Exhibition Design, Graphics and Merchandising Office and the Sustainability Division of the Politecnico di Torino, initiating a constructive institutional dialogue on the management of post-event materials and their potential reintegration into the university system.

Originating within an educational context, the project is intended to be further implemented and assessed at the institutional level, evolving from a teaching experiment into an operational strategy embedded in university practice. Preliminary results suggest promising impacts in terms of materials diverted from landfill and high participation levels; future developments will include more systematic monitoring of quantities, user engagement, and organisational uptake to assess long-term circularity performance.

The project shows how academic experimentation can contribute to shaping scalable and transferable approaches, potentially adaptable to other cultural contexts. While rooted in a specific institutional context, the proposed scenarios highlight a set of replicable elements - such as stakeholder collaboration, material mapping, and low-threshold access to reuse - that can be adapted to other universities and building-sector practices, where short life cycles and material turnover present similar challenges. Nevertheless, operational aspects (e.g. storage availability and internal governance) remain context-dependent.

From an educational perspective, the initiative supported the training of future professionals through research-through-design methodologies and interdisciplinary learning processes. By engaging with real-world constraints and opportunities related to the ecological transition, students are encouraged to adopt a systemic perspective that reframes

waste as a resource within circular design paradigms. More broadly, the project generates social impacts that extend beyond the students directly involved. By activating concrete practices of reuse and sharing within the university campus, it fosters a cultural shift across the academic community. Sustainability is thus approached not as an abstract principle but as an operational and situated practice rooted in everyday contexts and capable of influencing collective behaviours and ways of thinking.

Living Wall Systems As Educational, Cultural and Climate-Adaptation Devices: A Case Study

Carlotta Fasano(✉)

Department of Architecture and Design, Politecnico di Torino, Turin, Italy
carlotta.fasano@polito.it

Abstract. Climate change increasingly affects liveability and thermal comfort in dense urban areas, requiring cities to adopt adaptive and user-centered strategies. In this context, Nature-Based Solutions (NBS) represent efficient tools in urban regeneration and social cohesion. Turin is advancing this approach through its Climate Resilience Plan and Green Infrastructure Strategic Plan, promoting initiatives such as rooftop gardens on the Lidl supermarket in Via Bologna and the NBS Living Labs implemented within the EU project ProGIreg.

This contribution examines the Living Wall System (LWS) installed in 2025 in the courtyard of the Pertini School in Turin. Initially designed as a temporary installation for the ATP Finals, the system was repurposed as a permanent green infrastructure. The study investigates how the LWS evolved from a simple regeneration measure into an educational and cultural device that makes climate adaptation principles tangible, fostering environmental awareness and inclusive participation.

The methodology combines a qualitative assessment of spatial, cultural and pedagogical dimensions with a quantitative framework based on consolidated scientific data on LWS performance. Literature-based indicators provide a benchmark for understanding the system's potential for urban heat-island mitigation and air-quality improvement, while field-based qualitative analysis highlights the architectural and pedagogical value of the installation, which enables students to directly observe system functioning and translate environmental benefits into accessible learning experiences.

Results confirm the capacity of LWS to integrate environmental, social and educational benefits within school contexts. However, high installation and maintenance costs remain a barrier, underscoring the need for more scalable, affordable and circular solutions.

Keywords: Nature-Based Solutions (NBS) · Living Wall Systems (LWS) · Climate Adaptation · Environmental Education · Urban Regeneration

1 Introduction

Climate change is increasingly affecting urban liveability, thermal comfort and public health, particularly in densely populated areas where built surfaces intensify heat accumulation and limit ecological regulation processes. According to the Intergovernmental

Panel on Climate Change (IPCC), cities are both major contributors to climate change and highly vulnerable systems exposed to rising temperatures, extreme weather events and deteriorating air quality [1]. Consequently, climate adaptation has become a central objective of urban policy and design, requiring strategies that integrate environmental, social and infrastructural dimensions.

Within this framework, Nature-Based Solutions (NBS) are increasingly recognized as effective and multifunctional instruments to enhance climate resilience while producing co-benefits for biodiversity, health and social cohesion [2]. However, recent studies highlight that many NBS initiatives remain confined to pilot interventions, often lacking scalability, long-term monitoring or integration within circular economy models [3].

Among NBS, Living Wall Systems (LWS) represent a promising vertical greening strategy able to face multiple urban challenges simultaneously. Several studies demonstrate their contribution to surface temperature reduction, mitigation of the urban heath island effect, particulate matter retention and carbon sequestration [4–7]. In addition to environmental benefits, vertical greenery systems are associated with psychological well-being, improved spatial perception and enhanced learning conditions in educational environments [8, 9]. Nevertheless, large-scale implementation remains limited due to installation and governance costs [10]. Furthermore, the socio-pedagogical function of such systems as so far been marginally investigated.

This contribution therefore aims to explore the potential of LWS not only as environmental solutions but also as cultural and educational devices. In this context, the paper analyses the LWS installed in 2025 in the courtyard of the Pertini Comprehensive Institute in Turin as an example of circular recontextualization, where an event-based green installation is transformed into long-term public intervention.

2 NBS in Turin: From Strategy to Practice

The transition toward climate-resilient and circular urban systems requires policies capable of integrating environmental, social and infrastructural dimensions across scales [11]. In this regard, the City of Turin represents a relevant case of institutional alignment between climate adaptation strategies and green infrastructure planning.

Turin's current adaptation trajectory is shaped by two complementary instruments. The Climate Resilience Plan of the City of Turin [12] identifies urban heat island mitigation, soil de-paving and green infrastructure expansion as priority actions to address rising temperatures and climate-related risks. Complementarily, the Green Infrastructure Strategic Plan [13] frames urban greenery as a multifunctional system providing ecosystem services across environmental, social and economic spheres. It explicitly connects green infrastructure to climate mitigation, stormwater management, biodiversity enhancement and public well-being, and recognises the role of public–private partnerships and community engagement as enabling factors for scaling NBS.

Together, these instruments mark shift from fragmented greening interventions toward an integrated urban agenda that includes NBS within planning tools, regulatory processes and long-term development visions.

In addition to policy framing, local experimentation demonstrates progressive NBS implementation. Rooftop gardens realized on a commercial building in Via Bologna

demonstrate how private actors can contribute to ecosystem service provision into dense urban contexts. Similarly, the ProGIreg living lab in Turin [14], developed within the EU Horizon 2020 framework, has provided a structured environment for testing and co-designing NBS in post-industrial neighbourhoods, fostering collaboration among academia, public authorities, private stakeholders and citizens. Within this project an indoor green wall was implemented in schools to improve environmental quality and activate environmental educational pathways [15, 16].

Despite this supportive governance framework, challenges remain in translating strategic objectives into adaptable and resource-efficient interventions able to ensure long-term usability and effective integration into everyday urban spaces. The Pertini case study can therefore be interpreted as a bridging action, connecting policy objectives, circular reuse practices and pedagogical innovation within a single infrastructural intervention, where recontextualization extends the system's life and expand its function within an educational setting.

3 The Pertini Living Wall System

Installed in June 2025 in the courtyard of the Sandro Pertini Comprehensive Institute in Turin, the LWS was originally conceived as a temporary installation for the ATP Tennis Finals and later donated by the Japanese company Nitto to the City of Turin as a permanent green legacy of the event. The municipal administration accepted the donation within the framework of its climate-adaptation strategy and identified the Pertini school courtyard as a suitable site for relocation. The school lies near the Inalpi Arena, the venue of the tournament, and it is characterised by extensive asphalt paving and a blind façade. The relocation was also facilitated by the city's previous experience with the green wall implemented in schools during the ProGIreg project [15, 16].

The system is a 15 × 8m substrate-based modular LWS (VP Modulo®, Verde Profilo [17]) composed of independent expanded polypropylene tray containing growing medium and integrated irrigation components. Approximately 300 modular trays were installed, hosting about 950 plants including Fatsia japonica, Lonicera nitida, Hedera helix and Liriope muscari. The modules are installed on a lightweight aluminium supporting frame anchored to the existing façade, minimising structural load while ensuring durability and adaptability. The irrigation system is automated and designed to optimise water consumption (see Fig. 1).

A key technical feature of the system is its design for disassembly, allowing modules to be independently removed and replaced. This modularity enabled the dismantling of the installation from the event site and its reassembly in the school courtyard without structural reconfiguration, according to circular construction principles [18].

In line with established evidence on substrate-based LWS, this system can be framed within consolidated environmental performances ranges. Tabatabaei & Fayaz' (2023) studies report air temperature reductions of up to 3 °C in proximity to vegetated façades under specific climatic conditions, contributing to urban heat island mitigation [5]. CO_2 sequestration values between 0.44 and 3.18 kg CO_2eq/m^2/year have been documented depending on plant species and system configuration [7], while airborne particulate matter retention has been observed in comparable living wall typologies, contributing to improved urban air quality [6].

Fig. 1. Living Wall System installed in the Pertini School courtyard.

Although no direct environmental measurements were conducted in this study, the technical configuration of the Pertini installation aligns with those analyzed in the literature, suggesting that the LWS may contribute to local micro-climatic mitigation and environmental regulation in its immediate urban context. This assumption provides the basis for identifying a limited set of indicators that could be monitored in future phases, including surface-temperature variations between different surfaces, seasonal plant survival rate, irrigation demand, maintenance frequency and visible particulate deposition on leaf surfaces.

4 A Multilevel Approach

This research adopts a multilevel approach integrating quantitative aspects based on literature benchmarks with qualitative cultural and pedagogical analysis in order to provide a multidimensional interpretation of the Pertini LWS, in line with integrated NBS evaluation models [19].

The quantitative component relies on literature-reported performance indicators related to substrate-based LWS relevant to climate adaptation, including surface and air temperature mitigation, air quality improvement and carbon sequestration. These parameters serve as comparative references rather than site-specific measurements, positioning the Pertini installation within established environmental performance ranges and defining a scientifically grounded reference framework to be integrated into the educational design of the project.

A participatory educational programme was incorporated as both a dissemination tool and a qualitative research instrument. The activities, developed in collaboration with teachers, involved second-year middle school students and classroom-based sessions with courtyard hands-on activities in order to connect theoretical knowledge with direct observation.

Classroom-based discussions introduced climate change impacts, urban heat islands effect, evapotranspiration processes and air-quality dynamics. Literature-derived quantitative benchmarks were simplified and presented as scientific support to explain what LWS are, how different typologies operate and what environmental contribution they may provide.

Subsequently, courtyard hands-on exercises allowed students to test and critically reflect on the theoretical principles previously discussed. These activities were conceived as guided experiential sessions supporting the qualitative evaluation of the LWS as a cultural and pedagogical device.

In parallel the research also included an assessment of circular and spatial valorisation dimensions considering the system's design for disassembly, relocation and reuse, as well as its architectural impact on a previously neutral courtyard façade. This reflection contributes to understanding how material reuse and spatial enhancement reinforce the cultural potential of the system.

5 Pedagogical and Socio-Cultural Outcomes of the Pertini LWS

While temporary event-based installations are typically conceived for short life cycles and frequently dismantled after the event, the relocation of Pertini LWS extended its life beyond the sporting event and ensured functional continuity within a public educational setting. In this sense, circularity operates simultaneously at material, functional and spatial levels: the components were reused and their purpose evolved from temporary representational installation to long-term climate-adaptive educational device. Along with the material reuse, the intervention introduced a green landmark in the school courtyard strengthening the place identity. According to studies enhancing the positive effects of vertical greenery systems on perceived environmental quality and people well-being in built contexts [8], the Pertini LWS operates as a regenerative architectural tool, reconfiguring the school courtyard perception and increasing its attractiveness. This spatial requalification reinforces the socio-cultural dimension of the intervention, extending its impact not limited to environmental regulation alone.

Moreover, the developed educational programme allowed the enhancement of the LWS as a pedagogical device. Introductory classroom-based sessions functioned as interactive and participatory learning environments (see Fig. 2a). Simplified scientific data were shown through images, videos and guided questions, actively engaging students in the discussion. Examples of similar NBS implemented within the local urban context were presented to emphasise the tangible nature of these solutions. Students frequently recognised such installations, demonstrating the activation of curiosity and contextual awareness.

Field-based activities in the courtyard further consolidated this learning process. The opportunity to physically observe and analyze the wall's structure and components enabled true understanding of LWS's technological functioning. Subsequently, students measured surface temperatures of asphalt, the bare façade and the vegetated wall using a thermal camera, allowing discussion on solar radiation absorption, material albedo and cooling mechanisms. Air-quality awareness was supported through leaf-surface cleaning tests providing visible evidence of particulate deposition (see Fig. 2b). Finally,

plant inventory documentation allowed students to estimate potential CO_2 sequestration using online available carbon calculation tools [20], linking biomass presence to climate mitigation processes.

These activities enabled students to translate theoretical data into observable phenomena, experiencing the LWS as an interface through which climate-adaptation principles become tangible. Technical learning emerged from students' ability to relate the system's material and technological components to its environmental functions. In addition, a post-activity questionnaire was administered by the teacher to assess students' perceived learning, interest and awareness of NBS and urban sustainability, representing a first step toward a more structured evaluation of the initiative's educational and social impact.

Fig. 2. **a.** Classroom-based concept introduction. **b.** Hands-on "leaf-cleaning" test

Overall, the contribution recognizes the Pertini LWS qualitative potential that extends beyond the energy and environmental performance commonly addressed in literature. By integrating circular reuse, spatial requalification and structured educational engagement, the system operates as an environmental, pedagogical and socio-cultural device, reinforcing its relevance within contemporary climate-adaptation strategies.

6 Conclusions

The Pertini case study contributes to current debates on the sustainable and circular transformation of the built environment by demonstrating how LWS can operate simultaneously as climate-adaptation strategy, circular reuse intervention and educational device. While environmental performance of LWS has been extensively analysed in literature, this example highlights their potential as cultural and pedagogical tools.

The relocation of a temporary installation into a permanent school setting exemplifies a form of circular recontextualization, where material reuse, functional transformation and spatial regeneration converge, extending material lifespan and generating social value. Moreover, through structured pedagogical integration, the LWS becomes a tangible interface through which students engage with climate-adaptation principles, reinforcing environmental literacy and collective awareness.

However, installation costs, technical complexity and maintenance requirements remain critical constraints for wider diffusion, particularly in resource-limited contexts. The present study is also limited by the absence of long-term site-specific environmental monitoring, while the post-activity questionnaire already administered provides a basis for further assessing the educational and social impact of the initiative. Future research should therefore focus on scalable and economically sustainable models, supported by simple monitoring protocols that combine environmental indicators, maintenance data and educational and social-awareness assessment. This would allow future developments to integrate environmental performance, circular principles and pedagogical value within a more evidence-based framework.

How Well Do Circularity Indicators Describe Recovery Potential in Existing Buildings at the End of Life? A Case Study in Belgrade, Serbia

Milica Nikolić[1], Aleksandra Parezanović[1(✉)], Zorana Petojević[1,2], and Ana Nadaždi[1]

[1] Faculty of Civil Engineering, University of Belgrade, Belgrade, Serbia
aparezanovic@grf.bg.ac.rs

[2] School of Architecture, Design and Civil Engineering, Zurich University of Applied Sciences, Winterthur, Switzerland

Abstract. Achieving a circular built environment requires reliable methods for assessing existing buildings as material banks at the end-of-life, yet most circularity indicators are developed primarily for the early design phase. Even those indicators intended for end-of-life assessments remain insufficiently validated. This study examines how different circularity indicators describe the same existing building when applied under identical data constraints and system boundaries, enabling a controlled comparison of scenario-based end-of-life circularity assessments. Three frequently cited end-of-life indicators were applied to a 1930s residential building in Belgrade, Serbia, using a single and consistent material inventory derived from archival documentation and BIM-based quantification. The results show relatively high agreement between the compared MCI-based approaches at the material level, but substantial differences at the element, system, and building levels. This confirms that circularity indicators are not interchangeable and that their interpretation depends strongly on the assessment level, data availability, and methodological assumptions. While such assessments may be feasible for individual existing buildings to some extent, their application to neighborhood-scale studies remains limited without simplified input requirements and standardized calculation procedures.

Keywords: Building Circularity Indicator · Circularity Assessment · Material Circularity Indicator · Pre-Demolition Audit · Resource Recovery · Reuse Potential

1 Introduction

Since over 93% of virgin materials continue to enter the global economy [1], the need for comprehensive models capable of tracing material flows and identifying realistic recovery potential has become increasingly vital. The existing building stock, much of it aging [2, 3] and approaching unavoidable renovation or demolition, represents a

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 426–433, 2026.
https://doi.org/10.1007/978-3-032-34930-9_50

substantial yet unexplored reservoir of secondary materials that may be reintroduced into circular resource cycles at the end of their service life.

In response, a wide range of circularity indicators (CIs) has been proposed. A systematic literature review was conducted following PRISMA guidelines, searching Scopus, Web of Science, and ScienceDirect for peer-reviewed research published between 2010 and 2025. The search combined Boolean operators and terms such as ("circularity indicator" OR "circularity metric" OR "circularity index") AND ("construction industry" OR "built environment" OR "building"). Studies were included if they defined or applied a CI in the built environment; grey literature and unrelated sources were excluded. From over 880 screened records, a final set encompassing nearly 100 indicators was identified.

The identified indicators are primarily developed for the design phase [4–6], where input data are usually available and accurate. In contrast, only 11 construction-specific indicators address the end-of-life (EoL) phase. All are quantitative and vary considerably in their level of assessment, spanning material, element, and whole-building scales—a breadth that nonetheless reveals the absence of a standardized approach to assessing circularity at the EoL phase.

Finally, CIs are rarely tested and validated on real-life (existing) building case studies; only a small number of studies have been conducted [4, 6, 7], limiting their empirical robustness and practical reliability. This situation is further complicated by the fact that buildings constructed before the mid-twentieth century rarely have complete documentation; archival drawings are often fragmentary, material specifications are unavailable, and details of layers and joints are frequently unknown. Within the analyzed literature, no case studies were identified that focus on existing buildings built before the mid-twentieth century, despite their significance in the European urban landscape. These limitations raise a fundamental research question: How can circularity be assessed for existing buildings under real-world conditions when essential data are incomplete or absent?

The present research directly addresses this issue by examining how applicable and feasible CI assessments are for existing buildings at the EoL phase under incomplete documentation and data constraints. The most frequently cited indicators were applied to the same building using identical system boundaries and data limitations, ensuring a controlled and comparable scenario-based assessment. This comparison is particularly important for understanding the extent to which different indicators describe the circularity of the same building and how useful such results are for decision-makers in the end-of-life phase. Given the growing interest in applying circularity assessments beyond individual buildings, it is also essential to understand how feasible and meaningful such calculations would be at the neighborhood or higher scales. It further reflects on how sensitive each indicator is to the assumptions required when documentation is incomplete. Finally, it contributes to the knowledge base by providing an additional case study.

2 Methodology

2.1 General Approach

The methodology adopted in this study is structured to ensure a transparent, consistent, and replicable circularity assessment of existing buildings at the EoL phase. It consists of six steps, which are illustrated in Fig. 1: 1) creating a database of circularity indicators, 2) filtering the database to identify relevant EoL phase indicators, 3) ranking the indicators and selecting three most frequently cited, 4) adapting and calibrating the selected indicators for application to the case study, 5) acquiring all available data for the case study (including digital model generation), 6) calculating indicators and interpreting results.

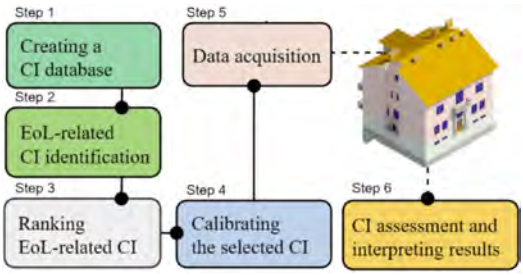

Fig. 1. EoL building circularity assessments' methodological steps

The workflow began with the creation of the CI database, and the identification of 11 EoL indicators. Using MAXQDA 24[1]'s automatic coding function, each indicator was searched in the literature using multiple name variants, full names, abbreviations, and alternate forms. This ensured that each occurrence of every indicator in the texts was recorded. The results of the automatic coding were then manually verified to eliminate duplicates and inaccurate occurrences. Based on the validated data, the indicators were ranked by frequency of occurrence.

For the case study application, the three indicators that appeared most frequently in the analyzed literature were selected: Material Circularity Indicator (MCI), Building Circularity Indicator (BCI), and Whole-Building Circularity Indicator (WBCI).

Given that this study aims to assess circularity at the building level, the BCI and WBCI were applied in accordance with their original formulations, as proposed by Verberne [5] and Khadim et al. [4]. Both indicators follow a hierarchical calculation that progresses from the material level to the element level, then to the system level, and finally to the building level. In contrast, MCI is originally defined only at the material level, which requires adapting it for building-level assessment to ensure comparability across all indicators. In the adapted approach, MCI was first calculated by material [8]; the resulting values were then weighted by material mass, and the overall building-level circularity was obtained by dividing the sum of the weighted values by the total mass of all materials.

2.2 Data Acquisition

An existing residential building situated in the Palilula municipality of Belgrade, Serbia, was selected as the case study. The building was constructed in 1932 and has a configuration of basement, ground floor, first floor, and attic (B + GF + 1 + A). According to the National typology of residential buildings in Serbia [9], it is classified as archetype B5, e.g., a multi-family house (MFH) built in a row in the period between 1919 and 1945. This archetype represents the most common multi-family residential building type within the dominant construction period identified in the selected study area of Palilula municipality, which is being analyzed as part of the Circ-Boost project funded by the Horizon Europe programme (Grant Agreement No. 101082068).

As the case study building was constructed in 1932, data collection was limited to the available archival documentation from the Historical Archives of Belgrade. The documentation included floor plans, sections, elevations, and a brief technical description covering the structural system, principal materials, floor and roof constructions, and wall finishes. It did not contain information on floor and ceiling finishes, joint details, and exact material specifications. This information had to be assumed using typology-based material assemblies and descriptions for the B5 MFH archetype.

To support material quantification needed for indicator assessment, a digital model of the building (BIM model) was developed and used to generate an inventory of building materials and elements (material take-offs). The model included the main structural and architectural elements, while furniture, equipment, and service systems were outside the scope of the assessment. Material quantities were extracted from the model, while material masses were calculated by multiplying the corresponding volumes by material density values. The resulting material inventory provided the common input dataset for the calculation of the selected circularity indicators.

The assumptions used in the circularity assessment cover a wide range of parameters, including material physical and chemical characteristics, feedstock composition, waste fractions, recovery efficiencies, service life, end-of-life pathways, and maintenance or construction phase losses. Their reliability ranges from high, where data come from standards or other formal sources, to low, supported mainly by grey literature, industry practice, or expert judgement.

3 Results and Discussion

3.1 CI Assessment at the Material and Element Level

Figure 2 presents the comparative results at material and element levels using a dual heatmap: a green-yellow-red scale for material-level performance (MCI-E, MCI-V, MCI-K) and a blue-red scale for element-level performance (MCI-E′, PCI-V, ECI-K). For acronym definitions, see the note accompanying Fig. 2.

At the material level, a high degree of convergence is observed among different methodologies, particularly for mineral-based materials. The convergence for mineral-based materials is expected, as all three formulations yield identical results when construction losses, maintenance flows, and bio-based fractions are negligible. The results show full alignment of MCI-E, MCI-V, and MCI-K for foundation materials and for

*Shearing layers: ST-structure; SP-space plan; SK-skin; Note: MCI-E = MCI based on the Ellen MacArthur methodology; MCI-V = MCI based on the BCI methodology (Verberne, 2016); MCI-K = MCI based on the WBCI methodology (Khadim et al., 2023); MCI-E' - mass- aggregated MCI-E on element level; PCI-V = PCI based on the BCI methodology (Verberne, 2016); ECI-K = ECI based on the WBCI methodology (Khadim et al., 2023);

Fig. 2. Material-level and element-level results

clay brick and concrete across most exterior and interior elements, while the largest discrepancies appear in timber components of the exterior envelope. The wooden roof structure is the most pronounced outlier, with MCI-V scoring 0.10 compared to 0.55 under MCI-E, and notable differences also occur for external wooden doors and window frames. Divergences in timber components reflect two methodological differences: MCI-E credits wood as a bio-based material from Sustained Production, while MCI-V treats it as virgin input; MCI-K additionally penalizes timber through construction and maintenance waste flows in M′, yielding intermediate values. Smaller variations are observed for glass and roof coverings, whereas interior elements remain largely consistent except for wooden internal doors, which again follow the pattern of higher MCI-E values relative to the other two indicators.

A comparative analysis of the element-level results across the three methodologies reveals significant discrepancies, with PCI-V consistently producing the most conservative results in nearly all elements. This is attributable to the disassembly-related factors in Verberne's approach, which penalize elements based on connection types and accessibility at the element level—aspects not accounted for in MCI-E and incorporated in WBCI only at higher aggregation levels. The largest differences occur in roof covering, roof structure, and both external and internal walls, where PCI-V falls 0.37 and 0.70 below the corresponding MCI-E′ and ECI-K results. Ultimately, the lowest PCI-V performances are recorded for slabs-on-grade, external walls, internal walls, and the roof structure.

3.2 CI Assessment at the System and Building Level

The results of the comparative CI assessment at the system and building levels are illustrated in Fig. 3. The system- and building-level comparison shows that discrepancies between methodologies intensify as the scale of assessment becomes more aggregated. At the system level, the data is categorized by shearing layers (structure, skin, and space plan). The skin layer exhibits the largest deviation (0.66 between MCI-E″ and SCI(p)-V), followed by the space-plan layer (0.50 spread between MCI-E″ and SCI-K), while the structure layer remains comparatively stable with only 0.15 variance (between MCI-E″ and SCI-K). At the building level, results show a sharp decline from the theoretical BCI(t)-V of 0.82 to a final WBCI-K of 0.23. This consistent downward trend (0.82 → 0.66 → 0.34 → 0.23) highlights a major discrepancy between different methodologies.

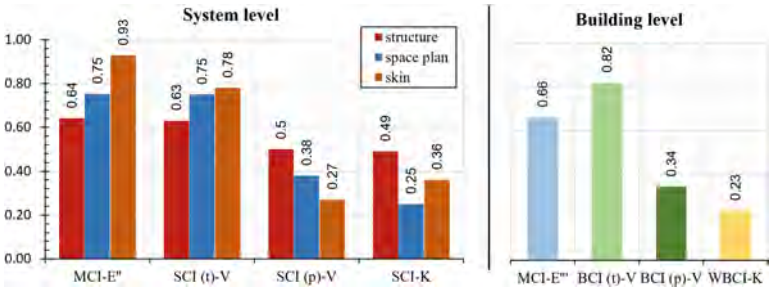

Fig. 3. System-level and building-level results

3.3 Discussion

The results show that the three circularity indicators cannot be used interchangeably, even when applied to the same building with identical boundaries and data. Each operates at a different assessment level and therefore captures different dimensions of recovery potential: material-level indicators identify which materials can be recovered based on physical properties, whereas element-level indicators—by incorporating DfD principles,

connection types, and accessibility—are better suited for guiding selective dismantling decisions. Building-level indicators, in turn, support broader comparisons and prioritization. For EoL decision-makers, this means that the choice of indicator directly shapes the type of information and may lead to different interpretations of a building's circularity performance.

The indicators are not equally sensitive to assumptions and system boundaries adopted in the assessment. Since assumptions are based on inputs with different levels of reliability, their effect on the result is not uniform across indicators. While the different methodologies produced relatively similar results at the material level, larger differences emerged at the element, system, and building levels, where the impact of sensitive assumptions was compounded by inherent differences in mathematical formulation, aggregation logic, and normalization factors.

Although the calculation of EoL CIs is not necessarily complex, it is challenging to apply it to existing buildings when documentation is incomplete, because the assessment requires extensive data preparation and a considerable number of assumptions. This makes transparent reporting of assumptions essential, as different assumptions may lead to different circularity values and, consequently, different EoL decisions. These constraints also question the feasibility of scaling such assessments to the neighborhood or higher level. In this study, even one building required a detailed inventory and multiple assumptions, suggesting that data-intensive methodologies such as MCI are not yet feasible for neighborhood- or city-scale application without substantial simplification.

Finally, the study has several limitations. It is based on a single case study, relies on incomplete historical documentation, and compares indicators developed from different conceptual perspectives and levels of application. Further research should therefore include additional existing building case studies, sensitivity analyses of key assumptions, and methodological simplification for application at larger scales.

4 Conclusion

This study compared three frequently cited CI under identical system boundaries and data constraints to examine how well they describe recovery potential in an existing residential building at the EoL stage. The results show that, although the compared approaches produce relatively similar values at the material level, substantial differences emerge at the element, system, and building levels. Because many key parameters must be assumed rather than measured, the choice of indicator directly shapes the outcome. This confirms that the selected indicators are not interchangeable, as they reflect different methodological logic, aggregation procedures, and sensitivities to assumptions.

From a practical standpoint, the study demonstrates that applying circularity indicators to existing buildings requires extensive data preparation and transparent reporting of assumptions. Even for a single building, the assessment is resource-intensive, raising doubts about the feasibility of scaling such methods to neighborhoods or larger territories without substantial simplification and standardization.

Overall, the findings highlight the need for greater methodological alignment, clearer guidance on assumptions, and more robust data frameworks before circularity indicators can reliably support end-of-life decision-making for existing buildings.

Repeated Assembly-Reassembly Behaviour of Dry Mechanical Joints in Digitally Fabricated Timber Structures

Mahmood Ali and Dan V. Bompa(✉)

University of Surrey, Guildford GU2 7XH, UK
d.bompa@surrey.ac.uk

Abstract. This study investigates the disassembly capability and reusability of dry mechanical connections (DMCs) in digitally fabricated timber structures, using a modular timber arch as a case study. Material characterisation was undertaken in tension, compression, and shear, supported by digital image correlation to establish reference properties and failure modes. At connection level, focused cyclic pull-out tests were conducted to quantify friction-based resistance, wear, and degradation under repeated assembly-disassembly actions. Resistance degradation envelopes were obtained for up to 1000 cycles, indicating gradual reduction of mechanical properties with increase in cycles. A modular arch was manufactured, assembled and tested under mechanical loading. Failure was governed by slip at the mortise-and-tenon connections, indicating that the properties of the DMCs are critical for this structural typology. Consequently, characterisation of cyclic pull-out behaviour at connection level is instrumental to evaluate the suitability of repeated assembly-reassembly of such structures. The study provides experimental evidence directly relevant to circular construction and modular design in the wider context of Performance Based Circular Structural Engineering framework.

Keywords: Design for disassembly · Dry mechanical connections · Cyclic assembly-reassembly · Structural reuse · Modular timber · Circular construction

1 Introduction

A circular solution is to adopt engineered timber systems that can be repeatedly assembled and disassembled (reused) without significant loss of mechanical performance to transform modern practices and aid the transition toward sustainable, circular built environments. Dry Mechanical Connections (DMCs) advance this objective by avoiding adhesives and fasteners through a system of interlocking designs and friction-based load transfer, enabling reversibility and element recovery [1, 2]. Digitally manufacturing integrates timber-to-timber DMCs back into modern, repeatable construction workflows. Computer Numerical Control (CNC) machining (3D subtractive manufacturing) produces planar joint geometries and allows interlocking geometries to be milled with controlled tolerances, supporting modular reuse without adhesives. This application has supported physical projects such as the WikiHouse and The Music Pavilion in Huis

ter Heide. The DMCs used are derived from traditional Japanese, Chinese, and European timber construction practices, including mortise and tenon (MT), Nuki, scarf, lap, pinned, and notched joints [3]. The connections rely on precise geometric interlock and friction to transfer loads into the foundations, and, with the advancements in digital fabrication, DMC's offer scalable, demountable, and modular design assemblies.

Circularity is a systemic approach that aims to minimise waste and retain the highest utility for as long as possible, expressed through design-for-disassembly that prioritises durability and allows multiple design lives [4]. Recent work on circular structural timber focuses on assessing and grading reclaimed members, highlighting the need to adapt existing grading methods if reused timber is to be treated as a reliable structural resource [5]. The field is shifting from circularity to a predominantly environmental or process-led discussion towards circularity as a problem of structural qualification and future performance, in the wider context of Performance Based Circular Structural Engineering (PBCSE). In the context of DMCs, circularity depends on the material's reclaimability and the structural system's demountability, without causing irreversible damage or significant loss of mechanical performance through repurposing/reusing structural elements in future lives. DMCs' reusability is governed by the stability of friction-based resistance and tolerance-sensitive contact conditions, which degrade over time due to wear, local crushing, and repeated assembly. Quantifying this degradation is essential to turn design-for-disassembly into a measurable reuse metric that can inform new life scenarios [6]. MT joints' cyclic pull-out resistance degradation is proposed and evaluated as key reuse control here.

2 Methodology

2.1 Material Properties

The engineered timber selected was Brazilian Pine Structural Plywood (BPSP), manufactured from Pinus elliottii (Slash Pine) sourced from plantation concessions in Paraná and Santa Catarina, Brazil, and fabricated in sheets measuring 2440 mm × 1220 mm × 18 mm (width × height × thickness). The plywood plates consist of seven veneer layers bonded in alternating grain directions using phenol-formaldehyde adhesive, conforming to BS EN 636:2012, with mechanical properties characterised per BS EN 789:2004. The homogeneous cross-laminated structure provides dimensional stability. Tests included tension (dog-bone), compression, shear, and cyclic MT joint loading, to evaluate stiffness, strength, and assembly-disassembly capabilities. The material tests aim to establish mechanical strength properties, evaluate the effectiveness of the interlocking MT dry connections, and identify failure modes to optimise future designs of timber-based modular structures.

2.2 Joint Response

The joint response is commonly determined by the shear interaction of vertical loading and frictional bearing capacities at the MT interface. As the connection is loaded vertically, the failure is governed by shear, which defines the joint's ultimate capacity. In

contrast, withdrawal (pull-out) loading, resistance is mobilised by the normal contact force arising from MT interference, generating frictional shear stresses that counteract removal. Cyclic assembly and reassembly modify this mechanism through surface wear and local crushing, leading to a progressive reduction in contact pressure and frictional resistance, as detailed later. Consequently, shear and cyclic responses quantify the degradation, MT joint stiffness, and the residual resistance.

To quantify the shear behaviour of the MT joint plated elements shown in Fig. 1c were manufactured. The setup assembles a CNC-cut, DIC-prepared central specimen (Fig. 1ci) with two extruding tenons (Fig. 1cii), which results in a 40 mm clearance from the base that allows vertical displacement of the central specimen under testing. For the shear tests, the testing procedure followed a displacement-control protocol at 1.0 mm/min via a 250 kN Instron machine, to allow the maximum compressive force to be reached within 180–420 s.

To assess degradation of MT joints under repeated assembly-disassembly, specimens consisting of plated elements shown in Fig. 1d were prepared. All CNC-cut specimens consist of a 20 mm long tenon specimen (Fig. 1di) and the base 20 mm deep mortise specimen (Fig. 1dii). The tenon specimens were clamped 40 mm into the Instron machine, and the base specimen was centred and fixed to the Instron via 4 bolts. Testing followed a 4-stage process: (1) 5 mm/min, displacement to –19 mm, to obtain the first cycle. (2) 5 mm/min, displacement to +9.5 mm to vertically centre tenon with mortise. (3) Cyclic testing at 5 Hz was selected to mimic the incision-removal behaviour and to obtain the penetration forces of each cycle until a plateau. (4) Loading rate: 20 mm/min, displacement: +9.5 mm to remove tenon from mortise.

Several methodological constraints bound the results. Material tests were limited to a single species (BPSP) and geometry; cyclic tests involved n = 5 specimens for the 20-cycle tests and n = 2 for the extended ~1000-cycle series, which is statistically limited.

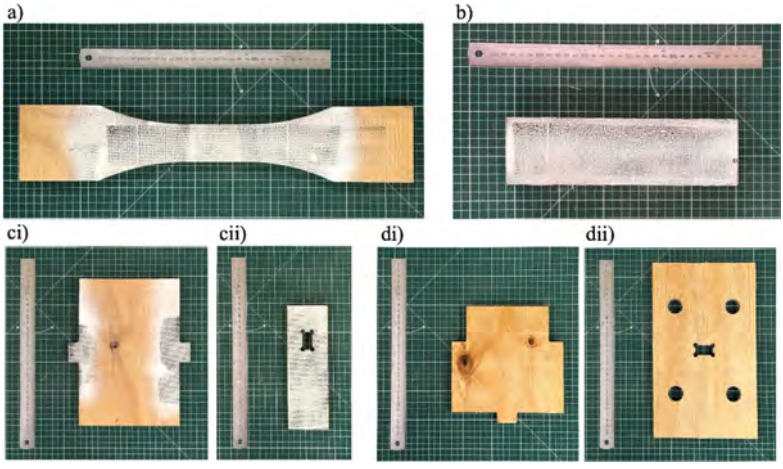

Fig. 1. CNC-cut material test specimen against a 30 cm ruler: a) tension (dog-bone), b) compression, c) MT shear connection, d) MT cyclic connection

The cyclic behaviour was evaluated only for MT friction without bearing between parts. The quantitative degradation trends should therefore be treated as indicative.

3 Results

3.1 Material Properties

For all tests, force-displacement curves from the testing machine and full-field images captured at a rate of 12 images/min were used for further analysis. Tensile tests assessed the BPSP's response under uniaxial loading, as shown in Fig. 2a and the representative image in Fig. 3a. The average ultimate tensile stress was 15.0 ± 1.76 MPa. The elastic region showed oscillations rather than a smooth slope because the DIC capture rate of 12 images per minute introduced gaps in the data. Over the full test, the oscillations evened out, resulting in a reliable Young's modulus (YM) data with a SD of ±1.02 GPa. Tension 3, which recorded the highest YM (5.27 GPa), exhibited a stepping failure with the stress dropping by 4 MPa, but it continued to deform until its second fracture point. Causes of failure include delamination, fibre tearing, and the natural heterogeneity of plywood layering.

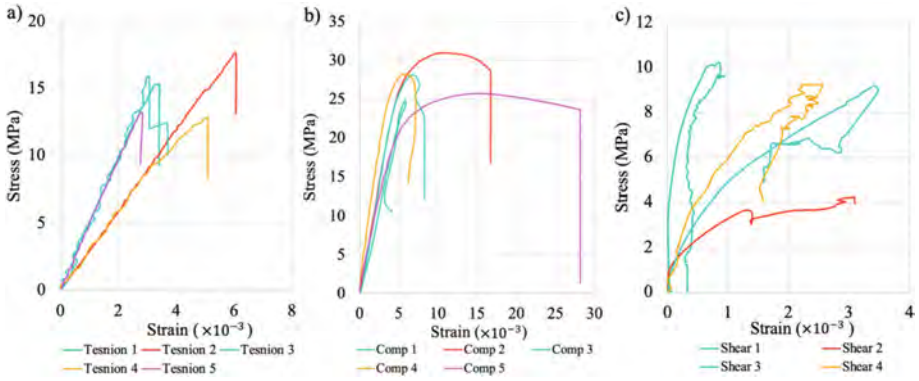

Fig. 2. Stress-strain curves for: a) tension, b) compression, c) shear connection specimens

Compression tests (Figs. 2b and 3b) found higher load capacities, with an average ultimate stress of 27.55 MPa (±2.15 MPa) and a YM of 5.18 GPa (±0.70 GPa). The 1.25 GPa difference between tensile and compressive moduli is consistent with the orthotropic, layered nature of plywood, where alternating face-grain and cross-grain veneers produce direction-dependent apparent stiffness in uniaxial tests [7].

Comp 1 exhibits snap-back behaviour, as the material momentarily loses load-bearing capacity, followed by a short recovery in displacement. This is due to delamination, shear plane failure, local buckling, or crack propagation. Localised crushing or progressive fibre buckling explains why Comp-2 and Comp-5 have a more ductile.

Shear results average ultimate shear stresses of 8.22 MPa (±2.32 MPa) and an average YM of 4.94 GPa (±0.84 GPa). All shear test specimens followed the same

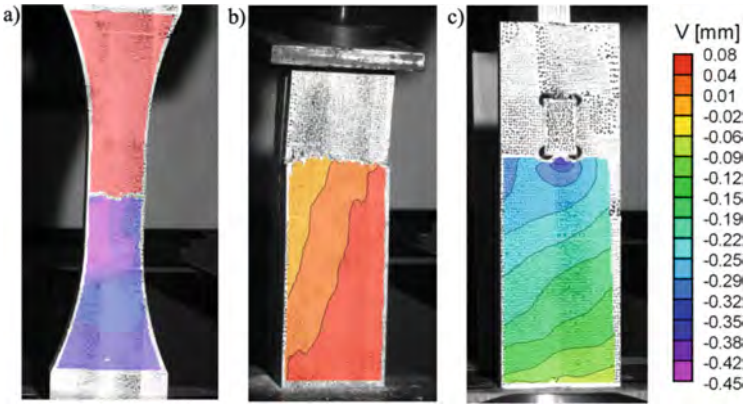

Fig. 3. Cyclic pull-out test data for samples subjected to a) 20 cycles, b) 1000 cycles

failure mode, with a splitting of the tenon that breaks away from the mortise plate and minute crushing of the mortise plate. Shear 1 achieved the highest stress and YM (10.20 MPa, 5.35 GPa). Shear 2 was an outlier, failing prematurely at 4.26 MPa – likely due to the loading rate being set too high, contributing to the higher standard deviation of ±2.32 MPa. Additional reasons include weak frictional interaction, prior micro-cracks from hammering during assembly, or localised crushing at the mortise wall. An average ultimate shear stress of 8.22 MPa indicated that the MT joints can resist moderate lateral forces before failure.

3.2 Repeated Assembly-Reassembly Response

The repeated assembly-reassembly tests include push-pull cycles of the tenon into the mortise. The tenon was pushed until its bottom part was in near contact with the bed of the machine, then then pull out at the upper face of the plywood base plate. This loading protocol engaged friction at the tenon-mortise interface, which degraded with increase in cycles. This is shown by the cycle-resistance degradation envelopes of the pull cycles only shown in Fig. 4. Note that the resistances for the push cycles were about 50% higher, but the degradation profile nearly identical. This degradation results from gradual compaction of the mortise walls and rounding of the tenon edges, which progressively reduces frictional resistance against withdrawal. The pull-out data were acquired for the first 20 cycles (Fig. 4a) and 1000 cycles (Fig. 4b), for five and two specimens, respectively. A maximum average pull-out force of 540.4 N (±74.16 N) and a minimum of 244.5 N (±72.9 N) were found, refer to Table 1. The variance is expected given the inherent plywood material characteristics.

Further tests were conducted to achieve a more sustained plateau in force readings, enabling a confident determination of the point at which the MT joint loses all friction-bearing capacity. Therefore, Cyclic 2 and Cyclic 3 were retested in the same manner, providing gradual force decay across ~1000 cycles. The representative decay in pull-out resistance over the number of cycles is illustrated in Fig. 4b, and the degradation of the MT joint is captured in Fig. 5. The residual pull-out forces were reduced to 55.14 N and

Table 1. Cyclic mortise and tenon data

Specimen ID	20 Cycles		1000 cycles
	Max. Force (N)	Min. Force (N)	Final Force (N)
Cyclic 1	540.3	366.1	–
Cyclic 2	476.0	244.6	55.1
Cyclic 3	558.6	317.2	128.1
Cyclic 4	668.0	467.8	–
Cyclic 5	458.3	329.6	–
Average ± SD	540.4 ± 74.2	345.1 ± 73.0	–

128.11 N, respectively, corresponding to 11% and 23% of their initial peak capacities, and to 23% and 40% of the capacity after 20 cycles. These values are based on n = 2 specimens and should be regarded as indicative of the degradation trend.

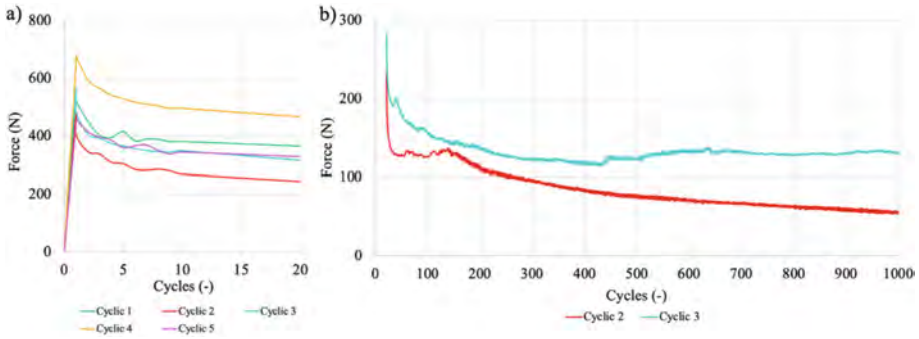

Fig. 4. Cyclic pull-out test data: a) cycles 0 to 20, b) cycles 21 to 1000

During retesting of the two specimens, the MT joint (Fig. 5) exhibited progressive surface wear, rounding of the tenon edges, fibre pull-out, surface abrasion, crushed fibres, and debris accumulation at the interface, which affected the pull-out readings. Cyclic 2 (Fig. 4b) exhibits spikes in force at cycle 145 and Cyclic 3 at cycles 440 and 640 due to the increased friction resistance given by the fallen debris into the mortise. However, the trend is that normal contact pressure steadily declines, explaining the rapid early drop followed by a slower decay toward a plateau.

3.3 Application to Timber Structures and Multiple-Life Reuse

At a conceptual level, for timber-timber joints used in temporary structures, structural performance beyond first use refers to the assessment of mechanical and functional performance after one or more cycles of assembly, service, disassembly, and reassembly. In such systems, repeated installation and dismantling, local embedment, and MT wear

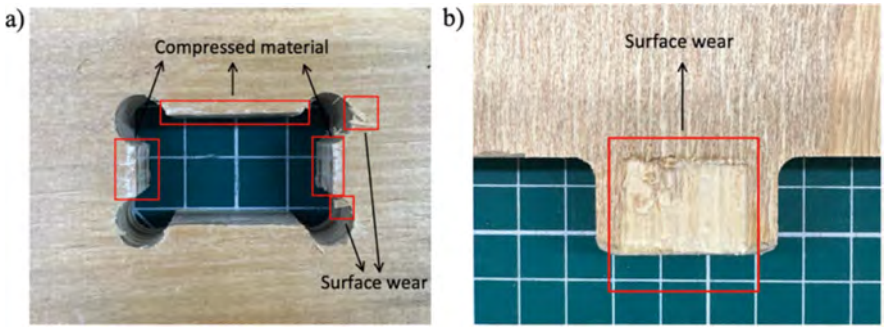

Fig. 5. Degraded cyclic specimen, Cyclic 2 after 1350 cycles: a) Mortise, b) Tenon

at contact interfaces progressively affect stiffness and strength, as indicated in (Fig. 4). Reuse across multiple lives therefore requires rigorous evaluation of the residual performance of both the timber members and, critically, the joints that govern load transfer and structural integrity. Conceptually, this may be represented as a sequence of beginning-of-life structural performance (BOLSP) and end-of-life structural performance (EOLSP) states across successive use cycles. Figure 6 illustrates the case of the MT joints tested under cyclic loading, correlating the conceptual PBSCE framework with the test results from this paper.

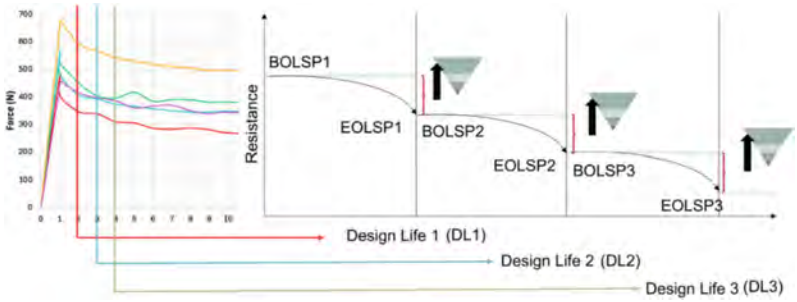

Fig. 6. Performance Based Circular Structural Engineering (PBSCE) framework for MT joints

An example is a modular arch comprising 252 mortise-and-tenon (MT) connections (Fig. 7). The arch was fabricated, assembled and tested under displacement control, reaching a maximum force of 26.0 kN before failure by tenon pull-out from the mortise along approximately one-third of the arch, following the thrust line. If resistance degradation is quantified through repeated assembly-disassembly tests on MT connections, the residual capacity of the structure can be estimated directly. For example, the average degradation of the five specimens in Fig. 4a indicates reductions of 27%, 32%, 35% and 37% after 5, 10, 15 and 20 disassembly cycles, respectively. These values provide a conceptual basis for estimating residual capacity over multiple lives, although further validation is required.

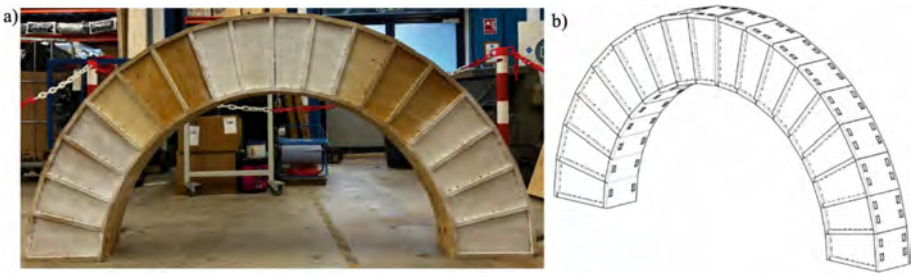

Fig. 7. a) Modular MT connected arch, b) 3D render

4 Concluding Remarks

Within the framework of Performance Based Circular Structural Engineering (PBCSE), this research examined how repeated assembly-reassembly affects the retained performance and reuse potential of CNC-fabricated dry mortise-and-tenon joints in Brazilian Pine structural plywood. The results showed that vertical load capacity is governed by combined shear and bearing actions, with failure defined by tenon splitting and local mortise crushing. Under repeated assembly cycles, pull-out resistance decreased as the interference fit progressively relaxed. At the first cycle, the average resistance was 540 N, reducing by 36% at 20 cycles and by 83% at ~1000 cycles. The main degradation mechanisms were: (i) damage of the mortise wall, (ii) wear and rounding of the tenon edges, and (iii) tolerance relaxation, with occasional local force increases caused by debris-induced frictional interlock. A modular arch was manufactured, assembled and tested under mechanical loading. Failure was governed by slip at the mortise-and-tenon connections, showing that focused connection-level testing is suitable for evaluating the assembly-reassembly capability of this structural typology. From a PBCSE perspective, the results show that reuse should be assessed through measurable retained performance rather than simple disassembly potential. Cyclic pull-out response, therefore, emerges as a practical reuse parameter for dry mortise-and-tenon joints, as it captures the progressive loss of friction and resistance over multiple lives. More broadly, the findings support a multi-life strategy for demountable timber systems, in which joints are classified according to residual performance thresholds rather than on binary reusable/non-reusable assumptions.

Abstract. A significant opportunity exists to move up the circular economy hierarchy by directly reusing structural elements from existing buildings, provided that rigorous and transparent assessment is undertaken. Within the wider remit of Performance Based Circular Structural Engineering (PBCSE) framework, which seeks to evaluate structural performance beyond first use and support evidence-based end-of-life decisions, this paper presents a case study for assessing the structural reuse of reinforced concrete. The investigation integrates geometry verification, non-destructive evaluation, material characterisation, and full-scale component testing to quantify structural response, serviceability behaviour, and governing failure modes. This included selective deconstruction and recovery of a full-scale cast-in-place reinforced concrete floor slab, followed by detailed laboratory testing. Experimental results showed that the reclaimed slab achieved an ultimate load capacity approximately 14 times greater than the design load required for an equivalent contemporary office floor, while serviceability performance remained acceptable at several multiples of the design service load. The results demonstrate that, when supported by a structured assessment and testing workflow, reclaimed reinforced concrete elements can meet or exceed modern structural performance requirements while delivering substantial environmental benefits. The study provides quantitative evidence to support reuse-led decision-making and illustrates how PBCSE can serve as an overarching framework for circular structural design.

1 Introduction

Recent research on circular construction has expanded rapidly, but the structural engineering dimension remains fragmented. Reviews of the circular economy in the built environment show that the literature is now mature in relation to definitions, end-of-life strategies and broad implementation barriers yet still lacks consistent methods for linking circularity decisions to residual structural performance, reliability and reuse qualification [1–3]. This gap is particularly important for structures because decisions

on retention, reuse, remanufacture or recycling tend to depend on environmental indicators, but safety on the residual stiffness, strength, ductility, robustness and durability of components after their first service life. In this context, the concept of Performance Based Circular Structural Engineering (PBCSE) is proposed as a direction that integrates life-cycle assessment, structural mechanics and reliability-based decision-making to evaluate structural performance beyond first use.

For reinforced concrete, recent work has moved the field from precedent mapping towards design and experimental validation. A critical review of 77 reuse precedents established that the piecewise reuse of extracted concrete in new structures is technically possible and has a longer history than generally acknowledged [4]. More recent work has then shown how cut cast-in-place reinforced concrete slabs can be reused in new floor systems, with substantial reductions in upfront carbon while still satisfying structural requirements [5]. At the same time, the literature is beginning to adopt performance-based decision tools for concrete end-of-life management. The CirCrete framework is particularly relevant because it explicitly combines circularity strategies with technical and sustainability indicators to guide decisions on refurbishment, remanufacture and recycling of concrete structures [6]. For structural steel, the literature has progressed further on reuse protocols, logistics and environmental benefits, but less so on quantified residual performance assessment [7]. These developments are highly relevant, but they remain material-specific and do not yet amount to a unified structural framework across different component types and future use scenarios.

The emerging literature indicates that the field is shifting from circularity as a predominantly environmental or process-led discussion towards circularity as a problem of structural qualification and future performance. This transition creates a clear opportunity for PBCSE as a unifying framework. Such a framework would evaluate residual and future structural performance using evidence from inspection, non-destructive testing, material characterisation, experimental testing, modelling and reliability analysis, while also embedding circularity, traceability and design-for-future-reuse principles. Within the wider remit of PBCSE, this paper presents a case study for assessing the structural reuse of reinforced concrete.

2 Performance Based Circularity Approach

The life cycle of buildings and infrastructure may be described through a sequence of interrelated stages, beginning with the identification of need and strategic briefing, followed by conceptual design, detailed design, construction, operation, and end-of-life decision-making. The operational phase is typically the longest stage and often accounts for most of the asset's service life. At the end of operational use, the key question is no longer whether the structure has reached a nominal design age, but whether it remains fit for purpose, adaptable, and technically viable for continued use, partial retention, or recovery. Recent design frameworks emphasise the concept of "end of operational life" rather than "end of design life". This distinction recognises that many structures remain structurally sound even when they are no longer suitable for their original function.

A hierarchy of resource use provides a useful basis for prioritising interventions. At the top of the hierarchy is waste prevention, which includes avoiding unnecessary

construction and maximising the continued use of existing assets. This is followed by preparation for reuse and direct reuse of components, which retain the greatest proportion of embodied energy and structural value. Recycling occupies a lower position because, although it recovers material, it is energy intensive and often results in downgraded performance. Recovery and disposal represent the least desirable pathways. For buildings and infrastructure, this hierarchy implies that refurbishment, partial retention, and component reuse should be prioritised over demolition and recycling wherever technically feasible.

Structural performance beyond first use refers to the assessment of mechanical and functional performance after a component or asset has completed its initial service life. During operation, degradation mechanisms such as corrosion, fatigue, moisture damage, carbonation, chloride ingress, and material ageing may reduce stiffness, strength, ductility, robustness, and serviceability. Reuse therefore requires a rigorous evaluation of residual performance at the end of operational life. Conceptually, the problem may be represented as a sequence of "beginning of life structural performance" (BOLSP) and "end of life structural performance" (EOLSP) states across multiple design lives, where the central engineering challenge is to quantify the residual structural parameters that can be carried into the next use cycle (Fig. 1).

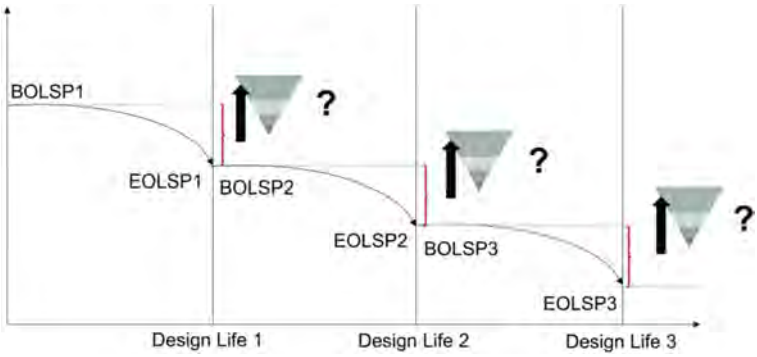

Fig. 1. Conceptual representation of PBCSE.

Building on the above, PBCSE may be defined as an overarching framework that integrates structural reliability, life cycle thinking, and circular economy principles to evaluate, retain, recover, and redeploy structural value across multiple lives. The aim is to develop evidence-based methods that support decisions on retention, refurbishment, reuse, upgrading, and end-of-life management using a combination of structural performance metrics, environmental indicators, and economic criteria. In practical terms, this includes: (i) physical inspection and visual assessment of existing assets; (ii) non-destructive testing and material characterisation; (iii) focused experimental testing of reclaimed components; (iv) analytical and numerical modelling of residual performance; (v) reliability-based assessment of capacity and uncertainty; and (vi) development of reuse-oriented design methods for both existing and future structures.

3 Selective Deconstruction and Testing

3.1 Case Study Background

The present study forms part of a broader circular construction initiative linked to the redevelopment of Euston Tower in London, in which the project team explored how the retained value of the existing structure could be increased beyond conventional demolition and downcycling routes. The wider redevelopment strategy retained the foundations and substantial parts of the core structure, corresponding to approximately 31% of the existing structure by volume, while also investigating whether selected floor elements could be harvested and reused in new structural applications [8]. Within this framework, a ribbed reinforced concrete floor slab was identified as a suitable candidate for recovery and structural evaluation. The concept was to cut discrete in-situ slab panels and reuse them as plank-type elements in a new building, thereby prototyping a high-value reuse route for concrete that would otherwise be crushed and recycled as aggregate [8]. The element was extracted from an existing office floorplate by selective deconstruction procedures intended to limit damage during removal (Fig. 2).

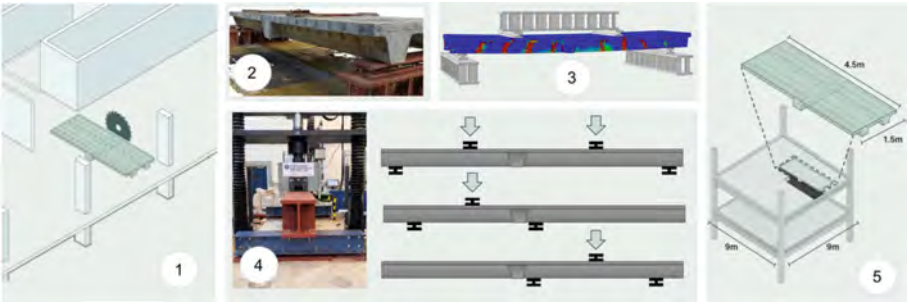

Fig. 2. Circular workflow for structural reuse: (1) site slab extraction; laboratory and numerical assessments (2) geometry [9], (3) nonlinear modelling, (4) selective testing; (5) slab reuse in a new structure (note: (1) & (5) by 3XN/GXN [8]).

A structured assessment workflow was developed to determine the suitability of the recovered element for structural reuse (Fig. 3). The preliminary stage involved estimating the likely structural capacity based on assumed material properties and reinforcement details, supported by sectional calculations and nonlinear modelling [10]. This was followed by geometry verification using direct measurements and photogrammetric survey techniques. Non-destructive investigations were then carried out to characterise the specimen, including ground-penetrating radar to identify the reinforcement layout, rebound hammer testing, and ultrasonic pulse velocity measurements to evaluate concrete quality. Material characterisation comprised estimation of concrete compressive strength from non-destructive correlations and tensile testing of extracted reinforcement bars. Structural response, which is the focus of this paper, was subsequently assessed by full-scale bending tests, including four-point bending to evaluate stiffness and serviceability-related behaviour and three-point bending to determine ultimate capacity and governing

failure modes. In the context of the wider project, this workflow also served as a prototype methodology for future qualification of reclaimed concrete panels prior to reuse in commercial developments [8].

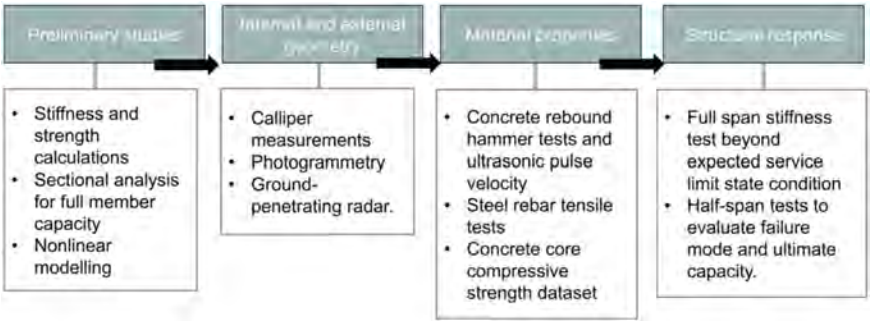

Fig. 3. Structural assessment procedure.

3.2 Experimental Programme

The panel extracted from the building had a width of 1210 mm and a length of 4517 mm. The floor was 270 mm thick, with the ribs 190 mm deep and the topping slab was 80 mm thick. Ribs were 140 mm wide at the bottom and 275 mm at the intersection with the slab. Ribs were spaced at 760 mm. There were three main square-twisted longitudinal bars in each rib which was one more per rib than expected. The two bottom bars were 33 mm/~1 ¼ in. square and the top middle bars were 27 mm/~1 in. square. Concrete cover to the bottom bars was 33 mm. A mesh was present in the topping slab with 5 mm bars spaced at around 153 mm, which was confirmed by ground penetration radar measurements. The extra reinforcing bars and thicker than expected concrete flange will result in enhanced strength. The slab arrived in good condition with a limited number of chips and cracks, which is to be expected for an element of its age. A transverse rib was present in the middle of the slab which was unreinforced. Non-destructive rebound hammer tests indicated that the concrete compressive strength is in the rage $f_{c,cube} = 49.1$ MPa, whilst the steel rebar properties were $f_{y,0.2\%} = 345$ MPa, for the proof strength and $f_u = 476$ MPa for the ultimate strength. Full-scale testing was conducted in displacement control in an Instron Satec frame with a 600 kN actuator. Three tests were performed. Test 1 used a full-span four-point bending arrangement to evaluate stiffness and serviceability-related response beyond flexural cracking (Fig. 4). Tests 2 and 3 used three-point bending on the two half-span specimens to evaluate the ultimate capacity and the main failure mode.

The load was transferred through a UC 305 × 305 × 198 steel beam and secondary loading beams; 40 mm rollers and 25 mm steel plates were used at both loading and support locations. Deformations were measured using the machine crosshead, 2–3 LVDTs, two string potentiometers, and two inclinometers. The LVDTs monitored rib displacements, the string potentiometers recorded mid-span flange deflections, and the inclinometers measured slab rotations near the support regions. All instruments were

Fig. 4. Image of the test slab in the rig.

calibrated before testing following standard laboratory procedures. The main results are shown in Fig. 5.

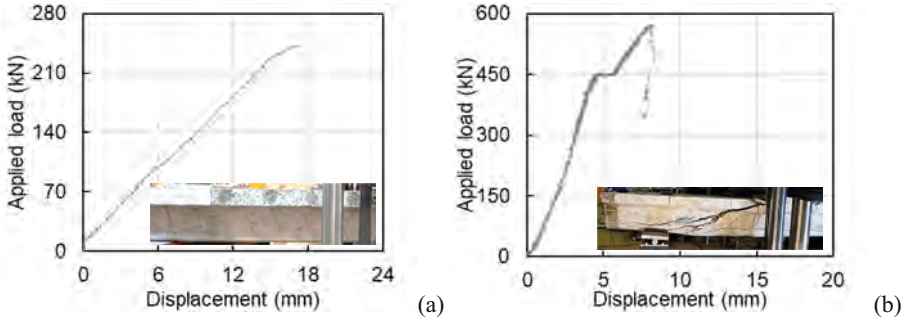

Fig. 5. Load displacement curves and crack details for (a) Test 1, (b) Test 2.

The full-span slab (Test 1) was tested under four-point bending in displacement control at 0.5 mm/min. The load-displacement response was broadly symmetric, with similar stiffness on both sides up to about 78 kN, after which limited softening was observed at one rib. Minor bedding-in effects were evident at low load, but the overall response remained largely linear up to the maximum applied load of 241.5 kN. Flexural cracking was first observed at about 31 kN, no shear cracking developed in any shear span, and all flexural cracks closed on unloading, indicating high stiffness and limited residual damage. The two half-span specimens were subsequently tested under three-point bending in displacement control. In both tests, loading was initially applied at 0.5 mm/min, reduced to 0.1 mm/min at the onset of shear cracking, and then increased again to 0.5 mm/min in the post-peak range to capture residual behaviour. In Test 2, after initial bedding-in up to about 150 kN, both ribs responded similarly until softening began at approximately 415–445 kN, corresponding to the onset of shear cracking; the peak load reached 571.9 kN, followed by widening of the governing diagonal crack and horizontal splitting at the level of the bottom reinforcement. Test 3 showed similar behaviour, with bedding-in at low load, comparable rib response beyond about 150 kN, shear crack initiation at about 405–435 kN, and a peak load of 537.7 kN, after which the

diagonal crack widened progressively in the post-peak range. In both tests, failure was governed by web shear.

In terms of design requirements for future reuse, the four-point bending tests indicated linear load-deflection response up to load levels exceeding those expected in service, highlighting that the recovered element retained substantial stiffness and structural integrity. The measured behaviour was consistent across the test configuration and confirmed the suitability of the slab under serviceability-related demand. Subsequent three-point bending tests produced a shear-governed failure at an average ultimate capacity of about 554.8 kN, with evidence of shear redistribution prior to failure. When expressed as an equivalent uniformly distributed action, the measured resistance corresponded to approximately 43 kN/m^2, significantly higher than that of a typical office floor design load of about 3 kN/m^2. These results indicate a substantial reserve of structural capacity relative to the intended reuse scenario. They also support the wider project claim that recovered in-situ concrete elements may provide technically credible alternatives to new precast-type components when appropriately assessed and detailed [8].

4 Concluding Remarks

This paper examined the structural reuse of reinforced concrete within the wider remit of Performance Based Circular Structural Engineering (PBCSE) framework, which aims to evaluate structural performance beyond first use and support evidence-based end-of-life decisions. A case study was presented in which a full-scale cast-in-place reinforced concrete floor slab was selectively deconstructed, recovered, and experimentally assessed to quantify the structural response. The main remarks are outlined below.

- Extraction of an in-situ reinforced concrete floor element from a central London building proved technically feasible, and the recovered slab met the structural performance requirements for reuse.
- A complete laboratory workflow was established for structural reuse assessment, combining geometry verification, non-destructive testing, material characterisation, analytical appraisal, and full-scale bending tests.
- The recovered element was in very good condition and exhibited substantial reserve capacity; four-point bending tests showed a largely linear response, while three-point bending tests produced shear-governed failure with an average capacity of 554.8 kN and evidence of shear redistribution.
- The measured resistance was well above the demand for a typical office floor application, confirming that the slab retained stiffness and strength beyond first use and could be assessed based on residual structural performance rather than assumed end-of-life value.
- The results indicate that reclaimed in-situ concrete floor elements may be reused in a manner analogous to precast plank systems, supporting higher-value retention of structural performance over conventional recycling and contributing to lower embodied carbon, reduced waste, and lower virgin material demand.
- Future work includes undertaking advanced nonlinear simulations and reliability-based assessments to evaluate structural performance beyond first use over a wider set of loading and material parameters representative for the second life scenario.

Design for Disassembly in Interior Fit-Out: An n-Dimensional Classification of Dry and Prefabricated Systems for Circularity

Elisabetta Ginelli, Laura Daglio, Giulia Vignati(✉), and Alessandro Marco Greco

Politecnico di Milano, Milan, Italy
giulia.vignati@polimi.it

Abstract. The growing commitment of the construction sector to the transition toward a circular economy has led to multiple approaches defining current practices in the built environment. Among them, Design for Disassembly (DfD) and Design for Adaptability (DfA) play a central role, yet their widespread adoption is limited by costs, time management, and labor requirements associated with assembly and disassembly processes. This paper focuses on interior fit-out systems, a critical layer for circularity due to short life cycles and frequent layout changes. Despite extensive research on DfD at the building scale, studies on interior systems conceived as independent, prefabricated, and reusable subsystems remain limited. The paper examines macro categories of dry and prefabricated systems and introduces an n-dimensional classification – linear (1D), planar (2D), and spatial (3D) – to compare disassembly operations, labor needs, and adaptability potential. Findings highlight how dimensionality influences disassembly time, flexibility, and reuse, stressing the importance of integrating DfD and DfA from early design stages.

Keywords: Design for Disassembly · Design for Adaptability · Interior Fit-Out · Dry Construction Systems · Prefabrication · Reuse

1 Introduction. Design for Disassembly and Dry Construction Systems

The construction sector plays a significant role in the European economy, providing 18 million direct jobs and contributing approximately 9% to the EU GDP. Nevertheless, it remains one of the main drivers of resource consumption, environmental impacts, and waste generation. As of 2023, the buildings and construction sector accounts for approximately 32% of global final energy consumption and generates 34% of CO_2 emissions, including both operational phases and material-related contributions. Production chains remain heavily dependent on cement and steel, while construction and demolition waste in Europe still exceeds one-third of total waste streams [1]. The transition toward circular models requires the adoption of the circular economy as a guiding paradigm, supported

L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 451–459, 2026.
https://doi.org/10.1007/978-3-032-34930-9_53

by a comprehensive understanding of processes, practices, tools and methods for their integration across design, construction, and management phases [2]. Decisions regarding volumes, materials, and technical solutions defined at the early stages of design and planning strongly influence building performance during operation and, most critically, its transformability at the end-of-life stage. Rarely considered at this stage, however, is how buildings and their components can be dismantled or disassembled to reduce or minimize waste generation [3]. A key strategy for circularity is design for disassembly (DfD), i.e. designing to simplify disassembly, to enable the recovery of components and materials, improving their reuse potential and reintegrating them into future life cycles [4, 5].

Transitioning to a circular built environment requires moving beyond conventional construction techniques and a new design approach, by promoting dry construction methods, prefabrication, and off-site construction. According to the American Institute of Architects, the adoption of DfD is constrained by four main factors. First, economic considerations, as initial design costs may increase and investments in workforce training and materials may be required, although these costs typically decrease over time with accumulated experience. Second, shared design objectives and clear, precise communication are required among all stakeholders, along with a clear allocation of responsibilities. Third, market conditions must be considered, as local markets do not always support the temporary storage and subsequent reuse of recovered construction materials. Finally, the design approach itself must prioritize solutions that enable the future reuse of components and construction materials, ensuring a high degree of adaptability over time – an essential condition for supporting multiple transformations during the building lifecycle [6].

Based on these considerations, this study analyzes technological solutions that enable the progressive integration of DfD through stepwise strategies and applications. The study focuses on partitioning and interior fit-out systems – referred to as the infill layer in the Open Building framework [7] – comprising elements such as partition walls, finishes, secondary systems, and internal divisions. These components typically exhibit short- to medium-term life cycles, are subject to frequent changes, and are directly related to user needs and activities.

Interior partitioning and fit-out systems represent the building layer most frequently modified, whether for layout reconfiguration to accommodate different functions over time [8] or for immediate convertibility of space (adjustability, versatility) [9]. Compared with structural systems, interior fit-out components have shorter life cycles and generate disproportionate amounts of waste [10], often limited to 5–15 years, particularly in office or retail buildings. Furthermore, interior systems generally have lower performance requirements, as they do not require strict control of thermal insulation or air- and water-tightness, simplifying their design and application. Despite a substantial body of research on Design for Disassembly, Adaptability, and Prefabrication at the building scale, peer-reviewed studies focusing specifically on interior fit-out systems as independent, prefabricated, and circular subsystems remain scarce.

Through the analysis of macro-categories of dry and prefabricated construction systems currently available on the market, this study introduces the n-dimensional variable of construction elements as an analytical tool for classifying design solutions, with the

aim of identifying their strengths and limitations. This approach is innovative in that it reframes existing dry and prefabricated systems through a unified geometric perspective, enabling a direct comparison of assembly logic, disassembly performance, and reuse potential across different scales of intervention.

2 Toward an n-Dimensional Classification of Fit-Out Systems

To understand the limitations and potential of the transition toward circular interior design, this study investigates products, systems, and components currently available on the international market. Dry and reversible connection solutions for interior partitioning and finishes were analyzed, revealing a growing market characterized by a drive for innovation in response to increasing demand for DfD, also following the emergence of European guidelines and regulations at both international and European scales [11, 12]. Academic, design, and industrial research on the industrialization of interior systems has accumulated a significant body of experimentation throughout the 20th century, particularly in the post-war period, within a broader interest in prefabrication in the construction sector [13]. However, these efforts have had limited impact on mainstream construction practices. This work primarily concerns off-site systems, as well as dry-assembly solutions where partitions are often integrated with furnishings to form system-based assemblies of modular, reusable components. While dry assembly enables reversibility at the connection level, prefabrication operationalizes this logic through standardized, off-site manufactured systems.

Building on classification proposals derived from prefabricated construction [14] and historical and spatial-functional analyses of interior [15], this study proposes a geometric categorization of systems that both integrates and surpasses the ambiguous distinction between dry assembly and prefabrication. In particular, the study reflects on the potential and barriers of different systems from a design perspective, extending to building transformability and component reuse.

The efficiency and feasibility of applying DfD principles are intrinsically de-pendent on the dimensional scale of the adopted construction elements. The concept of classification based on the n-dimensional variable – defined according to the morphology of the technical elements employed (i.e., 1D, 2D, or 3D) and the scope of actions and complexity during assembly, disassembly, and reuse - provides a useful framework to understand how the geometric multidimensionality of construction elements influences disassembly time, labor requirements, and spatial adaptability. From a DfA and DfD perspective, the greater the n-dimensional variable of the construction element, the shorter the potential on-site disassembly time. Conversely, the greater the n-dimensional variable, the lower the flexibility of the element for future reuse cycles.

Based on these considerations, it is therefore possible to categorize elements into three main morphological models, which summarize existing dry-assembly and prefabricated interior solutions, as well as emerging innovative systems on the market (Table 1).

Table 1. The n-Dimensional Classification of Fit-Out Systems.

	Level of prefabrication Labor intensity Level of flexibility fabrication		
Geometrical category	LINEAR Low (on-site assembly)	PLANAR Medium (panelized prefabrication)	SPATIAL High (off-site volumetric)
Example	Stud-and-rail partition with infill panels (gypsum/timber drywalls and ceilings, etc.)	Stud-and-rail partition with finished infill panels (drywalls, modular suspended ceilings, access floors, etc.)	Prefabricated bathrooms and systems, booths
Technology The manufactured system requires the definition of the (interfaces between different fit-out subsystems)	On-site customized interface	off the shelf system + possible special or on-site interfaces	juxtaposition (+ service connections)
Performance (acoustics, fire resistance, etc, depend on the manufactured system and on its interfaces with the other fit-out subsystems)	varies according to the on-site assembly and interfaces	varies according to the interfaces	totally off-site controlled
Design strategies Spatial layout requires specific measures for application of the construction systems for disassembly	free	modular coordination (flexibility depends on modules size)	free plan with functionally predefined spatial zones (served and servant spaces)
Disassembly for Adaptability The construction systems are reused locally	disposal and new construction low initial cost, high costs for refit with waste generation	high initial cost offset through the reuse of components	low customization
Disassembly for Reuse The construction systems are relocated	limited reuse potential	minimum transportation and handling issues related to spatial constraints and finish overlaps (including relocation and potential panel replacement) possibility of product system service purchase durability of components and joints guarantee reuse	transportation and handling issues low customization durability/fragility

2.1 Linear Model (1D) Discrete Components for Traditional Dry-Assembly Systems

The Linear Model includes all dry-assembly systems, such as partition walls, suspended ceilings made of gypsum or wood-composite panels with internal frameworks of cold-formed steel profiles or timber, which together form a system of linear elements with limited modularity. These elements are subsequently infilled with panels cut to size on-site, adapting to the framework geometry and offering spatial flexibility. Linear systems are widely used and offer a high degree of adaptability to interior contexts. However, their installation requires considerable on-site labor, particularly for finishing operations, which can sometimes compromise reversibility (i.e., joint plastering) and limit reuse potential.

Despite the possibility of partial disassembly, these elements are mainly recoverable only for disposal, and their adaptability depends largely on the simplicity of removal rather than inherent system flexibility.

Key advantages of linear systems include ease of storage and low material costs. Nevertheless, on-site assembly demands significant labor for both inter-element connections and interfaces between different systems, which directly affects the final performance of the installation. Reversibility is limited, and although the system allows some flexibility in layout modifications, it remains constrained compared with more modular or prefabricated alternatives.

2.2 Planar Model (2D): Modular Systems for Reversible Partitions

The Planar Model refers to more advanced solutions compared with linear systems, consisting of metal frameworks with simplified locking mechanisms and prefabricated panels that form a modular planar partition system. These systems significantly reduce assembly and disassembly time compared with traditional linear solutions, enabling integration with furniture (which can become part of the system) and mobile solutions such as retractable or foldable walls. Although the initial material cost of these systems is higher, this investment can be offset over time, as the same components can be reused for layout reconfigurations, providing economic and environmental benefits. The durability and ease of transport and assembly further support reuse in other contexts, opening opportunities for Product-Service System (PSS) models.

From a design and sustainability perspective, careful attention to interface detailing during on-site installation is critical to ensure high environmental performance. Designers are encouraged to preconfigure potential layouts to minimize intervention requirements and reduce the impact of future rearrangements. Overall, the Planar Model combines flexibility, modularity, and reuse potential, representing a significant step toward the practical application of circular principles in interior fit-out systems.

2.3 Spatial Model (3D): Prefabricated Volumetric Modules

The Spatial Model represents the highest level of prefabrication, employing three-dimensional modules that are partially or fully finished in the factory and then transported to the site. This approach drastically reduces on-site construction time, allowing rapid

assembly and disassembly on a large scale. Despite substantial operational efficiency and the near-elimination of on-site labor, the Spatial Model presents significant challenges, including high logistical costs associated with transporting large volumes and the need for heavy equipment to maneuver modules on-site. Functional modules often define the character of interior spaces, such as movable units on wheels or tracks, or wet-space modules (i.e., bathrooms or kitchens), which may constitute the only rigid elements in the spatial system.

The high degree of customization during initial fabrication can limit flexibility for subsequent layout reconfigurations or reuse in other contexts, representing a potential barrier for adaptive interior design. Nonetheless, for certain building types – such as healthcare, hospitality facilities and collective housing – the Spatial Model can achieve cost efficiencies through economies of scale. Proper organizational strategies for layout zoning (i.e., served and servant spaces) further support long-term adaptability. The Spatial Model prioritizes efficiency and speed of installation, with high initial investment and logistical requirements, but it offers considerable potential for large-scale prefabrication and circular interior design when integrated with careful planning and modular strategies.

3 Discussion: Design Implications of the n-Dimensional Variable for DfD

DfD requires confronting the n-dimensional nature of construction elements. This reflection does not constrain the designer's scope of action, but it seeks to guide the design process toward greater awareness in the strategic integration of each n-dimensional model in alignment with the objectives and requirements of each phase of the building's life cycle. Labor intensity, which is inversely proportional to the degree of prefabrication and directly proportional to system flexibility, affects the economic variable that has traditionally represented a barrier to the adoption of disassemblable systems.

Linear systems offer low material costs and moderate on-site labor requirements, but their performance is limited by labor-intensive assembly. While these systems provide the highest degree of interior adaptability, their potential for implementation within a circular economy framework is limited. Reversible adhesive-based interfaces may provide some flexibility, but the natural evolution toward reuse and easy transformability is most evident in the planar system.

For planar systems, the initial material cost is higher, despite minimal labor requirements due to mechanical simplicity and lightweight materials. However, this cost should be evaluated not only during initial construction but also in terms of layout reconfiguration and potential reuse, representing an investment that can be amortized over time. This is achievable when the design paradigm anticipates multiple spatial configurations over time, guided by modular grids, appropriate positioning of vertical service cores, and a structural system designed to minimize subsequent interventions. The high degree of reuse and flexibility of planar systems also makes them suitable for advanced commercial models, such as Product-Service Systems (PSS), which transition from physical goods to services and allow control over component end-of-life.

Three-dimensional systems, which are more complex to fabricate and transport, involve higher costs that can be mitigated through economies of scale, particularly in high-density building types such as healthcare facilities, hospitality buildings, and collective housing. In these cases, clear organizational strategies for functional zoning (served and servant spaces) support long-term adaptability with respect to unit size and separation. Conversely, in other typologies, such as commercial buildings that require large, highly adaptable spaces only partially influenced by natural daylight and with deep building volumes, a smaller-scale system is necessary to ensure versatility. Anticipating design decisions implies a paradigm shift in which each operation of the disassembly process must be addressed from the earliest design stages.

This anticipatory approach entails the obligation to plan assembly and disassembly procedures for every construction element. Through such design strategies, it becomes possible to overcome the current barriers to DfD previously identified.

4 Conclusion: Design and Production

From a Design for Manufacturing, Assembly, and Disassembly (DfMAD) perspective [16], the analysis of these systems highlights a paradigm shift that maximizes system benefits through modular design, zoned adaptability, suitability of building typologies, anticipation of future transformations, and a reconsideration of construction costs from a life-cycle perspective. This shift should guide designers toward a more integrated and systemic approach, in which the building, interior spaces, and equipment/furnishings are conceived as parts of a unified design process that involves all stakeholders in the construction sector, supported by the emerging regulatory framework. On the other hand, there are implementation and development perspectives for the systems themselves, particularly regarding planar and spatial systems, which represent the most promising avenue toward circular economy adoption.

For planar systems, the focus should not be solely on further increasing already high performance, customization, or versatility. Rather, emphasis should be placed on implementing adaptability features that allow integration of equipment and service cores [17]. Additionally, a limitation to adaptability lies in interface design, which requires renewed attention [18] to ensure high acoustic performance and fire safety. In this regard, digital transformation offers opportunities for developing off-site customized nodes, tailored on a case-by-case basis according to site-specific conditions. For prefabricated volumetric modules, development should move beyond the conventional wet-block approach toward creating ancillary spaces with varied functionality, potential mobility, and transformability, advancing the concept of “box-in-a-box” within a neutral spatial framework.

These considerations open interesting perspectives for both component and interior design, emphasizing the need for synergy between production and design disciplines and greater awareness within the real estate sector.

The Adaptive Skin: Circular Design Strategies for the Regeneration of Existing Buildings

Monica Cannaviello(✉) and Maria Gelvi

University of Campania "L. Vanvitelli", 81100 Caserta, Italy
monica.cannaviello@unicampania.it

Abstract. The regeneration of the existing built environment requires a reconfiguration of the relationship between building envelopes, material cycles, and architectural form, shifting the façade from a static boundary to an adaptive and circular system, designed to meet not only current needs but also future ones. This paper investigates how material choices and circular design applied to the building envelope can contribute to the sustainable regeneration of existing buildings, by extending their life cycle, improving environmental performance, and reducing embodied and operational emissions. The research adopts a systemic and multidisciplinary methodology that combines a literature review on circularity integration criteria in façades with a comparative analysis of relevant case studies. The paper outlines a methodological framework in which circularity is not treated as a purely technical add-on, but as a generative driver for architectural form, supporting renovation strategies that improve thermal performance, reduce resource consumption, and support low-carbon regeneration processes.

Keywords: Building envelope · Circular principles · Deep Renovation · Compositional dimension · Environmental dimension

1 Introduction

In contemporary architectural debate, the concept of the 'second skin' has gradually come to play a central role in redefining the relationship between architecture, the environment, and the home. In a context marked by the urgency of climate issues and the decarbonisation targets for the construction sector, the building envelope has emerged as one of the primary means through which architecture can simultaneously influence energy performance, the quality of the living space, and the reduction of environmental impacts throughout a building's life cycle. The gradual introduction of increasingly stringent energy standards has brought the envelope's role in regulating indoor environmental conditions back to the forefront of architectural design—a role that, in the era of modern architecture, had been delegated to mechanical and building services systems. Contemporary thinking has once again recognised architecture itself as playing an active role in environmental mediation. From this perspective, the façade ceases to be interpreted as a simple element separating the interior from the exterior, instead becomes a complex system that integrates climatic, spatial, and perceptual dimensions, assuming the form of a layered membrane capable of mediating between domestic space and the environment.

At the same time, the growing focus on the embodied carbon emissions of building materials and processes [1] has prompted architectural research to examine environmental impacts across the life cycle of building materials and components. In this context, the circular economy paradigm proposes a shift away from traditional linear models, promoting strategies focused on reducing resource use, extending the service life of building systems, and reintroducing materials into production cycles. Given that approximately 85–95% of Europe's building stock that will be in use by 2050 has already been built, the refurbishment of the existing built environment represents one of the main challenges for the ecological transition of the construction sector. In this context, deep renovation projects play a strategic role in reducing carbon emissions and improving the quality of living, with the building envelope identified as one of the main areas for intervention [2].

However, interventions on the building envelope cannot be interpreted purely as energy efficiency measures; rather, they require a balance between thermal performance, the quality of the architectural space, and the environmental impact of the materials. Despite the growing interest in adaptive façades and circular design strategies, the literature still tends to treat these two areas as distinct fields of research: on the one hand, studies on adaptive façades focus primarily on technological and performance aspects; on the other, research on the circular economy analyses mainly material cycles and resource management. Less explored, however, is the architectural and compositional dimension of these strategies, namely how the principles of circularity can translate into new ways of designing the building envelope and contribute to the construction of architectural form. The contribution of this research lies in proposing an integrated interpretation of the adaptive façade as a compositional device and a circular design strategy. From this perspective, the second skin is interpreted not merely as a technological system for improving energy performance, but as an architectural interface capable of reconfiguring the relationship between the existing building, material cycles, and the construction of the inhabited space. Through the design of the building envelope, the principles of the circular economy can thus be translated into architectural strategies that extend the useful life of buildings, reducing resource consumption, and activating new cycles of transformation within the built environment.

2 Methodological Approach

Starting from the theoretical premises outlined above, this research interprets the façade as an adaptive skin, that is, as a compositional and technological device capable of reimagining the existing built fabric as a dynamic field of transformation. From this perspective, the architectural envelope is not considered solely as a technical element, but as a multi-level interface through which the architectural organism mediates interiority and exteriority, permanence and transformation, memory and future projection. The building envelope thus becomes the point of convergence between the existing structure and new performance requirements, between energy efficiency and the quality of the living space, as well as between operational emissions and emissions embedded in the materials. The design of the second skin, therefore, plays a strategic role in the processes of transforming existing architecture, emerging as one of the key areas through which environmental, performance, and compositional objectives can be integrated. The research

adopts a systemic and multidisciplinary methodology, combining a critical review of the literature on adaptive façades and circular design strategies with a comparative analysis of case studies in which the introduction of a second skin represents a strategy for the redevelopment of the building envelope. Building on the resource cycles optimisation strategies developed by [3] and subsequently developed by [4], the research investigates how adaptive façades can contribute to the implementation of circular design principles in relation to four main strategies:

- *Narrowing*: reducing resource use;
- *Slowing*: extending the useful life of materials, components, and buildings;
- *Closing*: closing production cycles through the reuse and recycling of materials;
- *Regenerating*: using renewable materials and strategies that contribute to ecosystem regeneration.

Through this analytical framework, the research explores how the 'second skin' can serve as a point of convergence between principles of circularity and the construction of architectural form, transforming interventions on the building envelope into a strategy capable of combining environmental performance, resource management and the regeneration of the built environment.

3 Circular Design Strategies and Adaptive Façades

The circular economy paradigm proposes a radical shift away from the traditional linear models of the construction sector, which are based on a cycle involving the extraction of resources (*take*), the construction of buildings (*make*), and their subsequent decommissioning or demolition (*dispose*). In contrast, the circular approach aims to keep materials, components, and building systems in use for as long as possible, thereby preserving their value and reducing the need for new resources. In the context of regenerating the built environment, this shift implies a fundamental rethinking of design principles. Renovations to existing buildings cannot be viewed merely as technological upgrades but must become a process able to activate new life cycles for buildings and the materials from which they are constructed. From this perspective, the building envelope takes on a strategic role. The façade is, in fact, the element through which architecture can simultaneously influence the building's environmental performance, the quality of the living space and the durability of the building systems. Among the possible intervention strategies, the introduction of an adaptive second skin emerges as one of the most effective solutions for combining the requirements of energy efficiency, spatial transformation and material circularity. The layering of the building envelope makes it possible to improve the building's environmental performance without making invasive alterations to the existing structure, whilst at the same time creating new intermediate spaces that expand the possibilities for living. Several studies [3, 5, 6] have highlighted that, to contribute significantly to reducing environmental impacts in the construction sector, it is necessary to implement four main principles for optimising resource cycles: narrowing, slowing, closing, and regenerating. Each of these principles can be translated into specific design solutions within the context of adaptive façades, generating architectural solutions that integrate technological and compositional dimensions.

3.1 Narrowing

The 'narrowing' strategy primarily focuses on reducing resource consumption through a more efficient use of materials and energy. In the case of adaptive façades, this strategy translates into the building envelope's ability to optimise the building's energy performance during the operational phase. The second skin can, in fact, operate as a system for modulating climatic and microclimatic factors, helping to improve energy performance and comfort levels. Ventilated air gaps, adjustable shading devices, louvres, and filter screens are bioclimatic design elements that, if properly integrated into the architectural design, can significantly influence the building's energy balance. From an architectural perspective, such devices do not merely function in terms of performance but also introduce a new compositional depth to the building envelope. The façade thus becomes a layered structure capable of transforming the relationship between the building and its surroundings. A significant example is provided by Kengo Kuma's residential architecture, where the building envelope is often conceived as a sequence of filters consisting of wooden slats or permeable screens that control solar radiation and natural ventilation. Similarly, in the Moriyama House in Tokyo (SANAA, 2005), the lightness of the building envelope and the fragmentation of the volumes create a sense of porosity that allows light and air to pass through the architecture, demonstrating how energy consumption can be reduced through spatial and compositional strategies as well.

3.2 Slowing

The 'slowing' strategy focuses on extending the service life of materials, components, and the buildings themselves in order to avoid demolition and replacement. From this perspective, the 'second skin' is one of the most effective methods for regenerating existing buildings, as it allows the building's environmental performance to be upgraded without altering its load-bearing structure, transforming the regeneration project into an incremental process. A prime example is the transformation of the Tour Bois-le-Prêtre in Paris (Lacaton & Vassal with Frédéric Druot, 2011), where the addition of deep balconies and climate-controlled conservatories envelops the existing building, expanding the living spaces and improving its energy performance. The façade thus becomes an intermediate space that can increase the quality of life and extend the building's lifespan. Similar strategies were also adopted in the redevelopment project for the Grand Parc Bordeaux (Lacaton & Vassal, Druot and Hutin, 2017), where the introduction of greenhouses and deep balconies radically transformed the spatial and environmental conditions of the dwellings without resorting to demolition. In these interventions, the second skin acts as a tool that can activate regeneration processes based on the continuity and transformation of the built environment.

3.3 Closing

The closing strategy involves reintroducing building materials and components into production cycles through reuse and recycling practices. In the case of adaptive façades, this approach means using modular, demountable components, designed according to the principles of 'design for disassembly' [7], which allow for the replacement, reuse and

relocation of materials over time. The building envelope thus becomes part of a circular system capable of reducing waste production and extending the life cycle of building components. A significant example is the Resource Rows project in Copenhagen (Lendager Group, 2018), in which the building envelope is constructed using bricks recovered from demolished buildings. In this case, the reuse of materials is not merely a technical choice, but becomes an integral part of the architectural composition, transforming the material memory of the built environment into a generative element of the façade. Further developments of this approach are evident in experimental projects such as Circle House (BIG, GXN, 3XN, 2020), conceived according to systematic principles of circularity and designed to be disassembled and reassembled using modular prefabricated systems. Similar experiments can be found in the work of Superuse Studios, such as in Villa Welpeloo (2009), where the building envelope is constructed using reused industrial recovered components. In these cases, circularity is not limited to the management of materials, but becomes a principle capable of generating new architectural configurations.

3.4 Regenerating

The regenerative strategy involves the use of renewable materials and design solutions capable of contributing to ecosystems' regeneration. In the case of adaptive façades, this approach translates into the integration of bio-based materials, vegetation systems, and devices designed to improve the microclimatic conditions of buildings and urban spaces. A prime example is Stefano Boeri's Bosco Verticale in Milan (2014), where the façade incorporates layered vegetation capable of contributing to microclimatic regulation through shading, air filtration, and the mitigation of the urban heat island effect, transforming the building envelope into an active ecological system—although not without its challenges in terms of economic sustainability. A further experiment is represented by the BIQ House in Hamburg (Splitterwerk and Arup, 2013), in which the building envelope incorporates bioreactor panels containing microalgae that can produce biomass and contribute to the building's energy regulation [8]. Similarly, in the residential architecture of the WOHA studio in Singapore, the building envelope often takes the form of a multi-level ecological system in which vegetation, shading, and natural ventilation combine to create living spaces capable of actively interacting with the climate.

4 The Second Skin's Dimensions

4.1 Compositional Dimension

From an architectural perspective, the second skin represents a design field in which the construction of form and the logic of transforming the built environment converge, redefining the role of the building envelope in shaping the inhabited space. The introduction of an adaptive skin effectively transforms the façade from a simple boundary between interior and exterior into a layered spatial threshold capable of creating depth, regulating the climate, and establishing new relationships between architecture and landscape. From this perspective, the second skin operates through three main compositional dimensions: the depth of the architectural space, the modulation of atmospheric conditions, and the shaping of the building's form.

The first dimension concerns the introduction of a habitable depth within the building envelope. Whilst a significant part of modern architecture reduced the façade to a thin surface, the layered envelope restores a thickness to the architectural threshold capable of mediating between domestic space and the external environment, introducing intermediate spaces that expand the conditions of living.

The second dimension concerns the modulation of atmospheric conditions—light, air, and solar radiation—which, through filters and shading systems, become constituent elements of the quality of architectural space and contribute to the building's climate regulation.

The third dimension concerns the construction of the architectural form. Shading systems, grilles or slats transform the façade into an articulated surface capable of generating rhythm, depth and perceptual variations, contributing to the definition of the building's formal identity.

4.2 Environmental Dimension

The three compositional dimensions identified converge in the definition of a broader environmental dimension of the building envelope.

In the contemporary context, marked by climate and energy challenges, the second skin takes on an infrastructural dimension, emerging as one of the principal mechanisms through which architecture mediates the relationships between the building, the environment, and resource cycles. As Kenneth Frampton [9] observes, the architectural project is called upon to engage with the specific conditions of climate and place, integrating technology and form in the construction of space.

From this perspective, scholars such as David Leatherbarrow [10, 11] and Michael Hensel [12, 13] have highlighted how architecture can be interpreted as a dynamic system of interaction between building and environment, in which the envelope plays a central role in mediating the flows of light, air, and energy.

The second skin thus emerges as a device capable of integrating environmental dimensions and architectural composition.

The façade therefore becomes a habitable threshold, a mediating structure between domestic space, the city, and the landscape. From this perspective, the second skin represents not merely a technological solution but a new grammar of the building envelope, through which contemporary architecture explores forms of habitation that are more porous, adaptive, and responsive to environmental conditions.

5 Towards a New Grammar of the Building Envelope

The analysis of the case studies highlights how adaptive façades can serve as one of the key devices for operationally translating the principles of circular design into architectural projects. The strategies of narrowing, slowing, closing, and regenerating find a prime area of application in the design of the building envelope, enabling a reduction in resource consumption, an extension of buildings' service life, and the reactivation of material cycles (Fig. 1).

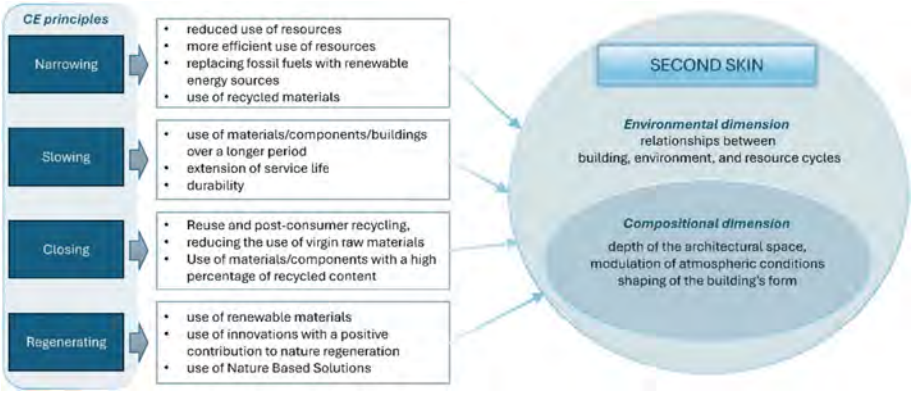

Fig. 1. Circular design principles for second skin.

Although some of the examples shown relate to new-build projects, the design solutions employed can also offer interesting ideas for the refurbishment of existing buildings. From this perspective, the building envelope emerges not merely as a technical device for improving energy performance but as an element able to integrate environmental, structural, and compositional aspects. The multi-layered façade introduces intermediate spaces that mediate the relationship between interior and exterior, improve the building's thermal performance, and enhance the living environment.

The second skin thus becomes a critical interface between the existing building, the environment, and material cycles, through which the regeneration project can simultaneously work to reduce energy consumption, extend the building's lifespan, and circularly manage resources.

In this context, the multi-layered façade represents not merely a technological upgrade of the building envelope, but a new grammar of regeneration. Through the second skin, the circularity of materials and the construction of the architectural form converge in a design paradigm in which the transformation of the built environment becomes an opportunity to rethink architecture as an open system of relationships between space, climate, and material cycles.

It should, however, be noted that architectural projects are often not accompanied by life-cycle assessments that allow their environmental benefits and impacts to be assessed. With a view to the ecological transition of the construction sector, such assessments should instead be made available to the public to promote greater transparency. Future research should aim to quantify the actual benefits associated with the use of adaptive façades in terms of decarbonisation potential, both during the design phase and once the building has been constructed.

A Hierarchical Structural Documentation Framework for Modular Timber Structures Using Structural Component Passports Toward Circular Construction

László Mangliár(✉), Jiayi Li, and Lars Vabbersgaard Andersen

Civil and Architectural Engineering Department, Aarhus University, Aarhus, Denmark
lm@cae.au.dk

Abstract. Modular timber construction offers a strong potential for circularity, but structural engineering workflows remain project-specific, documenting modular buildings as conventional assemblies of individual members. Structural verification is repeated for each project, and structural information is not retained in a transferable form that would enable component reuse. This paper proposes a hierarchical structural documentation framework that reorganises verification and documentation across building, component, and connection levels. The framework combines reduced-order modelling with code-compliant capacity envelopes to generate a structural component passport containing certified performance and lifecycle information. A portal frame case exemplifies the approach compared to a conventional documentation workflow and shows how reusable structural performance data can support traceability, reduce repetitive engineering effort, and enable structural reuse.

Keywords: Modular Timber Structures · Structural Documentation · Reduced Order Modelling · Circular Construction · Structural Reuse · Structural Design

1 Introduction

Modular timber construction offers a pathway to high-value component reuse through efficient fabrication and design for disassembly, while timber inherently minimises embodied carbon [1, 2]. However, whereas modularity facilitates manufacturing, construction, and development, the structural engineering practice supporting it remains largely linear [3]. The current documentation process sees modular buildings as assemblies of individual members rather than considering the structural performance of the modules. This requires repetitive verification, and once the modules are assembled, their performance data are effectively lost and cannot be reused in other projects, even if the modules are the same.

The inability to transfer reliable structural information across similar projects and multiple life cycles is a critical barrier to the circular economy. To resolve this, the paper proposes a hierarchical structural documentation framework that decouples verification

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 468–475, 2026.

from individual projects. By utilizing substructure analysis and code-compliant capacity envelopes, we generate a structural component passport (SCP), including a condensed stiffness matrix and pre-certified safety domains, providing modules with a permanent structural identity, enabling immediate re-integration and re-verification in secondary life cycles or across similar construction projects.

The workflow is validated by a 10 m × 4 m portal frame case study, demonstrating how pre-certified structural data enables seamless component reuse and provides the digital infrastructure required for high-value circular timber construction.

The paper is structured as follows: Sect. 2 introduces the concept, and Sect. 3 describes the methodology as well as the case used for illustration of the workflow. Results and analysis of the case study can be found in Sect. 4, while Sect. 5 provides a discussion of the implications and limitations, and Sect. 6 lists the main conclusions.

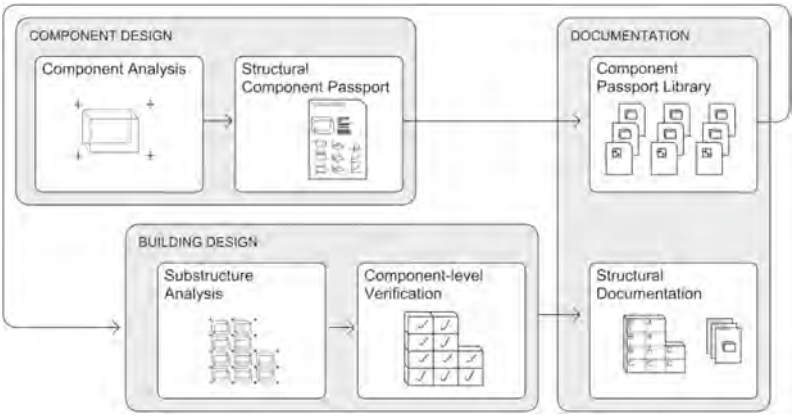

Fig. 1. A hierarchical structural documentation framework, workflow diagram.

2 Background and Concept of the Framework

Today's engineering practice creates a "documentation lock-in" where structural performance data is valid only for a single building context. Once the modules are assembled, their structural identity is lost, making high-value recirculation technically unfeasible due to the absence of verifiable, machine-readable performance data.

The proposed framework aligns structural documentation with the physical hierarchy of modular construction (Fig. 1). By shifting verification from the global assembly to the component level, the workflow decouples a module's structural capacity from its specific project context. This hierarchical approach employs substructure analysis and a code-compliant capacity envelope calculation method. The result is a pre-certified structural unit that carries its performance data as an intrinsic attribute, ensuring seamless integration into diverse architectural designs across multiple lifecycles.

Using substructuring enables the analysis of modular systems in a hierarchical manner, where modelling and the analysis components as discrete subassemblies are straightforward and efficient [4, 5]. Each component type is initially modelled in high fidelity

to provide detailed insight into the stresses. Next, a reduced-order model is extracted by static condensation, keeping selected degrees of freedom to allow coupling to other parts. In this process, it is to be ensured that the reduced stiffness matrix is representative of the macro-level response of the module, contributing to the stiffness of a structure at the global level. Also, the coupling approach and the attachment nodes must be selected such that the internal forces in the component itself will be correctly determined in a back-calculation process at the component level, following a global static analysis of the entire building.

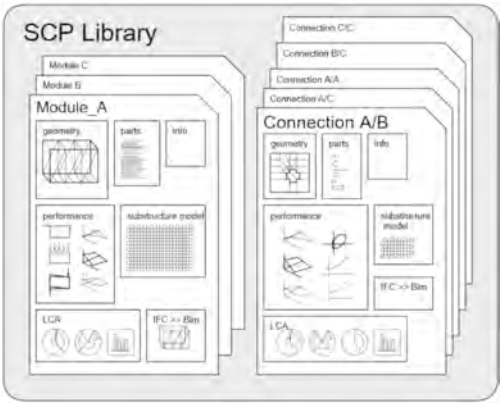

Fig. 2. Conceptual diagram of a structural component passport library.

To maintain compliance with the applicable structural code, we introduce a code-compliant capacity envelope (CCCE) calculation method applicable for spatial or planar subassemblies. The method maps the structural resistance of a component into a multi-dimensional load space [6]. This approach allows the definition of a capacity domain, calculated in accordance with the latest building standards. Therefore, load combinations within the capacity envelope are inherently code-compliant, enabling instantaneous verification of a module's resistance without repeated, project-specific calculations.

Lastly, the SCP documents the module's structural and environmental identity. It stores the condensed stiffness matrix and the code-compliant capacity envelope with essential metadata, including 3D geometry, material specifications, and embodied carbon indicators (Fig. 2). By providing a persistent digital record of structural performance, the SCP ensures that the module remains a verifiable asset throughout its service life and into secondary life cycles.

Building-level documentation follows a component verification protocol. The load distribution and reaction forces are backcalculated from the global static analysis of the building via substructure analysis. The reactions at the interface nodes are then checked against the components' capacity envelope to ensure code compliance.

3 Methodology

We implemented the proposed hierarchical documentation workflow on a single-bay portal frame modelled and partitioned into components to represent a simplified modular structure (Fig. 3). It features a 10-m span and 4-m eave height, utilising glue-laminated timber members (GL30h), with moment-resistant slotted-in steel plate doweled connections and fixed supports, subjected to a horizontal point load. This portal frame is divided into components to illustrate a modular structure. The frame is partitioned into three components by cuts at the connecting steel plate mid. This results in two structural component types: A (column), and B (beam), each including the respective part of the dowelled steel plate connection. The first step in the module's structural documentation is generating the substructure model.

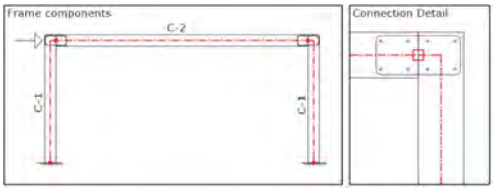

Fig. 3. Shematic design of the structure, components and the connection detail. The attachment nodes are shown with square rectangles.

The components are modelled at high fidelity using solid finite elements. The dowel connections are defined using surface-to-surface penalty-based contacts. The beams are defined with orthotropic linear elastic material behaviour [7, 8]. The finite element analyses were performed in Simulia Abaqus 2025, with Python 3.0 scripting used to automate the generation of geometry, material properties, assembly, boundary conditions, and substructure generation, as well as the global modelling approach. Each substructure is condensed to a few attachment nodes coupled to representative boundary regions of the components via kinematic coupling.

In parallel, to define the limit states of the components, the capacity was calculated as a function of the load space in accordance with EN 1995.1. Section 3, Section 8. Component load space axes are axial load, bending moments, and shear at end nodes. Finally, the SCP is generated by encoding the substructure model, the capacity envelope, and the additional metadata including EPD (Fig. 4).

Once the components' structural documentation is prepared, we proceed with the building-level documentation. A global structure is assembled using the component substructure models, tied together via interface nodes. Based on the reaction forces from the substructure analysis, the components are then checked against their respective CCCE.

The framework's accuracy and efficiency are assessed by comparing it with the typical project-specific linear workflow in accordance with EN 1995-1-1 standards, to a monolithic FEA model. The benchmarking aims to verify that the productised performance data in the SCP remains as reliable as traditional, project-bound engineering reports and that the numerical results are valid.

4 Results and Analysis

The numerical results confirm that the hierarchical documentation framework method maintains sufficient precision. The results show sufficient correlation with the benchmark calculations (Table 1). Differences in global results, such as reaction forces and sway, are negligible. At the component level, general stress values in members match results yielded from internal forces. However, higher values are experienced in stresses parallel to the grain. This is due to a more precise definition of the parts and their connection interactions, which captures stress concentrations at the slots' inner corners and effects of force redistribution and eccentricities in the connections on stress distribution (Fig. 5c, d).

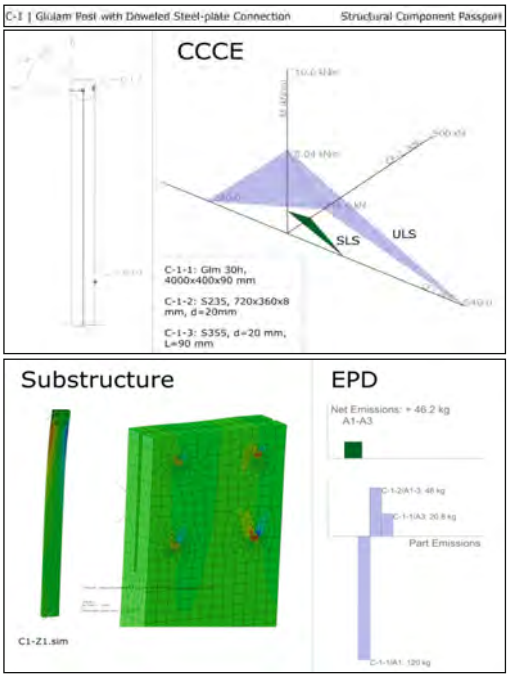

Fig. 4. Structural Components Passport of C-1, including design data, code-compliant capacity envelope, substructure model, and environmental product declaration.

Compared to the monolithic finite element analysis and the substructure analysis, slight deviations can be observed due to component partitioning. Changes in stress distribution can be experienced in the divided steel-plate parts of two adjacent components (Fig. 5a), compared to intact steel-plate parts in the full model (Fig. 5b).

The gains in engineering effort of the hierarchical documentation approach are clear. While the initial effort to prepare the component documentation is higher, building-level documentation becomes more straightforward and quicker. This is thanks to simpler computational modelling of the global model, reduced computation time, and decreased documentation effort.

Table 1. Comparison of the substructure analysis results with the baseline calculations.

	Sway	C-1: S11max	C-1: S11min	C-2: S11max	C-2: S11min	RF-x	RF-z	RM-y
	mm	MPa	MPa	MPa	MPa	kN	kN	kNm
Substructuring	11.3	5.3	−5.68	8.47	−7.93	1.23	5.48	10.84
Baseline	12.2	3.67	−4.02	7.92	−7.82	1.22	5.21	10.62

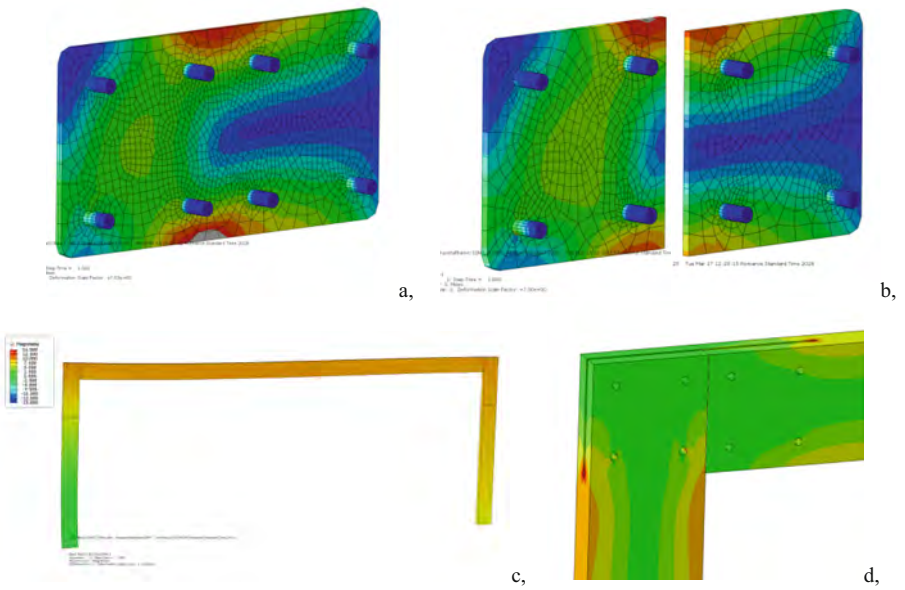

Fig. 5. Mises stress distribution in monolith FE model (a) and of the substructures (b); Displacement of the global structure (c) and extreme stresses at the connection details (d).

5 Discussion

The results demonstrate that hierarchical structural documentation can accurately represent modular structural systems while enabling a simpler and more effective engineering workflow. The combination of reduced-order modelling with capacity envelopes allows the structural behaviour of a module to be described by a concise mechanical summary and a defined performance boundary. This approach partially decouples structural verification from specific building configurations, allowing component-level performance data to be reused across multiple assemblies.

The proposed framework shifts structural verification from repetitive, project-specific analyses to a product-oriented approach in which the structural capacity of

a module is defined once and documented at the component level. Predefined performance boundaries enable modules to be incorporated into multiple structural configurations without necessitating repeated verification, consequently reducing engineering effort and shortening design-to-fabrication workflows. This approach aligns structural engineering with the principles of industrialised construction, as clearly defined product performance requirements allow manufacturers to adjust production parameters, support the use of local or secondary materials and encourage modularisation within the construction supply chain.

The SCP provides a mechanism for preserving structural knowledge over the lifecycle of building components. By storing structural performance data alongside geometric and lifecycle information, it creates a persistent digital record associated with the physical module. This supports later transformation, reuse, and relocation, addressing the loss of structural performance information over time as a key barrier to circular construction [9].

The illustrative case was primarily used to present the SCP and CCCE concepts, rather than to fully validate the method under realistic structural conditions. Further studies are therefore needed for panel-based and volumetric modular systems, including inter-module connections. The simplified case also limits discussion of scalability challenges, such as defining multi-dimensional capacity envelopes for complex components, implementing the framework in system-level analyses, and linking structural data with BIM and LCA workflows through standardised data protocols.

Future work should further investigate the incorporation of nonlinear behaviour and the integration of additional performance domains, such as vibration and building physics. Minor deviations observed in the component-level results, primarily due to partitioning choices and interface coupling, indicate that more complex connection geometries may lead to larger discrepancies, highlighting the need to further develop robust component partitioning strategies and assess their influence on accuracy.

6 Conclusion

This paper presents a hierarchical structural documentation framework for modular timber construction that shifts structural verification from project-specific building assemblies to reusable component-level performance data. The framework addresses a key barrier to circular construction: the loss of structural component information over a building's service life. The workflow combines substructure analysis with code-compliant capacity envelope calculations within a structural component passport (SCP). This enables product-oriented verification, where modules carry their own structural information throughout their lifecycle.

The framework links structural analysis to component documentation, supporting reuse and reconfiguration of timber modules in future buildings. The SCP provides a practical basis for component-based structural verification and supports the safe reuse of structural elements across projects.

Circular Economy Gaps in Environmental Certifications: A Comparative Study of LEED and Selo Casa Azul

João Vitor Battaglin Loureiro(✉), Sérgio Fernando Tavares, and Maria do Carmo Duarte Freitas

Universidade Federal do Paraná, Curitiba, PR, Brazil
joao.battaglin@gmail.com

Abstract. The adoption of circular economy principles in the construction sector has increased the potential of environmental certification systems to promote resource efficiency, waste reduction, and lower life-cycle impacts. This study evaluates how circular economy strategies are incorporated into environmental certification systems by analyzing the latest versions of LEED and Selo Casa Azul + CAIXA. The research combines a literature review with a structured content analysis of certification criteria to assess the alignment with circular strategies, including reuse, recycling, durability, life-cycle extension, and embodied carbon assessment. The results show that LEED exhibits a higher level of integration of circular principles, especially through life-cycle assessment, material transparency, and embodied carbon considerations, although it still faces limitations regarding material reuse and design for disassembly. Conversely, Selo Casa Azul mainly incorporates circular aspects through efficiency-focused criteria, with limited emphasis on closed-loop material strategies. The study concludes that there is an uneven integration of circularity and identifies critical gaps in both systems, such as the reuse of materials and design for disassembly.

Keywords: Circular economy · Environmental certification · LEED · Selo Casa Azul · Resource efficiency

1 Introduction

The construction industry plays a key role in global environmental impacts due to its heavy use of natural resources and the significant production of construction and demolition waste, which accounts for about 30–40% of worldwide solid waste and includes large amounts of recoverable materials [11–17]. These effects have raised concerns about resource depletion, waste management, and greenhouse gas emissions throughout the building's lifecycle. In response, environmental certification systems have become important tools for encouraging more sustainable building practices by incorporating environmental objectives into measurable criteria [4].

Meanwhile, the circular economy (CE) paradigm has gained importance as a systemic approach that aims to separate economic growth from resource depletion. Circular

strategies focus on reducing material use, reusing, recycling, increasing durability, and extending product life cycles, moving away from traditional linear "take–make–dispose" models toward closed material loops and regenerative systems [6–12]. In the built environment, circular economy principles offer a comprehensive framework for managing material flows across all life-cycle stages, from design and construction to operation and end-of-life management [18].

Integrating circular economy principles into environmental certification systems remains uneven. Most certifications still prioritize operational performance, such as energy and water efficiency, while giving limited attention to material flows, adaptability, and life-cycle recovery. This creates a mismatch: certification systems could support circular strategies but often lack clear mechanisms for reuse, design for disassembly, and material traceability [1–18].

This study addresses this gap by critically examining how circular economy principles are incorporated into environmental certification systems, focusing on the latest versions of LEED (Leadership in Energy and Environmental Design) and Selo Casa Azul + CAIXA. LEED is a globally recognized certification framework that increasingly emphasizes life-cycle impacts and embodied carbon. At the same time, Selo Casa Azul represents Brazil's national approach to sustainability in residential construction, particularly within social housing programs. By comparing these systems, the study aims to identify strengths, limitations, and opportunities to align circular economy strategies with certification standards better.

To achieve this, the research combines a literature review with a structured content analysis of certification criteria. As a contribution, the study proposes a framework structured around four dimensions to bridge the gap between current building standards and the Circular Economy (CE) paradigm. This framework shifts the focus from mere operational performance toward regenerative, closed-loop construction practices. The four dimensions are:

1. Design for Circularity: Integrating durability, adaptability, and Design for Deconstruction (DfD) to prevent premature obsolescence and facilitate resource recovery.
2. Material Cycles: Moving beyond basic recycling toward high-value component reuse and material traceability (e.g., through Material Passports) to manage resources across multiple life cycles.
3. Life Cycle Impacts: Establishing Life Cycle Assessment (LCA) and embodied carbon accounting as baseline criteria, ensuring a holistic view of environmental performance.
4. Incentives and Governance: Utilizing certification as a governance tool to create market incentives for circular business models, such as product-as-a- service and urban mining.

2 Circular Economy and Construction

2.1 Principles of the Circular Economy

The circular economy is based on strategies designed to preserve the value of products, materials, and resources for as long as possible while reducing waste. Key approaches include reducing material use, reuse, high-quality recycling, and design strategies that

improve durability, adaptability, and lifespan extension. Unlike traditional linear "take–make–dispose" models, circular systems focus on closed material loops and regenerative thinking, aiming to eliminate waste and pollution during the design phase and keep materials at their highest value across multiple use cycles [8–10].

2.2 Circularity in Construction

In the construction industry, circularity can be applied at various stages, from early design and material choice to construction, building operation, and end-of-life management. Important strategies include modular design, using recycled and reused materials, designing for disassembly, and maintaining material traceability throughout the entire lifecycle [3].

Despite increasing interest from academia and industry, the practical use of circular strategies remains limited. Barriers are typically categorized as technical (e.g., lack of standardized design for disassembly), economic (e.g., higher initial costs), and institutional or regulatory (e.g., fragmented supply chains and limited policy support) [7]. These obstacles hinder the widespread adoption of circular principles in everyday construction practices [12].

Environmental certification systems can assist in addressing these challenges by transforming abstract circular economy concepts into clear, measurable performance standards. However, the effectiveness of current certification schemes in implementing circular strategies varies significantly, revealing inconsistencies in how they manage material flows, adaptability, and long-term value retention within their assessment frameworks [2–13].

3 Environmental Certification Systems: LEED and Selo Casa Azul

3.1 Overview of LEED

LEED is one of the most widely adopted international environmental certification systems, organized into thematic categories such as Materials and Resources, Energy and Atmosphere, and Indoor Environmental Quality. Its recent versions explicitly align with circular economy principles by rethinking how materials are selected, used, and recovered throughout a building's life cycle. LEED v5 enhances its focus on near-zero carbon, resource responsibility, and resilience, broadening the system's scope to address whole-life environmental performance [21] better.

But, in fact, LEED v4.1 already advanced circularity by promoting durable design, maintenance, repair, reuse, remanufacturing, and closed-loop recycling, shifting the built environment away from the traditional linear "take–make–dispose" model. Through its Materials and Resources category, LEED encourages whole-building life- cycle assessment, responsible sourcing, reduction of construction and demolition waste, and material ingredient transparency—mechanisms that help keep materials in circulation at their highest value for as long as possible [20].

3.2 Overview of Selo Casa Azul

Selo Casa Azul is a Brazilian sustainability certification created by Caixa Econômica Federal to encourage improved environmental, social, and economic performance in residential buildings, especially within social housing programs. The system assesses projects across various aspects—including urban quality, architectural design, energy efficiency, water management, and responsible material use—using a structured set of socio-environmental indicators [5]. After 10 years of use, the certification needed updated guidelines to comply with new regulations, include recent innovations in the construction sector, and address changing urban and social conditions. The update aimed to make sustainable construction more appealing to developers and motivate projects with stronger environmental commitments. This led to the launch of the second phase of Selo Casa Azul + CAIXA in 2020, introducing a renewed framework better aligned with modern sustainability challenges [6].

Current versions of Selo Casa Azul emphasize efficient resource use and reduced environmental impact. Still, the integration of circular strategies—such as material reuse, design for disassembly, and closed-loop material flows—remains limited within its guidelines. This gap presents an opportunity to strengthen circularity-focused criteria and better support Brazil's shift toward regenerative construction practices.

4 Methodology

This study uses a qualitative research design that combines a literature review with a content analysis of environmental certification systems. The research was carried out to identify circular economy strategies relevant to the construction industry, based on peer-reviewed journal articles, conference proceedings, and institutional publications. Previous research consistently highlights strategies such as reuse, recycling, durability, design for adaptability, life-cycle extension, and embodied carbon reduction as key elements of circularity in the built environment [9–16]. Based on these findings, a unified set of circular strategies was developed to serve as the analytical framework.

Subsequently, the most recent versions of LEED and Selo Casa Azul were examined through structured content analysis. Certification credits, prerequisites, and performance requirements were systematically reviewed and mapped against the circular strategies identified in the literature review. This mapping enabled an assessment of the degree of alignment between each certification system and key circular economy principles, highlighting convergences, gaps, and opportunities for further integration [19].

5 Results

5.1 Integration of Circular Strategies in LEED

The analysis indicates that LEED shows a progressively stronger alignment with circular economy principles, especially in its most recent update, LEED v5. The system places increasing emphasis on whole-life carbon assessment, material circularity, and supply-chain transparency, reflecting a broader shift in global sustainability standards.

LEED v5 advances circularity by requiring project teams to evaluate embodied and operational carbon across the full building life cycle, positioning life cycle assessment (LCA) as a baseline expectation for certification. Credits related to material transparency, such as Environmental Product Declarations (EPDs), and incentives for low-carbon procurement further reinforce material awareness and responsible sourcing. Despite these advances, gaps remain, particularly regarding incentives for material reuse, design for disassembly, and multi-cycle material traceability. While LEED v5 introduces stronger requirements for carbon-aware material selection, it still offers limited mechanisms to ensure that materials can be recovered and reintegrated into future value cycles—an essential dimension of circularity.

By embedding these evolving requirements into a globally recognized certification framework, LEED serves as a practical driver of the adoption of the circular economy in the construction sector. Its structured credit system translates systemic circularity principles—such as resource loops, long-term value retention, and reduced material extraction—into measurable, project-level actions that can be implemented across diverse building contexts.

5.2 Integration of Circular Strategies in Selo Casa Azul

The analysis shows that Selo Casa Azul + CAIXA, the latest version, incorporates sustainability criteria that partially intersect with circular economy principles, though in a more limited and less explicit manner than international systems. The certification emphasizes responsible material use, water efficiency, urban integration, and social value, reflecting priorities specific to the Brazilian housing context [6]. Some criteria indirectly support circularity—such as waste reduction during construction, durability-oriented design choices, and incentives for efficient resource management. However, strategies central to circular economy frameworks, including material reuse, design for disassembly, and multi-cycle material traceability, remain underdeveloped or absent. The update expanded the system's scope to incorporate new regulatory and technological advances, yet its operationalization of circularity continues to prioritize efficiency over closing material loops. As a result, Selo Casa Azul contributes to sustainability in housing but still offers limited mechanisms for enabling circular material flows across the building life cycle.

6 Discussion

A cross-analysis of both certification systems uncovers different levels of alignment with circular economy strategies. LEED shows a more advanced and clear integration of circularity, especially through credits related to life cycle assessment, embodied carbon reduction, material transparency, and product disclosure. These aspects directly align with circular strategies found in the literature, allowing LEED to implement concepts such as long-term value retention and reduced material extraction. Although gaps remain—particularly in reuse and design for disassembly—LEED offers a structured way to bring circular practices into mainstream building projects.

In contrast, Selo Casa Azul adopts a broader sustainability framework but is less focused on circular material flows. Its criteria prioritize efficiency, social value, and responsible resource use but provide fewer incentives for strategies such as reuse, adaptability, or closed-loop material cycles. This difference reflects contextual priorities: while LEED responds to global decarbonization and transparency efforts, Selo Casa Azul tackles national housing challenges, affordability, and regulatory constraints. As a result, LEED more closely aligns with circular economy principles, while Selo Casa Azul offers opportunities for future improvement, especially in incorporating material circularity and lifecycle thinking into its criteria.

6.1 Expanding the Contribution: The Four Dimensions of Alignment

The comparative analysis reveals that while certification systems have evolved, they still lack explicit pathways for closing material loops. The framework proposed in this study addresses these gaps through four strategic dimensions:

Dimension 1: Design for Circularity. Current systems often prioritize the operational stage, yet circularity requires buildings to be designed as independent layers. By rewarding Design for Deconstruction (DfD) and adaptability, certifications can ensure that components are easily maintained or replaced without entire structure demolition, addressing the limitation found in both LEED and Selo Casa Azul regarding multi- cycle reuse.

Dimension 2: Material Cycles. A critical gap is the lack of material traceability. This study suggests integrating Material Passports into the criteria to verify the quality and history of secondary materials, thereby building market trust and facilitating reverse logistics.

Dimension 3: Life Cycle Impacts. The study demonstrates that embodied carbon is frequently overshadowed by energy efficiency. The proposed framework advocates for whole-building LCA as a mandatory pillar, allowing for a fair comparison between carbon-intensive monolithic structures and low-impact, flexible, demountable designs. Dimension 4: Incentives and Governance. To overcome economic barriers, certifications must act as systemic enablers. This dimension proposes specific weighting systems that favor ‘circular premiums’—awarding extra points for the use of materials from urban mines or the adoption of circular business models that redefine product ownership.

7 Conclusions

The study used a qualitative research approach that combined a literature review with content analysis of certification systems to evaluate how circular economy principles are integrated into building sustainability. The research helped identify key circular strategies relevant to the construction industry—such as reuse, recycling, durability, adaptability, life-cycle extension, and embodied carbon reduction—which were then combined into an analytical framework to assess certification criteria.

Applying this framework to the latest versions of LEED and Selo Casa Azul revealed clear levels of alignment with circularity. LEED shows increasingly strong integration

of circular economy principles, especially through credits focused on life cycle assessment, material transparency, and embodied carbon reduction. These elements indicate a shift toward whole-life performance and supply-chain accountability, turning systemic circularity ideas into measurable project actions. However, gaps still exist in areas like material reuse, design for disassembly, and multi-cycle material traceability, which are crucial for closing material loops.

The Selo Casa Azul, in contrast, incorporates sustainability criteria that intersect with circularity mainly through efficiency-focused strategies such as waste reduction, durability, and responsible material use. The update broadened its scope to reflect new regulatory and technological contexts, but the certification still offers limited mechanisms for enabling circular material flows. Its focus remains on social housing priorities, resource efficiency, and contextualized sustainability outcomes rather than on explicit circular-economy pathways.

The comparative analysis shows that LEED aligns more fully with circular strategies identified in the literature. In contrast, Selo Casa Azul offers opportunities for future improvement, especially in incorporating life-cycle thinking, material recovery, and design for adaptability. These findings highlight the need for certification systems to go beyond efficiency-based approaches and adopt strategies that support regenerative, closed-loop construction practices.

celialeoudi@gmail.com

Abstract. Think-Inside-the-Box is a modular, box-in-box construction system incorporating reversible design, dry connections and the integration of bio-based and waste-derived materials. The project develops a construction logic where each timber frame functions simultaneously as a transport container and a building element. All components required for one structural grid are delivered in 3.7 m^3 kit −1.4 t- which unfolds on site into structure, insulation and cladding. This consolidation reduces packaging waste and delivery trips by ~80%, enabling up to 17 kits per standard truck (6 × 10 m building unit = 12 kits). Materials are merged into a single truckload, replacing ~6 conventional deliveries and reducing transport-related emissions by ~60% (freight factor: 139 g CO_2e/t-km). The system combines reclaimed laminated timber frames with CNC-cut OSB puzzle panels and mycelium insulation blocks, supplemented by reused egg cartons enclosing cotton for enhanced acoustic performance. Heat-pressed mycelium and spent coffee-ground composite tiles are used for finishing. Bio-grown mycelium offers CO_2-negative potential, fire resistance and low thermal conductivity (~0.05 W/mK), while coffee composites valorise a waste stream at optimal stability. Assembly relies on interlocking joints and wedges, facilitating full disassembly. Material and process development (mould and recipes) and a full-scale mock-up validated assembly logic and revealed tolerance and mould-performance limits, informing revisions. The system targets scalable single-storey buildings, demonstrated via a 60 m^2 office case study. Regulatory feasibility requires further testing for fire, structural performance and weathering. By integrating all building elements into a kit-of-parts, Think-Inside-the-Box transcends material substitution to achieve system-level reuse, simultaneously reducing waste, transport impacts and assembly complexity.

1 Introduction

The construction sector faces a dual challenge: reducing embodied environmental impacts and minimising End-of-Life (EoL) waste. This challenge is increasingly addressed through circular economy policies aimed at reducing virgin material consumption and waste generation. In the Netherlands, this agenda is articulated in *A Circular*

Economy in the Netherlands by 2050 [1], while at the EU level the *European Green Deal* identifies circularity as central to achieving climate neutrality by 2050 [2]. EU waste policy further supports this transition by setting re-use and recycling targets, including 65% municipal waste recycling by 2035 [3]. Together, these frameworks position circular material use, design for reversibility and waste prevention as key strategies for the built environment. Modular and prefabricated construction offer significant potential to improve material efficiency, reduce waste and shorten construction time. Advances in digital design and CNC-based fabrication enable the precise manufacture of components and interlocking geometries for dry assembly [4]. In parallel, circular construction increasingly integrates reclaimed, bio-based and waste-derived materials, including reclaimed timber, mycelium-based composites (MBCs) for insulation and spent coffee grounds (SCG) as a valorised food-waste resource for building applications [5, 6].

Despite these advances, circularity in modular construction is still constrained by irreversible joints, complex assemblies, extensive packaging and fragmented logistics, which limit disassembly, recovery and transport efficiency. In response, the Think-Inside-the-Box concept proposes a circular box-in-box construction approach that integrates dry connections, reclaimed timber, bio-based and waste-derived materials within a transport-efficient kit-of-parts. Each building element functions both as a transport container and a permanent architectural component, embedding the shipping box within the building system and reducing construction waste. Based on a demountable timber frame, CNC-cut puzzle panels, modular insulation units and cladding, the approach enables efficient on-site assembly, disassembly and reconfiguration. The paper's main contribution is a logistics consolidation strategy linking reversible timber framing with experimental material streams: MBCs for insulation and interior tiles and SCG composites for exterior finishes. A design methodology is demonstrated through a scalable single-storey office case study and evaluated initial thermal and transport performance, assembly processes and material behaviour via a full-scale prototype.

2 Methodology

2.1 Design Approach

Criteria. The system is structured around four interrelated criteria, each associated with measurable performance indicators. *Logistics consolidation* serves as the primary design driver, reducing multiple shipments to one combined delivery to minimise transport and packaging waste. *Reversibility* is defined as a dry, mechanical assembly using wedges and interlocking joints, wherever feasible. *Standardisation* is achieved by repeated grid kits, supporting interchangeability and scalable layouts. *Material circularity* prioritises reclaimed timber for the primary structure and incorporates bio-based and waste-derived materials in replaceable subcomponents.

Waste Streams and Bio-Based Materials. Waste streams vary across sectors creating opportunities for integration into closed-loop material systems. The agri-food sector is promising because its by-products are bio-based, generated consistently and, depending on processing, can remain compatible with organic EoL routes such as biodegradation.

Upcycling low-value residues into high-performance applications can extend material service life and improve overall resource efficiency.

MBCs provide a sustainable alternative to conventional fossil-based insulation materials such as polyurethane and polystyrene [9]. These composites are produced by inoculating agricultural by-products such as hemp, flax and straw, typically with white-rot fungi. This low-energy bio fabrication process forms lightweight, biodegradable materials, offering high fire performance, depending on formulation [7]. MBCs typically exhibit densities of 60–180 kg/m^3 and thermal conductivities of 0.04–0.06 W/mK, making them suitable for insulation. The mechanical performance of MBCs is strongly influenced by substrate processing, with fibre size compaction generally leading to higher density and improved mechanical strength [9]. Prospective life cycle assessment (LCA) studies typically assume a 30-year reference service life for mycelium insulation, rather than reporting an empirically validated lifespan for these composites. EoL scenarios include sequential reuse and potential reintegration as substrate in new composite production [8].

SCG, the solid residue of brewing, account for about 6×10^6 t annually worldwide [6]. Composed mainly of lignocellulosic matter with residual oils and proteins, SCG can be dried, milled and sieved into a filler for composites [9]. Mechanical performance depends on particle size and content: particles $\leq$125 μm and a filler loading of 45 wt% yielded the best strength and rigidity. Hot pressing (~150 °C, ~6 MPa, ~15 min) enables stable and repeatable panel production suitable for façade applications [9].

Geometric Analysis. The system is demonstrated through a single-storey 6 × 10 m office prototype, organised through the repetition of modular structural grids (0.80 × 6.00 m) (Fig. 1). The primary load-bearing structure consists of laminated OSB columns and beams (300 × 50 mm) assembled through a dry connection system and wedges. Precise fit and repeatability are achieved through CNC-cut interlocking geometries, which also support self-alignment during assembly. Lateral stability is supported by the shelf elements, which act as secondary structural diaphragms within each grid. Their wedged, interlocking connections provide in-plane stiffness, enabling shear redistribution through the shelf-column assembly. This connection logic is extended beyond the primary frame; the enclosure layers are likewise conceived as removable subcomponents, reinforcing reversibility at both structural and architectural scales. The building is supported by a gabion foundation (400 × 600 mm) filled with rubble, raising the floor ~580 mm above ground level to improve moisture protection while maintaining reversible interface with the ground.

As shown in Fig. 1, the façade and roof adopt a layered envelope strategy, incorporating 150 mm mycelium insulation blocks, followed by 20 mm CNC-cut OSB puzzle panels as the primary enclosure layer. The external finish is formed by 10 mm SCG composite tiles mounted on 20 × 50 mm timber battens, creating a ventilated and replaceable outer skin. The floor assembly combines structural timber framing with 70 mm mycelium insulation blocks and cotton-filled reused egg cartons as porous acoustic infill for vibrations, impact-sound and cavity-resonance control. The walking surface is formed by 12 mm heat-pressed mycelium tiles installed over 20 mm underlayment layers. To enable scalable production of the bio-based components, the mycelium elements are fabricated

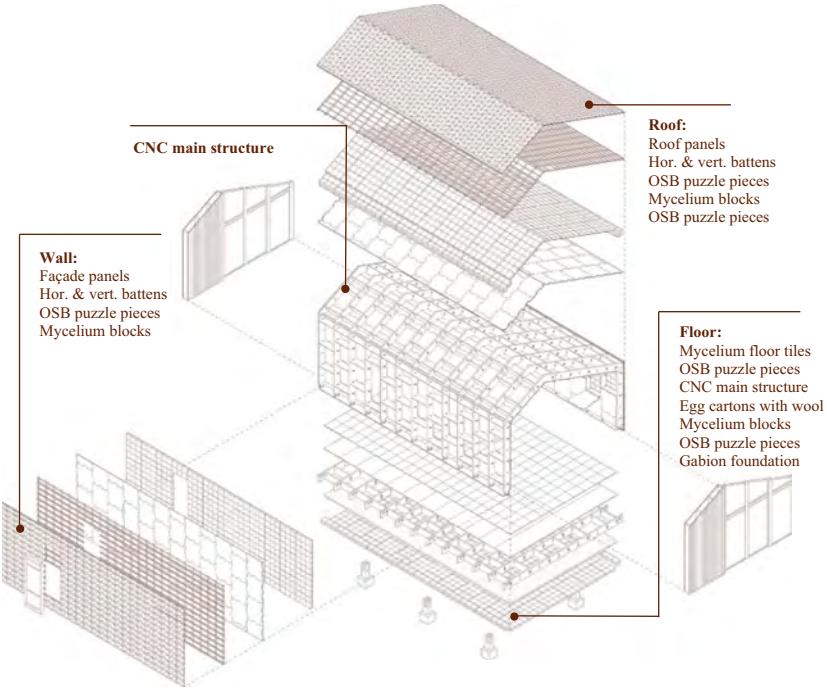

Fig. 1. Exploded axonometric analysis of the 60 m^2 building unit.

using three mould types: (i) heat-pressed floor tiles, (ii) floor insulation blocks and (iii) adjustable wall-block mould, generating a stacked interlocking geometry (Fig. 2).

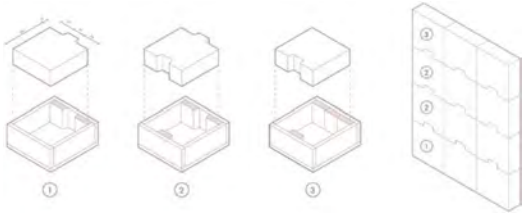

Fig. 2. Adjustable wall-block mould and configuration of mould elements.

Performance Analysis. The system applies circular design principles across materials, design and manufacturing, with logistics consolidation as the primary performance strategy. It was evaluated by comparing conventional multi-supplier delivery to a consolidated kit-of-parts system for a functionally equivalent 60 m^2 single-storey unit, defined by comparable floor area, structural stability and envelope thermal performance (targeted Rc $\approx$ 3.5–6.0 m^2K/W). In the baseline scenario, each material stream is assumed to travel 100 km/trip; transport work was calculated as Σ (mass $\times$ distance) and emissions

were derived using the STREAM (2020) factor (139 g CO_2e/t-km). Impacts from material production, construction equipment, operational energy, maintenance, replacement cycles and End-of-Life (EoL) processing are excluded. The kit-based model reduces deliveries by ~80%, transport emissions by ~60% and saves 0.512 t CO_2e per building unit (Table 1).

Table 1. Comparison table of transportation parameters.

Parameter	Conventional baseline	Kit-based model
Delivery structure	Six separate shipments due to supplier specialisation and material incompatibility	One consolidated truckload
Shipment breakdown	(i) Concrete & framing 24 t; (ii) Hardware 0.5 t; (iii) Cladding 18 t; (iv) Insulation 4 t	12 kits × 1.4 t each
Total transported mass	46.5 t	16.8 t
Total transport work	4650 t-km	1680 t-km
Transport emissions	0.646 t CO_2e	0.234 t CO_2e

Packaging is integrated into the structural container, eliminating supplier-specific pallets and protective wrapping and thus reducing packaging waste (Fig. 3).

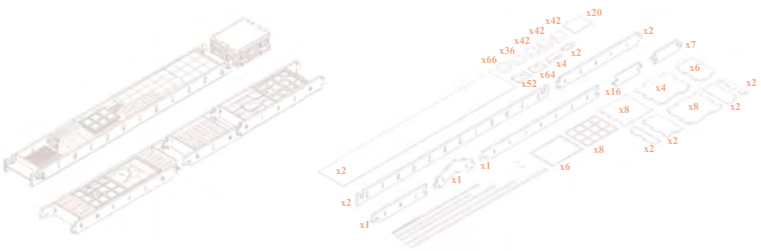

Fig. 3. One kit, where the building elements are designed to convert into a shipping box.

At the material level, thermal performance was evaluated through a steady-state 1D Rc calculation based on the wall build-up (ISO 6946 approach). Thermal conductivities (λ) were adopted from datasheets. The external cladding (coffee tiles, profiles, battens) was treated as a rainscreen zone and excluded from the insulating build-up, while the 210 mm void was modelled as an air cavity under two boundary conditions (airtight vs. intermittently open shelf use). The wall achieves an estimated Rc of ~3.5 m^2K/W, depending on the assumed λ values and cavity conditions.

2.2 Experimental Approach

A full-scale mock-up was fabricated to validate assembly tolerances and interface behaviour of the "box-in-box" kit-of-parts -primary frame, CNC puzzle panels, mycelium infill and pressed mycelium finishes- under dry-fit conditions (Fig. 4).

Fig. 4. (left) full-scale mock-up design; (right) pictures of realised mock-up.

Mycelium insulation blocks were produced using inoculum supplied by ECO Consult (Bleiswijk) and grown on wood shavings. Reusable styrofoam moulds were wrapped with plastic cling wrap and covered after filling to limit moisture loss and maintain a closed microclimate during incubation. Growth time in mould was 4 days, while post-growth deactivation was conducted in a domestic convection oven using an isothermal hold at 180 °C/60 min, followed by a staged cool-down to 160 °C and 140 °C with 20 min holds each. Mycelium floor tiles were manufactured via heat pressing, with a 600 × 600 mm press bed. Two mould frames were tested in plywood and OSB. A heat-resistant baking sheet was used as a release layer. Three heating cycles were tested at a nominal pressure of 0.5 bar with controlled temperature: 50 °C/5 min, 180 °C/35 min and 200 °C/35 min. The structural mock-up used reclaimed 18 mm wood panels laminated into members by bolting three layers to reach desired thickness; joints were marked and cut as a single member. The column-beam dowel geometry was cut manually to test fit sensitivity, while puzzle panels were CNC-milled to evaluate fit accuracy and assembly speed.

3 Results and Discussion

The full-scale mock-up highlighted main issues in hot pressing of mycelium, tolerance control in dry joints and façade substructure buildability. For the mycelium floor tiles, process stability depended on mould stiffness and thermal exposure. The plywood mould frame deformed under heat and it was replaced by an OSB mould. Heating cycle governed consolidation: 50 °C/5 min yielded insufficient bonding, 180 °C/35 min produced a structurally stable tile and 200 °C/35 min maintained stability but produced a darker surface, consistent with higher thermal exposure. For the primary structure, tolerance accumulation became evident at the dry joints. The manually cut column-beam dowel geometry introduced fit variability, demonstrating that demountable assembly requires either jig-guided machining or redesigned joints with explicit tolerance allowances. Cladding substructure exposed a detailing gap: the initial design did not provide a robust fastening zone between battens/rails and the supporting layer, leading to on-site modification of geometry and fixing logic to achieve practical installation (Fig. 5).

Fig. 5. (left) Process of mycelium tile development; (right) Redesign of batten substructure.

Overall, at the current stage, the timber frame, CNC-milled OSB panels and dry-fit assembly logic can be considered prototype-ready, whereas the mycelium insulation and tiles and SCG composite cladding remain experimental. Their circular applicability depends on achieving sufficient durability and service life without protective coatings or additives that compromise bio-based content or EoL pathways.

4 Conclusions

Think-Inside-the-Box presents a circular box-in-box construction system in which each structural module serves both as a transport container and as a building frame, enabling dry assembly. The system is characterised by rapid deployment, reconfiguration and transport consolidation, yet at the current stage of development, its implementation remains limited by the tolerance requirements of dry joints and the certification readiness of bio-composites. In the demonstrated logistics scenario, one single-storey 60 m^2 building unit is delivered as 12 kits in one trip, resulting in reduced packaging, approximately 80% fewer delivery trips and an estimated 60% reduction in transport-related emissions.

Feasibility was examined through a prototype-driven methodology combining material selection, digital fabrication and full-scale iteration. The full-scale mock-up integrated reclaimed timber, CNC-milled puzzle panels, mycelium insulation and heat-pressed floor tiles. SCGs were identified in the literature as a potentially suitable local waste-stream feedstock for cladding composites but were not experimentally implemented due to equipment limitations within the project timeframe. Prototype testing informed design revisions: tile consolidation was achieved at 0.5 bar, 200 °C/35 min; mould tooling was changed from plywood to OSB due to thermal deformation; manual cutting of the column-beam dowel joint resulted in tolerance drift, indicating the need for CNC machining and defined clearances; and the hanging interface was redesigned to provide a clearer fastening zone. The study therefore demonstrates the technical feasibility of a logistics-integrated modular kit-of-parts based on reclaimed timber, CNC-milled OSB panels and MBCs.

Future work should focus on generating certification and benchmark-ready evidence through expanded performance testing and regulatory alignment, including reaction-to-fire classification (EN 13501-1), durability and moisture testing and structural compliance of timber elements and connections. Circularity should be assessed under ISO 20887, while environmental evaluation should be extended from transport logistics to a whole-system LCA, including virgin material production and transportation, durability, maintenance, replacement cycles and EoL scenarios.

Acknowledgements. This paper presents selected outcomes from *"Think Inside the Box: A Circular Construction System"*, developed in the Circular Product Design elective course at TU Delft. The authors thank Dr.ir. Olga Ioannou and Jan Jongert for their guidance and feedback and Mia Barnard for advice on mycelium cultivation. Prototyping was supported by The Green Village (TU Delft) and the ROC carpentry team, who also provided reclaimed wood, cutting assistance and expertise on timber connections.

Selective Deconstruction Versus Business-as-Usual Demolition: An LCA-Based Assessment of CDW Management Scenarios

Jan Pešta(✉), Barbora Vlasatá, and Tereza Pavlů

Czech Technical University in Prague - University Centre for Energy Efficient Buildings, Třinecká 1024, 273 43 Bustěhrad, Czech Republic
jan.pesta@cvut.cz

Abstract. Pre-demolition audits represent a key instrument for enabling selective deconstruction and improving the environmental performance of construction and demolition waste (CDW) management. This paper presents a life cycle assessment (LCA)–based case study in which a pre-demolition audit and the subsequent real deconstruction of a administrative building were used to systematically map and evaluate alternative CDW management scenarios. The study compares a real deconstruction scenario, implemented on the basis of a detailed pre-demolition audit, with a conventional business-as-usual (BAU) scenario reflecting standard demolition and waste treatment practices. The system boundary covers demolition-related life cycle modules C2–C4 and benefits beyond the system boundary (module D), including transport, processing, disposal, and recycling benefits, in accordance with EN 15804 + A2. Modelling was performed in SimaPro software using the ecoinvent 3.7 database. The results show that the real scenario based on selective deconstruction achieved substantially higher environmental benefits than the BAU scenario. Overall, the selective approach resulted in a net saving of 872 t CO_2 equivalent, corresponding to approximately 15% higher climate benefits compared to conventional demolition practices. Transport impacts were found to be relatively low, while the most significant environmental benefits originated from recycling of aluminium, steel, and glass. Concrete recycling also contributed to climate benefits, particularly when highquality recycling routes were applied. The case study demonstrates how predemolition audits can serve as a robust data source for scenario-based LCA of CDW management and for identifying environmentally preferable waste treatment pathways.

Keywords: LCA · CDW · waste management · predemolition audit · selective deconstruction

1 Introduction

The construction sector is a major contributor to resource consumption, greenhouse gas emissions, and waste generation. Construction and demolition waste (CDW) accounts for approximately 25–30% of total waste in the European Union, making its effective management essential for achieving circular economy objectives [1].

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 493–500, 2026.
https://doi.org/10.1007/978-3-032-34930-9_58

Selective deconstruction has emerged as a key strategy to improve CDW management by enabling better separation of materials and increasing recycling and reuse rates compared to conventional demolition [2]. An important supporting tool is the pre-demolition audit, which provides a structured inventory of materials and facilitates the identification of appropriate waste treatment pathways [3].

However, current predemolition auditing is focused on ambitions framed with recovery rates, which describe only impact on availability of materials and do not assess other environmental impacts.

Life cycle assessment (LCA) is widely used to evaluate environmental impacts of buildings, including end-of-life stages [4]. Previous studies have shown that improved CDW management can significantly reduce impacts, particularly global warming potential (GWP) [5]. However, results are often based on simplified assumptions, highlighting the need for studies using real project data [6].

This paper presents a case study of a residential building demolition where a pre-demolition audit informed selective deconstruction. An LCA-based approach is used to compare a real scenario with a conventional business-as-usual (BAU) scenario. The aim is to quantify environmental impacts and demonstrate the potential of selective deconstruction to improve CDW management and reduce environmental burdens.

2 Methodology

2.1 General Approach and LCA Framework

The methodological approach is based on linking quantified material flows with corresponding environmental datasets in order to calculate the resulting environmental impacts. The life cycle assessment (LCA) was performed in accordance with relevant standards for construction products and building assessment, particularly EN 15804 + A2, ensuring consistency in system boundaries, impact categories, and reporting structure. Material quantities were derived from project documentation provided by the client, with a key input being a detailed bill of materials delivered in a spreadsheet format. This inventory formed the basis for the life cycle inventory (LCI), where individual material flows were systematically matched with environmental datasets within the SimaPro software environment. The software integrates both specific Environmental Product Declaration (EPD) datasets and generic datasets, primarily from the ecoinvent database (version 3.7), enabling a consistent and transparent modelling approach.

The calculation principle consists of assigning each material flow to an appropriate dataset representing its treatment process (e.g., recycling, disposal) and associated transport. The resulting environmental impacts are then aggregated across all materials and processes to quantify the overall environmental performance of the assessed scenarios.

2.2 System Boundaries and Life Cycle Modules

The system boundaries of the study focus on end-of-life stages of the building, specifically modules C2–C4 and module D, in accordance with EN 15804 + A2. The following life cycle stages were included:

- C2 – Transport: transport of demolition materials from the site to processing or disposal facilities, including distances specific to each material stream,
- C3 – Waste processing: operations related to sorting, treatment, and recycling of materials,
- C4 – Disposal: final disposal processes such as landfilling or energy recovery,
- Module D – Benefits and loads beyond the system boundary: potential environmental benefits and impacts associated with material recovery, recycling, and substitution of primary materials.

Processes related to on-site activities, including dismantling, selective deconstruction, and handling at the demolition site (module C1), were excluded from the system boundary. This exclusion reflects the focus of the study on downstream waste management processes and ensures comparability between the assessed scenarios.

2.3 Life Cycle Inventory and Data Sources

The life cycle inventory (LCI) was based on a detailed overview of material flows obtained from the demolition project. The inventory data were provided by a designated contact person responsible for material flow documentation and were considered representative of the real deconstruction process.

Environmental datasets used in the modelling were sourced primarily from the ecoinvent 3.7 database. The selection of datasets followed a hierarchy prioritizing geographical and technological representativeness. Whenever possible, datasets reflecting Central European or specifically Czech market conditions were used.

2.4 Modelling of Recycling and Substitution Effects

Potential environmental benefits associated with material recovery were modelled using the substitution approach in module D. Recycled materials were assumed to substitute equivalent products made from primary raw materials, thereby avoiding the environmental impacts associated with primary production.

The modelling of substitution effects was material-specific and reflected realistic recycling pathways. High-value recycling (e.g., metals and glass) was assumed to result in substitution of primary materials with similar functional properties. In contrast, lower-quality recycling processes (downcycling), such as the use of recycled concrete for backfilling applications, were modelled with reduced substitution benefits, reflecting their limited ability to replace primary materials in high-performance applications.

2.5 Description of the Assessed System

The analysed system represents the actual management of materials and products resulting from the demolition of a residential building located in the Holešovice district (Prague). The system includes all processes related to the transport, treatment, recycling, and disposal of demolition waste, as well as the associated environmental benefits from material recovery.

2.6 Definition of Scenarios

Two scenarios were defined and compared:

- Real scenario (selective deconstruction): based on actual demolition practices informed by a pre-demolition audit, with an emphasis on material separation and high-quality recycling,
- Conventional scenario (business-as-usual, BAU): representing standard demolition and waste management practices, defined based on expert assumptions and common industry practice.

The key differences between the scenarios lie in the level of material separation and the resulting waste treatment pathways. In the conventional scenario, lower levels of sorting and recycling efficiency are assumed.

For example, in the case of concrete, the conventional scenario assumes its use as recycled aggregate primarily for backfilling applications. This represents a typical down-cycling pathway, where the material does not substitute natural aggregate in structural concrete. In contrast, the real scenario includes higher-quality recycling routes, enabling greater substitution of primary materials and thus higher environmental benefits.

The definition of the conventional scenario is based on the authors' experience and reflects typical practices observed in the construction and demolition sector. This approach allows for a meaningful comparison between current standard practices and improved waste management strategies enabled by pre-demolition audits.

3 Results and Discussion

3.1 Results by Demolition Phases

To evaluate the effectiveness of the applied selective deconstruction approach, a conventional (business-as-usual, BAU) scenario was developed as a benchmark representing typical material management practices. This scenario, defined based on expert assumptions and common industry practice, enables a direct comparison with the real deconstruction scenario derived from the pre-demolition audit.

When comparing the two scenarios using the global warming potential (GWP) indicator, the conventional scenario shows approximately 15% lower environmental benefits than the real scenario. In other words, the selective deconstruction approach achieves a significantly higher reduction in greenhouse gas emissions, confirming its environmental advantage over standard demolition practices.

For a more detailed interpretation of the results, the demolition process was divided into three phases:

- Demolition phase 1: removal of interior materials,
- Demolition phase 2: removal of structural components,
- Demolition phase 3: removal of exterior building elements.

The comparison of scenarios across these phases reveals that the most significant differences occur in demolition phase 1, which includes interior materials. This phase is particularly sensitive to the level of material separation and the choice of waste treatment pathways.

3.2 Interpretation of GWP Results

The aggregated GWP results by demolition phase (Fig. 1) illustrate the contribution of each phase to the overall environmental performance of both scenarios.

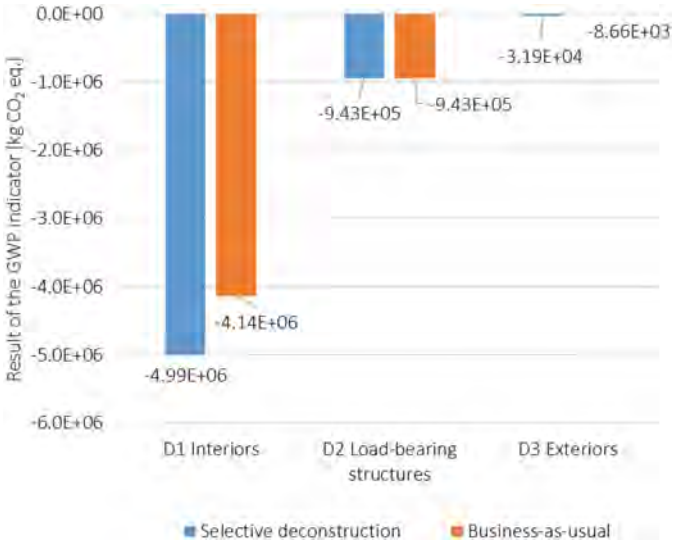

Fig. 1. The aggregated GWP results by demolition phase, comparing two scenarios.

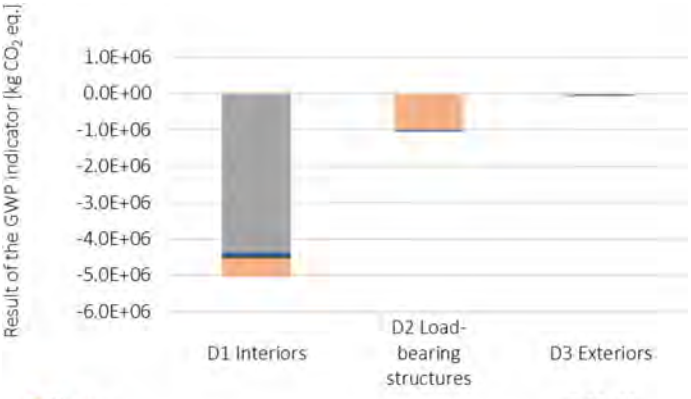
The figure clearly shows that:

- demolition phase 1 is the main driver of differences between the scenarios,
- demolition phase 2 contributes substantially to total impacts due to the large volume of materials, but with relatively small differences between scenarios,
- demolition phase 3 plays a secondary but still relevant role.

Overall, the results confirm that selective deconstruction, supported by a pre-demolition audit, enables more efficient material recovery and leads to improved environmental outcomes, particularly in material streams where multiple treatment options exist.



The findings also indicate that the greatest potential for improvement lies in optimizing the handling of interior materials and increasing the share of high-quality recycling and reuse pathways.

3.3 Results of Module D

Potential environmental benefits associated with recycling and reuse were modelled using a substitution approach, where secondary materials replace equivalent products made from primary raw resources. The results for individual material streams, disaggregated by demolition phases, are presented in Fig. 2.

The most significant environmental benefit was associated with aluminium recycling, modelled as a substitution of primary aluminium ingot production. This result is primarily driven by the high energy intensity and corresponding emissions of primary aluminium production processes. Consequently, even relatively small quantities of recovered aluminium lead to substantial avoided impacts in terms of GWP. It should be noted, however, that the choice of datasets and environmental data can strongly influence the overall results and conclusions of the study. In this case, datasets were selected with regard to geographical relevance and the comparability between the recycled material and the substituted product. A similar effect was observed for steel, which represents another major contributor to environmental benefits. Due to the high energy demand of primary steel production, recycling of steel elements from both interior components and structural systems results in considerable avoided emissions.

Further notable environmental benefits were identified for materials such as glass wool, flat glass, and gypsum-based products (e.g., plasterboard). Although their individual contributions are lower compared to metals, their cumulative effect is significant due

Fig. 2. Potential benefits of material recovery calculated in module D, aggregated GWP results by demolition phase, real case scenario.

to their presence across multiple demolition phases. In addition, despite relatively small quantities, electrical and electronic waste (WEEE) showed a favourable environmental impact, highlighting the importance of proper collection and recycling of these material streams.

The results also indicate that not all material flows lead to positive outcomes in module D. In the case of expanded polystyrene (EPS), the benefits were modelled based on energy recovery. Although this process provides some substitution benefits through energy generation, the overall impact remains negative in terms of GWP due to emissions associated with incineration.

Overall, the results of module D confirm that the environmental performance of CDW management is strongly influenced by the quality of recycling pathways and the substitution potential of individual materials.

Although the study is based on a single case study, the results are considered relevant for a broader range of buildings where conventional demolition still dominates CDW management. Buildings with higher shares of metals or reusable components are likely to achieve even greater benefits from selective deconstruction, while mineral-based structures may show smaller relative improvements. An important advantage of selective deconstruction is also the prevention of material contamination during demolition. For example, cleaner separation of concrete fractions enables their use in higher-value recycling applications instead of low-grade backfilling, thereby increasing their substitution potential and associated environmental benefits.

4 Conclusion

The LCA study of the demolition of the administrative building demonstrated the significant role of selective deconstruction and environmentally responsible waste management in reducing the carbon footprint of demolition activities. The analysis confirmed that the real scenario, based on selective material separation, recycling, and reuse, achieves approximately 15% greater climate benefits (in terms of GWP reduction) compared to the conventional scenario, which assumes a higher share of landfilling and less efficient material recovery. The most substantial environmental benefits were associated with the recycling of materials with high embodied emissions, particularly aluminium, steel, and glass. In contrast, concrete, due to its large volume, was identified as a major contributor to total emissions, despite relatively similar treatment pathways in both scenarios. This highlights the importance of improving recycling quality and utilization pathways for mineral materials.

Overall, the findings confirm that environmentally conscious demolition practices can significantly improve the environmental performance of CDW management and support the transition towards more circular construction practices. Future research should focus on integrating module C1 impacts into comparative assessments, evaluating multiple building typologies and regional contexts, and improving the modelling of material quality and reuse potential. Further work is also needed to better connect pre-demolition audits with design-for-deconstruction strategies and digital material documentation approaches supporting circular construction.

Comparative Environmental Assessment of Waste- and By-product-Based Compressed Earth Block Wall Systems

Adilson Paula Junior(✉), Cláudia Jacinto, Elisabete Teixeira, and Ricardo Mateus

ISISE, ARISE, Department of Civil Engineering, University of Minho, Guimarães, Portugal
id8639@alunos.uminho.pt

Abstract. The environmental performance of masonry systems strongly influences the overall environmental impact of buildings. This study presents a comparative environmental assessment of wall systems built with compressed earth blocks (CEBs) incorporating industrial waste and by-products, alongside conventional masonry solutions. The analysis is based on life cycle assessment (LCA) using life cycle inventory data obtained from a Portuguese producer. The CEB solutions correspond to previously optimised formulations. These include blocks incorporating cork granules and waste tyre textile fibres (WTTF), as well as two types of construction and demolition waste (CDW): railway concrete and ceramic tile waste. The earthen solutions are compared with conventional masonry systems, namely fired ceramic bricks and concrete blocks. The functional unit adopted is 1 m^2 of interior partition wall. The assessment follows a cradle-to-gate perspective (modules A1–A3 of EN 15804:2012 + A2). It includes raw material supply, transport and block production. Environmental impacts were quantified through eight indicators, primarily the Global Warming Potential (GWP). Results show that all CEB wall solutions present lower environmental impacts than conventional masonry systems across all indicators. The GWP of the optimised CEB walls ranges from 16.9 to 21.5 kg CO_2 eq/m^2. This corresponds to reductions of 38–51% compared with ceramic hollow brick (34.4 kg CO_2 eq/m^2) and 31–46% compared with concrete block (31.1 kg CO_2 eq/m^2). The best-performing formulations – CG5 (cork granules) and CT15 (ceramic tile waste) – achieve the lowest GWP, without environmental trade-offs. These results support the positioning of waste-based earthen products in the construction market and the development of Environmental Product Declarations for CEB wall systems.

1 Introduction

The building sector accounts for approximately 36% of global final energy use and nearly 40% of total CO_2 emissions, associated with conventional materials like fired bricks and concrete [1]. Earthen construction, particularly compressed earth blocks (CEBs),

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 501–508, 2026.
https://doi.org/10.1007/978-3-032-34930-9_59

has attracted interest as a low-impact alternative, combining mechanised production with ecological properties like low embodied energy and recyclability [2, 3]. However, wider adoption is hindered by functional limitations, specifically the trade-off between mechanical strength – relevant for both load-bearing and non-load-bearing walls – and thermal insulation for envelope elements [4].

To address this limitation, several optimisation strategies have been investigated, including particle size adjustment, alternative binders and the incorporation of natural or industrial materials [5, 6]. Among these, the use of industrial wastes and by-products is particularly promising, as it combines the environmental benefits of earthen construction with circular economy principles. Literature reviews confirm the technical feasibility of these approaches while highlighting the need for integrated assessments that simultaneously consider mechanical, thermal and environmental performance [5–7].

A critical gap in the existing literature concerns the environmental performance of functionally optimised CEB formulations incorporating industrial wastes and by-products. Within the scope of the BTCPro research project, four series of optimised residue-based CEBs were developed in collaboration with Betão e Taipa, a Portuguese earthen construction company based in southern Portugal. Each series incorporates a distinct waste or by-product: railway concrete waste (RC series), ceramic tile waste (CT series), cork granules (CG series), and waste tyre textile fibres (WTTF, TF series). Supported by a multi-criteria sustainability assessment (MARS-SC methodology [8]), the best-performing mixture in each series was identified at the block level in terms of the balance between functional, environmental and economic indicators. However, a wall-scale comparison is now required to fully characterise the environmental potential of these solutions in real construction applications.

Life cycle assessment (LCA) is the standard methodology for quantifying the environmental performance of building materials over their life cycle. In the Portuguese context, Fernandes et al. [3] conducted a cradle-to-gate LCA of CEBs and rammed earth produced by the same company, following the EN 15804 standard and using real production data from the company. Their wall-scale comparison showed that a 15 cm thick CEB partition wall achieves a global warming potential (GWP) of 16.6 kg CO_2 eq/m^2 and an embodied energy (EE) of 165 MJ/m^2, representing reductions of approximately 57% in GWP and 53% in EE relative to a ceramic hollow brick wall, and of 48% and 33% respectively relative to a concrete block wall. These results established a robust, reproducible baseline for earthen wall systems in Portugal and are widely cited as benchmarks in the field.

The present study addresses this gap by translating the block-level LCA data calculated during the BTCPro project to the wall scale, adopting the same functional unit (1 m^2 of partition wall), system boundary (cradle-to-gate, A1–A3) and inventory data for mortar and conventional walls as [3]. This approach reproduces the established methodological baseline and enables a direct and consistent comparison between the optimised waste- and by-product-based CEB solutions, the reference earthen wall, and conventional masonry alternatives. In doing so, it contributes a quantitative environmental basis for material selection in sustainable building design.

2 Materials and Methods

2.1 Environmental Performance Assessment

The environmental performance assessment is organised around the following impact categories: (i) Global Warming Potential (GWP); (ii) Ozone Depletion Potential (ODP); (iii) Acidification Potential (AP) for soil and water; (iv) Eutrophication Potential for marine (EPM), freshwater (EPF) and terrestrial (EPT) environments; (v) Photochemical Ozone Creation Potential (POCP); and (vi) Abiotic Depletion Potential of fossil resources (ADP_FF). Environmental indicators were quantified following the Life Cycle Assessment (LCA) framework defined by ISO 14040 [9] and the characterisation factors of the EN 15804:2012 + A2:2019 [10] reference standard for quantifying environmental impacts in building products.

2.2 Goal, Functional Unit, and System Boundary

The goal of this study is to quantify and compare the potential environmental impacts of five CEB-based partition wall solutions – a control sample (CS) and four optimised formulations – against two conventional partition wall systems – ceramic hollow brick and concrete block – in the Portuguese construction context. The CS consists of a mixture of local soil stabilised with 5% by volume of natural hydraulic lime (NHL5). The optimised CEB series each incorporate a different industrial waste or by-product at the volumetric proportion identified as optimal by the MARS-SC multi-criteria assessment: railway concrete waste (RC15, 15% v/v), ceramic tile waste (CT15, 15% v/v), cork granules (CG5, 5% v/v), and WTTF (TF7.5, 7.5% v/v).

For the environmental comparison, the functional unit is 1 m^2 of interior partition wall, meeting the requirements for residential dwellings in Portugal. This definition is consistent to that adopted by [3], ensuring direct comparability of results and a like-for-like benchmarking against conventional masonry systems. The system boundary is cradle-to-gate (modules A1–A3): raw material supply and transport to the production site, and manufacturing. Wall assembly and end-of-life stages are excluded.

2.3 Selection of CEB Formulations

From the experimental campaign carried out within the BTCPro project, three mixtures per series were produced and evaluated. The best-performing mixture from each series was selected for the wall-scale assessment based on the overall Sustainability Score (NS) achieved by the MARS-SC multi-criteria assessment – an integrated indicator encompassing functional, environmental and economic dimensions – under the scenario reflecting real-world transport distances in the Portuguese context. The selected formulations and their key characteristics per block are presented in Table 1. While thermal conductivity and unit cost are reported only for reference, the present study focuses exclusively on performance in the environmental dimension.

Table 1. Selected CEB formulations and key performance indicators per block.

Series	Mix	GWP [kg CO_2 eq]	λ [W/mK]	σc [MPa]	Cost [€]
Baseline (Control, CS)	CS	0.479	0.65	1.84	0.16
Railway Concrete	RC15	0.526	0.68	2.12	0.18
Ceramic Tile	CT15	0.435	0.59	2.29	0.15
Cork Granules	CG5	0.402	0.52	1.89	0.24
WTTF	TF7.5	0.480	0.53	2.41	0.16

GWP = Global Warming Potential; λ = thermal conductivity; σc = compressive strength.

2.4 Wall Inventory

Table 2 addresses inventory of all wall scenarios per functional unit. All CEB wall solutions consist of a single leaf of blocks in a 15 cm configuration (block width = 150 mm), with earth mortar joints. The blocks have standard dimensions of 300 mm × 150 mm × 80 mm, yielding approximately 36 blocks per m^2 of wall after accounting for 10 mm mortar joints in both height and length directions, consistent with the geometry of the blocks produced by Betão e Taipa.

Table 2. Material inventory per functional unit (1 m^2 of partition wall).

Inputs	Units	Wall Solution						
		CEB wall (15 cm)					Ceramic brick (15 cm)	Concrete block (14 cm)
		CS	RC15	CT15	CG5	TF7.5		
CEB	kg/m^2	250.9	246.9	233.6	239.1	230.5		
Earth mortar	kg/m^2	38.9	39.2	37.3	37.2	38.4	–	–
Ceramic hollow bricks	kg/m^2	–	–	–	–	–	63.6	–
Concrete blocks	kg/m^2	–	–	–	–	–	–	90.6
Cement mortar	kg/m^2	–	–	–	–	–	92.5	88.6

The earth mortar for block laying consists of a soil–lime mixture applied without render, following the company's standard practice and the composition documented by [3]. The mortar quantity per m^2 of wall was calculated from the number of blocks required to fill the functional unit. The mass of blocks per m^2 is the product of the number of blocks (36) and the average dry mass per block for each series, estimated from the bulk density measurements. For the conventional wall solutions – ceramic hollow brick (15 cm) and concrete block (14 cm) – the complete material inventory is taken directly from [3].

2.5 Life Cycle Impact Assessment

The life cycle of the CEB mixtures was modelled using SimaPro v9.5.0.0 software. Environmental impact characterisation followed the EN 15804:2012 + A2:2019 framework, using the Ecoinvent v3.9.1 database for all background inventory processes. The environmental impacts of the ceramic brick, concrete block and cement mortar systems were calculated from generic inventory data in the same database, ensuring consistency across all wall solutions.

3 Results and Discussion

3.1 Wall-Scale Environmental Performance

Table 3 provides the full environmental impact profile per m^2 of partition wall for all solutions across the eight impact categories assessed. Table 4 summarises the main indicator (GWP), together with the percentage reductions compared with conventional alternatives.

Table 3. Environmental impact categories analysed and for each m^2 of wall partition solution investigated.

Units: GWP [kgCO2eq]; ODP [kg CFC-11eq]; AP [mol H+ eq]; EPM [kg N eq]; EPF [kg P eq]; EPT [mol N eq]; POCP [kg NMVOC eq]; ADP_FF [MJ]

Table 4. GWP per functional unit (1 m^2 partition wall) and percentage reductions versus conventional walls.

Wall solution	GWP [kg CO_2 eq/m^2]	*vs* ceramic brick	*vs* concrete block
CEB wall CS	19.7	−43%	−36%
CEB wall RC15	21.5	−38%	−31%
CEB wall CT15	18.1	−47%	−42%

(*continued*)

Table 4. (*continued*)

Wall solution	GWP [kg CO_2 eq/m^2]	*vs* ceramic brick	*vs* concrete block
CEB wall CG5	16.9	−51%	−46%
CEB wall TF7.5	19.8	−43%	−36%
Ceramic brick (15 cm)	34.4	—	+11%
Concrete block (14 cm)	31.1	−10%	—

All CEB wall solutions present substantially lower environmental impacts than both conventional alternatives across all eight impact categories. In terms of GWP – the most climate-relevant indicator – the optimised CEB walls range from 16.9 to 21.5 kg CO_2 eq/m^2, compared with 34.4 kg CO_2 eq/m^2 for ceramic hollow brick and 31.1 kg CO_2 eq/m^2 for concrete block. Reductions range from 38 to 51% relative to ceramic brick and from 31 to 46% relative to concrete block. The same ordering is preserved across all other categories: CEB walls systematically outperform their conventional counterparts in ODP, AP, EPM, EPF, EPT, POCP, and ADP_FF, with reductions of comparable magnitude.

The acidification potential (AP) and marine eutrophication potential (EPM) of all CEB walls are dominated by the hydraulic lime content, which is the primary production-stage input. For CT15, where 15% of soil is replaced by locally sourced ceramic tile waste, both AP and EPM are the lowest among all evaluated solutions (0.054 mol H^+ eq/m^2 and 0.019 kg N eq/m^2 respectively), reflecting the reduction in lime and soil quantity per block. The same driver explains the lowest ADP_FF of CT15 (162 MJ/m^2), representing a 29% reduction versus ceramic brick. CG5 achieves the lowest GWP (16.9 kg CO_2 eq/m^2) due to the minimal transport burden of its low-density cork additive, but its ODP value (2.14×10^{-7} kg CFC-11 eq/m^2) is marginally higher than CT15, as the absolute reduction in soil mass is smaller at the 5% substitution level.

3.2 Comparison Between Optimised Formulations

CG5 achieves the lowest GWP among all evaluated solutions, 14% below the control sample wall (CS). This result reflects the partial substitution of soil by low-density cork granules: at 5% by volume, the reduction in soil and lime mass per block lowers all production-stage impacts, while the very low density of cork (~75 kg/m^3) keeps transport emissions negligible even at longer sourcing distances.

CT15 achieves the lowest values in seven of the eight impact categories and ranks second in GWP. The low environmental performance of CT15 is driven by the local sourcing of ceramic tile waste from the vicinity of the producing company (transport distance: 30 km) and the null production-stage burden allocated to CDW under ISO 14040 [9]. The 15% soil replacement is sufficient to reduce total lime and soil consumption per block, lowering all material-intensive impact categories simultaneously.

TF7.5 achieves a GWP and ADP_FF profile essentially equivalent to the control sample, since WTTF is incorporated as a volumetric additive rather than a soil substitute, introducing a small but consistent incremental burden across all indicators.

RC15 presents the highest GWP among the CEB walls (21.5 kg CO_2 eq/m^2) due to the long transport distance for railway concrete waste (195 km), which, combined

with the high density of the material, result in greater transport-related impacts. This transport penalty propagates consistently across all eight indicators, making RC15 the least environmentally favourable CEB solution under real-world sourcing conditions. Under a hypothetical scenario in which railway concrete waste is sourced regionally (30 km), this ranking could be reversed, as the transport contribution would be reduced to a level comparable to that of CT15.

A notable feature of these results is the high cross-category consistency of the ranking: CT15 and CG5 occupy the top two positions in virtually every impact category, while RC15 consistently ranks last among the CEB solutions. This coherence across GWP, ODP, AP, EPM, EPF, EPT, POCP and ADP_FF indicates that the environmental drivers are fundamentally the same – lime and soil mass per block, and transport distance of incorporated residue – and that optimising for one indicator implicitly improves the others. There is therefore no environmental trade-off between categories in the choice of CEB formulation, which simplifies decision-making for practitioners.

4 Conclusions

This study presents a wall-scale LCA comparison of optimised compressed earth block partition walls incorporating industrial wastes and by-products, benchmarked against conventional ceramic brick and concrete block walls in the Portuguese construction context. The main conclusions are:

- All five CEB wall solutions outperform both conventional alternatives across all eight impact categories assessed. GWP reductions relative to ceramic hollow brick range from 38 to 51%, and 31 to 46% relative to concrete block, confirming the environmental advantage of earthen walls over conventional masonry.
- CG5 achieves the lowest GWP (16.9 kg CO_2 eq/m^2), 14% below the control sample. The minimal mass and very low density of cork granules per block make the transport contribution negligible, even at longer sourcing distances.
- CT15 achieves the lowest values in seven of the eight impact categories (wall-scale-related), while also offering competitive compressive strength (2.29 MPa), thermal conductivity (0.59 W/mK) and unit cost per block. It represents the most balanced formulation for general-purpose earthen partition walls in Portugal.
- TF7.5 achieves environmental performance equivalent to the control sample across all categories, while offering the highest compressive strength (2.41 MPa) and one of the lowest thermal conductivities (0.53 W/mK) and prices (€0.16) at block scale, making it suitable for applications where structural performance is the primary requirement.
- RC15 presents the highest impact among CEB solutions due to real-world transport distances. However, local sourcing would bring its performance closer to CT15, confirming that logistical optimisation is critical to unlocking the environmental potential of railway concrete waste.

These findings provide a quantitative basis for the market positioning of optimised earthen products and support the development of Environmental Product Declarations (EPDs) under EN 15804. Future work should extend the system boundary to cradle-to-grave, incorporating operational energy savings from improved thermal performance

and the benefits of closed-loop recycling, further enhancing the environmental advantage of earthen wall solutions.

[3] The University of British Columbia, Vancouver, Canada

Abstract. The construction industry is known for its environmental impacts, high consumption of natural resources, and waste generation. The introduction of circular economy (CE) principles is considered a strategy to achieve increasingly sustainable projects. This research reports on circular economy practices found in the literature for construction projects and highlights recent practices investigated from previously published surveys. The chosen technique was a systematic literature review from 2020 to early 2023 and a content analysis for data processing. This article presents a summary of the innovations and trends found in the review. Twelve new circular economy practices in civil construction were identified, highlighting the fundamental role of digital technologies—such as BIM, Digital Twins, and Artificial Intelligence—and projects focused on energy efficiency. The authors correlate these practices with the life cycle stages of the EN 15804 standard and the 10 Rs of sustainability, demonstrating the priority of the actions of "Rethink," "Reduce," and "Reuse." In addition to cataloging methods such as the use of bio-based materials and on-site waste management, the text points out gaps in the practical applications of methodologies such as DfAD (Design for Assembly, Adaptability, and Disassembly). In short, the work offers an initial overview of scientific progress in the transition from linear value chains to sustainable and technologically advanced construction models. Finally, the study presents an initial view of recent advances in the transition to a circular economy in the construction industry during the indicated period and offers suggestions for future research in this area of knowledge.

1 Introduction

The construction sector consumes a considerable amount of natural resources, produces high volumes of waste and causes a range of negative environmental impacts, including carbon emissions. These challenges are inherent in traditionally adopted linear value chains (Ajayebi et al., 2021). It is estimated that the construction area consumes around

L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 509–518, 2026.
https://doi.org/10.1007/978-3-032-34930-9_60

3 billion tons of natural resources annually, which represents a costly environmental impact. According to research conducted by the World Resources Institute, the construction industry accounts for 40% of total waste generated on a global scale. To address this problem and reduce the inefficient use of resources, CEPs need to be adopted in construction projects (Hassan et al., 2023).

The circular economy has emerged as a promising approach to drive sustainability and is typified as a strategy towards achieving more sustainable buildings in the construction industry (Cellucci, 2021). Adopting the EC is geared towards realizing sustainable development, which benefits the environmental, economic and social dimensions (De Oliveira Neto et al., 2022). However, implementing the concept of circular construction is still in the development phase (Hassan et al., 2023).

The importance of the topic has driven the development and discovery of knowledge, particularly globally in the area of civil construction. Benachio et al. (2020) investigated the development of the circular economy (CE) from 2015 to 2019 based on a literature review and compiled a list of practices observed in construction projects, cited by the authors of the publications analyzed. The study, in addition to being pioneering in the technical literature on circular economy in Brazil, is also an international reference with hundreds of citations in several high-impact journals.

The construction industry is recognized for its significant environmental impact, high consumption of natural resources, and excessive generation of waste. Traditionally, adopted linear value chains result in inefficient resource use and carbon emissions. Despite its importance, the implementation of the circular construction concept is still in the development phase.

The current research seeks to explore the advances published between 2020 and the beginning of 2023 to update knowledge on Circular Economy Practices (CEPs) in the Architecture, Engineering and Construction (AEC) sector.

The objective of this study is to systematically analyze scientific advances and emerging practices related to the circular economy in the AEC sector, focusing on publications produced after Benachio et al. (2020). The research aims to update the list of CEPs by exploring recent research while aligning them with the international standard EN 15804 and the 10 Rs of sustainability.

2 Research Method

This study adopts a systematic literature review approach based on a structured and replicable search strategy to identify recent scientific contributions related to circular economy practices in the construction industry. The review followed a structured systematic search protocol, including the definition of the research question, database selection, keyword definition, application of eligibility criteria, and qualitative analysis of the selected studies. The methodological procedure expands the literature review conducted by Benachio et al. (2020), aiming to map the evolution of the field following the publication of their study.

The methodology included a search was performed in the Scopus, Science Direct, and Web of Science databases using the keywords “Circular economy” and “Buildings”. Data for this review update was collected through a full reading of the selected texts.

Simultaneously, a list was prepared of circular economy practices mentioned in the surveys to identify new CEPs applicable in construction projects. The practices listed were part of the categorization for content analysis according to Bardin's (1977) approach. The publications were thoroughly examined in order to delve deeper into the relevant topics and, subsequently, to discuss the knowledge related to the mapped practices (see Fig. 1).

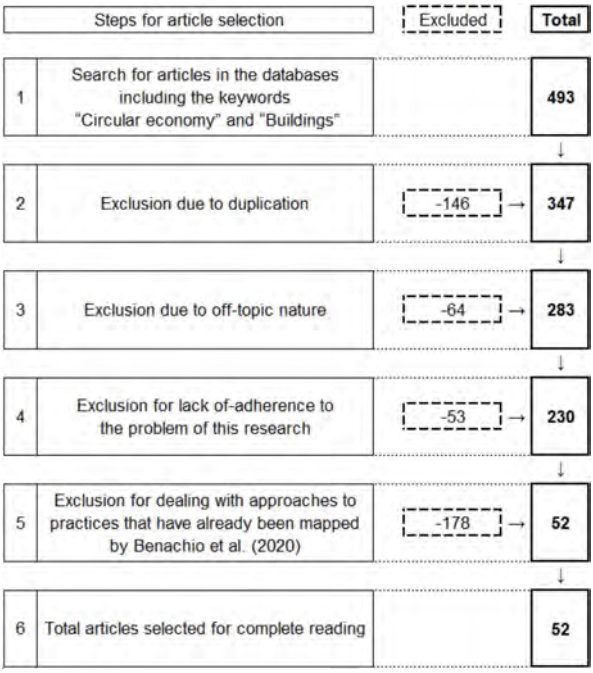

Fig. 1. List of articles by selection stage. Source: The authors (2026).

The Temporal Scope review covered publications from 2020 to the beginning of 2023. Articles were screened using the Rayyan web app. Out of 493 initial publications, 52 articles were selected for full reading after excluding duplicates, off-topic materials, and practices already mapped in the 2020 study (see Fig. 1).

After the complete reading of the selected articles, a table was prepared with the new practices described in a generic and broad way, which will be introduced and discussed following this article. Due to the limitations of the template, it will not be possible to present all the analyses obtained, such as the relationship between the new practices and the R's of the Circular Economy and the phases of the building life cycle.

3 Applied Analysis

The life cycle stages to which each measure refers were also updated according to the classification of EN 15804 described in Fig. 2.

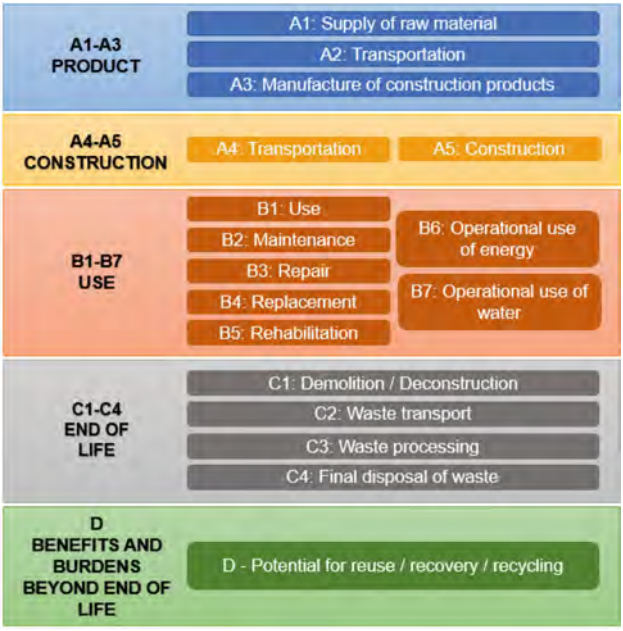

Fig. 2. Life cycle stages according to EN 15804. Adapted from CEN (2019).

A final analysis was made of the outcome to establish the connection between the CEPs identified in the literature and the main "R" of sustainability with which each aligns. This evaluation was based on the listing by Többen and Opdenakker (2022) and on the circular structure of the Rs in order of priority by Munaro and Tavares (2022), listing the 10 R's in the transition from the linear economy to the circular economy, as illustrated in Fig. 3.

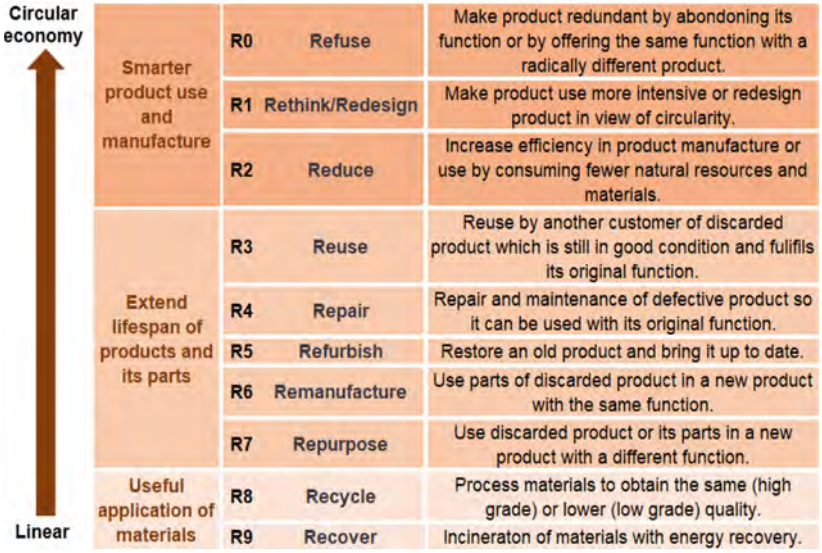

Fig. 3. List of the 10 R's of sustainability. Source: Adapted from Munaro and Tavares (2022) and Többen and Opdenakker (2022).

4 Contributions of Literature Review

The review made it possible to complement the list of CEPs for the built environment. Based on a complete reading of the 52 selected articles, 12 new construction CEPs were identified and compiled in Table 1, along with the respective authors who mentioned them.

In addition to Table 1, a qualitative content analysis was performed to gain a clearer understanding of the mapped practices, which will be presented below. This approach facilitated an in-depth grasp of the current state of practices in the literature, providing a more complete and detailed view of each of them.

Table 1. Additional circular economy practices in construction projects

Practice/CEP	Description	Author(s)
1. Use of digital technologies to help promote the circular economy	Digital technologies such as Internet of Things (IoT), BIM, robots, Artificial Intelligence (AI), 3D printing, blockchain, drones, and Augmented Reality (AR) have the potential to work alongside circular strategies… management of operations and optimization of material flows.	Akbarieh *et al.* (2020); Çetin *et al.* (2021); Jin *et al.* (2021); Lima *et al.* (2021); Medina e Fu (2021); Baduge *et al.* (2022); Caldas *et al.* (2022); Çetin *et al.* (2022); Gómez-Gil *et al.* (2022); Oviedo Hernandez *et al.* (2022); Setaki e Van Timmeren (2022); Yu *et al.* (2022); Giovanardi *et al.* (2022); Kaewunruen *et al.* (2023); Oluleye *et al.* (2023).
2. Use of bio-based materials	Biobased materials… are a sustainable alternative because they provide renewable supply chains and reduce carbon emissions through the natural process of carbon sequestration	Pujadas-Gispert *et al.* (2020); Dams *et al.* (2021); Oorschot e Asselbergs (2021); Besana e Tirelli (2022); Rabbat *et al.* (2022); Butt e Dimitrijevic (2022).
3. Design of energy efficiency	Energy efficiency projects are intended to reduce energy consumption over the life cycle of a building… optimizing the geometry and orientation, natural lighting and ventilation, efficient heating and cooling systems.	Foster *et al.* (2020); Franković *et al.* (2020); Li *et al.* (2020); Marconi *et al.* (2020); Mercader-Moyano and Escape (2020); Pujadas-Gispert *et al.* (2020); Rucinska *et al.* (2020); Antolinc and Filipič (2021); González *et al.* (2021); Ipsen *et al.* (2021); De Lucia *et al.* (2021); Majumder *et al.* (2021); Mercader-Moyano *et al.* (2021); Neri *et al.* (2021); Serrano *et al.* (2021); Mazzoli *et al.* (2022); Díaz-López *et al.* (2022); Oviedo *et al.* (2022); Piotrowska and Słyś (2023); Sadowski (2023).
4. Use of BIM for construction and demolition waste management	BIM is a tool that facilitates optimizing and reducing construction waste… compare different design layouts based on estimated waste production, promoting reuse and recycling.	Akbarieh *et al.* (2020), Copeland and Bilec (2020), Ganiyu *et al.* (2020), Hussien *et al.* (2021); Jin *et al.* (2021).

5 Main Findings and Discussion

Analyzing the complementary practices listed in the bibliographic review of this research, the most cited were found to be: use of digital technologies to help promote the circular economy and energy efficiency projects. A growing technological development has been recognized to support the implementation of circular economy principles in the built environment.

- Digital Transformation: There is a clear trend of incorporating Industry 4.0 technologies to stimulate CEPs, with digital technologies and energy efficiency being the most cited practices.
- Priority of Rs: The analysis showed that "Rethink" (28%), "Reduce" (19%), and "Reuse" (16%) are the most correlated strategies with the mapped practices. Over 53% of total practices refer to the top 3 priority Rs in the transition to a circular economy.
- Life Cycle Impact: The Product stage (A1–A3) remains the most impacted by circular practices, emphasizing the importance of predicting impacts during the design phase.
- Research Gaps: Gaps remain in the practical application of DfMA and LCC, as well as a lack of correlation with the "Restore" strategy.

The literature review identified new emerging practices, such as operational space management and the use of biobased and vernacular materials. These practices have gained traction in recent literature given their conversion to the circular economy by seeking to extend the useful life of buildings and reduce the negative impact on natural resources. In this scenario, compared to the current study, researchers were more concerned about the end-of-life phase of the building.

The energy efficiency project, pointed out as a practice in this research, is related to the circular economy based on the goal of reducing energy consumption and improving energy efficiency throughout the life cycle of buildings. The measures addressed in this

theme also refer to the reduction of greenhouse gas emissions, which provides for a more circular and sustainable approach in the construction sector.

There are, however, still some gaps in the research, especially regarding the practical application of approaches such as Design for Assembly, Adaptability and Desassembly (DfAD) and Life Cycle Cost (LCC). As for updating the life cycle stages according to EN 15804, it turned out that the product stage is more subject to interference from mapped circular economy practices.

The article also brought on an analysis of CEPs in relation to the 10 Rs of sustainability. The predominance of "Rethinking" as the main "R" associated with a greater number of practices highlights the frequent reassessment of processes and consumption patterns in CEPs and emphasizes the need for proper management throughout the life cycle of the construction project. Also, the significant correlations with "Reduce" and "Reuse" demonstrate how implementing these practices results in minimizing the consumption of resources and reducing the disposal of products in the industry. It was also noted that more than half of the practices focus on the three priority "R's" of the circular structure outlined by Munaro and Tavares (2022), illustrating the ability of these practices to strengthen the presence of the circular economy in the scope of construction project management.

6 Conclusions

This research sought, within the limitations of space, to incorporate new concepts and technological tools from the perspective of the Circular Economy in the Built Environment, based on the review by Benachio (2020). New technologies, their relationship to the 3 Rs of sustainability, and the phases and stages of the life cycle were observed in the current review and highlight sensitive points of change in the construction industry. Research in this area should be encouraged to seek alternatives to the scarcity of natural resources, raw materials, and energy, technologically improving, reducing costs, and minimizing the environmental impact of the construction industry in all its aspects.

Deconstruction and Salvage of Light-Gauge Steel Partition Walls: Comparing Three Disassembly Approaches

Alexander Dhesi[1(✉)], Teresa Domenech[1], and Charnett Chau[2]

[1] Bartlett Institute for Sustainable Resources, University College London, London, UK
alexander.dhesi.24@ucl.ac.uk
[2] Saint-Gobain UK & Ireland, Coventry, UK

Abstract. This paper investigates the disassembly of light-gauge steel frame (LGSF) partition walls to assess component salvage feasibility. Disassembly of non-loadbearing partitions was observed in three contexts: typical demolition contractor strip-out, experimental deconstruction aiming to minimise steel damage, and a controlled disassembly trial at a manufacturer training academy. Data on process steps, equipment, labour, and timing were collected to compare the efficiency and effectiveness of the three approaches. Salvaged steel components from each trial were visually inspected and damage characterised. The study found that while the LGSF could be dismantled with minimal damage under controlled conditions, practical demolition site constraints and standard practices significantly impeded careful disassembly. Typical demolition strip-out prioritises rapid removal using heavy tools, causing significant steel deformation that likely prevents reuse. Access to connection points and influence of connected building components hindered interventions aimed at minimising damage. This research suggests that although circular economy and design for disassembly principles can deliver systems suitable for careful component recovery, such processes are neither time nor labour efficient in practice and would likely increase demolition contractor costs. These practical gaps between theoretical circular economy principles and actual demolition practices must be addressed to enable efficient and effective material recovery. The findings also highlight the need for further empirical research into how disassembly processes affect recovered steel condition and support material salvage and reuse outcomes.

Keywords: Light-gauge steel · Design for Disassembly · Circular Economy · Material reuse · Demolition practice

1 Introduction

Reuse in construction aims to prevent the early disposal of functional building materials and systems, supporting circular economy objectives by avoiding unnecessary consumption of replacement raw materials and energy [1, 2]. Fit-out systems like light-gauge steel frame (LGSF) partitions often undergo short installation, removal, and disposal cycles

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 519–527, 2026.
https://doi.org/10.1007/978-3-032-34930-9_61

driven by space division changes and tenant turnover, rather than performance deterioration [3]. Strip-out and demolition practices prioritise rapid removal and minimal handling, often destroying components with residual functional performance [4].

LGSF systems are thin-walled galvanised steel profiles for constructing internal partition walls, external façade supports, and structural elements. They mostly feature mechanical connections (screws, bolts) and are often modularised for rapid installation. The design basis of LGSF systems is to provide mechanical support for insulation and plasterboard assemblies, dividing space or framing building structures and delivering acoustic insulation and fire resistance [5].

Despite the theoretical suitability of LGSF systems for disassembly and reuse [6–8], empirical evidence of material recovery outcomes under real demolition conditions is limited. This study compares LGSF partition disassembly across three contexts: a manufacturer training academy, an experimental deconstruction approach on a dormant demolition site, and typical strip-out operations on an active site.

Material reuse in construction depends on the ability to recover materials during strip-out and demolition without significant damage to components. Design-for-disassembly principles aim to enable component recovery through reversible connections, accessible fixings, and material separability [9]. However, the assumed effectiveness of design-for-disassembly relies on ideal deconstruction conditions that may not reflect practical demolition constraints [10].

Light-gauge steel frame (LGSF) systems are targeted for disassembly due to standardised components and reversible mechanical connections [6]. Previous studies demonstrate LGSF disassembly in experimental settings [7, 8], but empirical evidence from actual demolition operations is limited. The gap between controlled deconstruction studies and real demolition practice represents a critical barrier to recovering LGSF components for reuse.

Mayer [11] developed certification criteria for construction workers conducting material salvage operations, identifying key process indicators including site safety, tool requirements, deconstruction techniques and material handling protocols. Cabral et al. [12] assessed material recovery interventions through indicators including recovery rate, skill requirements, workplace constraints, and material preservation outcomes. Hradil et al. [13] proposed a framework for evaluating component reuse feasibility based on ease of deconstruction, handling, separation, quality checking, and geometry verification.

While existing frameworks establish criteria for assessing material recovery, empirical application in varying disassembly contexts is limited. This study addresses the gap by combining three assessment frameworks, comparing LGSF partition disassembly in training, experimental deconstruction, and typical demolition contexts.

2 Methodology

2.1 Framework Development

A three-part assessment framework was developed from existing material recovery evaluation methodologies to enable systematic comparison between disassembly contexts.

The first component addresses site features, tools and work sequences, drawing on deconstruction worker certification criteria to characterise safety requirements, equipment, site layout, and process steps [11]. The second component considers material salvage process interventions, assessing recovery rates, skill requirements, workplace constraints, labour demand, and material preservation outcomes [12]. The third component evaluates material condition and reuse feasibility, considering ease of deconstruction, handling, separation, quality checking, and geometry verification [13].

Three disassembly trials were conducted representing a progression from ideal to typical conditions. The training academy trial reflects ideal conditions: LGSF systems were installed and deinstalled by the same team, under the guidance of training staff; connection points were left accessible, and there were no time constraints on the steel recovery operation. The deconstruction trial took place on a dormant demolition site, where recovery activities attempted to minimise damage to steel components despite site constraints. The demolition trial observed standard strip-out practice on an active site, prioritising rapid partition removal using typical demolition tools and techniques.

All three trials considered the same LGSF partition system (British Gypsum Gypframe, Fig. 1), selected based on training academy availability and presence in the chosen demolition site, with components recovered for condition assessment.

Fig. 1. Gypframe non-loadbearing interior partition system, British Gypsum [14].

2.2 Data Collection and Analysis

Data collection combined observational methods, photography, timing estimates, and physical sample recovery and inspection. For each trial, disassembly process sequences were documented including tool and equipment use, labour requirements, safety measures, and approaches to handling removed materials. Approximate timing data were recorded based on observation of how long different process steps required. LGSF components were recovered from each trial, visually inspected and photographed to characterise defects including deformation, cut edges, connection zone damage, and screw holes.

Observational notes, photographs, videos and timing estimates recorded during each trial were retrospectively assessed against the three-part framework. Indicators were adapted from source frameworks [11–13] and interpreted individually based on observed

differences between trials: comparative ranking (High/Moderate/Low) were assigned to reflect the author's judgement of how the three approaches compared against each indicator.

3 Results

3.1 Site Features, Tools, and Work Sequences

The three disassembly approaches differed significantly in safety requirements, tooling, and site organisation (Table 1).

Table 1. Observational assessment of site features, tools, and work sequences [11]

Indicator	Training Academy	Deconstruction	Demolition
Site safety	Controlled training environment. Gloves, safety glasses, steel-capped boots.	Dormant site scheduled for demolition. Gloves, helmet, safety glasses, dust mask, steel-capped boots.	Active demolition site. Gloves, helmet, safety glasses, dust mask, steel-capped boots, overalls, ear defenders.
Tools	Impact driver, hammer.	Angle grinder, screwdriver.	Reciprocating saw, crowbar.
Site layout	Training bays with clear access.	Constrained by remaining building elements, limited staging area.	Constrained by demolition sequence, materials handled in situ.
Deconstruction techniques	Plasterboard removal, unscrewing, steel frame disassembly with impact drivers.	Plasterboard cutting, unscrewing, steel cutting with angle grinder.	Plasterboard cutting, steel frame destruction with crowbar.
Layered materials	Tape and joint materials only. Clear access to connection points.	Heavy timber skirting fixed through studs, suspended ceiling grid obstructing access.	Skirting and ceiling previously removed; connections accessible.
Debris handling	Full-length stud sections removed, waste segregated and recycled.	Cut stud samples removed.	Samples recovered from scrap steel segregation.

Deconstruction techniques varied from systematic unscrewing (training academy, Fig. 2a) to strategic cutting around obstructions (deconstruction, Fig. 2b) to rapid destructive removal (demolition, Fig. 2c). Critically, layered building elements, particularly the skirting board and suspended ceiling grid, prevented direct access to steel frame connection points in the deconstruction trial, necessitating cutting interventions that limited material recovery rates.

Fig. 2. Photographs showing (a) training academy, (b) deconstruction and (c) demolition trials in progress.

3.2 Material Salvage Process Interventions

The deconstruction trial resulted in the lowest material recovery rate due to severe workplace constraints that prevented effective intervention: inaccessible connection points, layered building elements, and limited staging area combined to undermine careful disassembly attempts (Table 2).

Table 2. Assessment of material salvage process interventions (High/Moderate/Low) [12]

Indicator	Training Academy	Deconstruction	Demolition
Material recovery rate	High	Low	Moderate
Skill level requirement	Moderate	High	Low
Workplace constraints	Low	High	Moderate
Safety risk level	Low	High	Moderate
Labour requirements	High	Moderate	Low
Operational flexibility	Low	Moderate	High
Material preservation	High	Moderate	Low

Interventions aimed at minimising steel damage in the deconstruction trial were limited by the need to cut through studs where skirting boards and ceiling grids prevented unscrewing, resulting in short sections being recovered for assessment.

3.3 Material Condition and Reuse Feasibility

Component condition assessment revealed that only the training academy trial yielded sections suitable for potential reuse (Table 3).

Table 3. Assessment of material condition and reuse feasibility (High/Moderate/Low) [13]

Indicator	Training Academy	Deconstruction	Demolition
Ease of deconstruction	High	Low	Moderate
Ease of handling	High	Moderate	Low
Ease of separation and cleaning	High	Moderate	Low
Ease of quality checking	High	Moderate	Low
Ease of geometry checking	High	Moderate	Low

Full-length (2400 mm) steel stud sections were recovered from the training academy trial with minimal damage beyond holes from screw connections (Fig. 3a). Deconstruction trial samples showed moderate handling and assessment feasibility, but incurred damage at cutting points and connection zones, especially where layered materials had been fixed to the steel studs (Fig. 3b). Demolition trial samples exhibited the lowest feasibility scores across all indicators due to severe deformation from crowbar use, sharp edges from cutting, and twisted sections that prevent safe handling and reassembly. The LGSF installation deviated from manufacturer specifications, with unnecessary fixings between studs and channels adding disassembly complexity (Fig. 3c).

Fig. 3. Photographs showing (a) full-length intact sections recovered from the training academy, with screws still attached; (b) damaged sections recovered from the deconstruction trial; (c) installation error fixing studs to head channel in demolition trial.

4 Discussion

4.1 Design Implications

The training academy trial demonstrates that LGSF components can be removed without severe deformation when connections are accessible and time is unconstrained, supporting findings from controlled disassembly studies [7, 8]. The deconstruction and demolition trials develop these findings to show how site constraints prevent careful removal in operational contexts.

Alternative connection designs could address specific damage modes. The use of screws in plasterboard fixing could be addressed through clips or interlocking boards.

Modular panel-based LGSF systems, designed to improve installation efficiency and reduce material waste, may offer an additional benefit for deconstruction by enabling removal of intact panels rather than components [10]. Any design intervention intended to improve recovery outcomes requires validation in comparative trials under site conditions.

Improper installation significantly affected the condition of recovered LGSF components: unnecessary screw fixings between studs and head channels prevented component disassembly and encouraged destructive removal. Standardised installation and deconstruction protocols provided by manufacturers or enforced through certification [11] could improve recovery outcomes but requires validation under typical project constraints.

4.2 Policy Implications

The dormant period between building vacation and active demolition in the deconstruction trial represents an under-utilised window for material recovery. Policy mechanisms like pre-demolition audits [4] or material recovery credits that encourage early contractor engagement and phased soft-strip works could facilitate careful component removal before time-critical strip-out phases begin.

5 Conclusions

This study compared light-gauge steel frame disassembly in three contexts: controlled training conditions, experimental deconstruction on-site, and typical demolition strip-out, revealing significant gaps between circular economy principles and demolition practice. Only the training academy trial yielded components in reusable condition; site constraints including layered building elements, time pressure, and installation errors prevented effective material recovery despite intervention attempts.

These findings demonstrate that design for disassembly principles are insufficient to optimise reuse outcomes without parallel changes to installation practices, demolition timelines, contractor capabilities, and economic incentives that currently prioritise speed over material preservation.

Advancing Circular Economy and Decarbonisation in Infrastructure: The Case for Steel Sheet Piles

François Fohl(✉), Michael Bezzo, and Oliver Hechler

ArcelorMittal Sheet Piling, Esch-sur-Alzette, Luxembourg
francois.fohl@arcelormittal.com

Abstract. Infrastructure constitutes one of the largest global consumers of construction materials and a major source of embodied carbon emissions. Despite growing momentum toward a circular built environment, deep foundations and retaining structures remain domains in which circularity principles are insufficiently implemented, even though their potential is considerable. This paper examines how steel sheet piles - modular, reusable, recyclable, and increasingly optimised through digitalisation - provide a practical pathway with regards to a part of the 9R framework for reducing environmental impacts across the full life cycle of infrastructure assets. Refuse is addressed by structural health monitoring opportunities. Reduce is outlined through a Life Cycle Assessment showing that permanent sheet pile walls can achieve substantial CO_2e reductions when compared with conventional alternatives. The potential of structural optimisation using products with enhanced efficiency is analysed. Reuse and refurbish is examined by presenting an industrialised reuse model enabled by rental and refurbishment, offering multiple use of sheet piles and carbon savings. Finally, recycle is addressed by analysing how different steel production routes influence overall climate performance. Overall, the findings highlight the essential role of advanced circularity considerations for the decarbonisation in infrastructure.

Keywords: Circular economy · 9R · Steel Sheet Piles · LCA · Infrastructure

1 Introduction

The construction sector is progressively advancing the implementation of circular economy principles, yet adoption rates vary across domains. Infrastructure and deep foundation works, in particular, lag behind sectors such as housing in applying low carbon and circular construction practices. Infrastructure is the backbone of the built environment and subject to over €120 billion investment yearly only in Europe [1]. Considering the number of projects, in maritime, waterway or urban environments, infrastructure represents a big opportunity for applying circular economy principles, noting that in infrastructure, construction materials typically account for over 80% of a project's total carbon footprint [2]. Retaining walls are frequently employed in infrastructure and sheet

piling is one technical solution. Sheet Piles are prefabricated and modular steel members, that are connected one to another with interlocks. As a consequence, they form continuous retaining walls that can be temporary or permanent with design life up to 120 years.

This paper will address parts of the 9R framework, and discusses, based on the keywords 'refuse', 'reduce', 'reuse/refurbish' and 'recycle', levers and opportunities on implementing circular economy. Focus lies on retaining walls and reduction potential on the so-called embodied carbon emissions, measured in CO_2-equivalents. Every Life Cycle Assessment (LCA) cited in this paper is based on product-specific Environmental Product Declarations (EPDs), whenever they were available. Highly impacting construction materials, such as steel or concrete, always refer to publicly available product-specific EPDs. The cited LCA modules are those defined by EN 15804+A2. Module B, representing the use stage, is generally not worth quantifying for infrastructure projects, as emissions are rather moderate compared to the overall environmental impact, given that infrastructure projects are generally not cooled or heated over the entire service life.

2 Service Life of Infrastructure

Highest degree of circularity can be achieved with a refuse approach, as this strategy avoids waste generation and the use of resources and energy. One way of interpreting the refuse strategy in the current context is to simply avoid the construction of new infrastructure. Certainly, not a viable and realistic option in most cases as infrastructure is essential for a working society (see railway stations, ports, dykes, bridges, etc.). A softer variant of the refuse strategy would be the extension of the service life of infrastructure, generally designed for 50–120 years depending on the different applications. Strict monitoring, as already implemented for bridges, can significantly extend the service life of structures. Taking the example of sheet pile retaining walls, there are concepts available that monitor the health state of the structure with specific sensors. The data is collected, synthesized and made available in a digital twin model, that can be assessed at any time. Preventive maintenance work can be scheduled or hidden capabilities revealed to ultimately extend the life of the structure. Furthermore, Artificial Intelligence helps to analyse the vast data and take data-driven decisions [3]. Lengthen the service life of infrastructure, can significantly reduce the pace of new constructions, hence reduce the use of construction materials.

3 Structural Optimisation of Retaining Walls

3.1 Choice of Construction Method

For a specific application, be it temporary or permanent, multiple technical solutions can be considered and are in many cases technically equivalent. The task of a consulting engineer is indeed to find the most adequate solution that fits the project's and project owner's needs on a technical and financial level. The technical catalogue of an infrastructure or deep foundation project can contain requirements on circularity and environmental impact of used construction materials. However, this is rarely the case.

The benefit of studying alternative solutions in reference to technical, financial and environmental criteria is demonstrated via an underground car park (UCP) example in a usual urban setup. The underlying technical design and financial assessment of the variants is carried out by the German consultant GRBV [4]. The study compares the following technical equivalent solutions: (V1) Permanent sheet pile wall; (V2) Temporary sheet pile wall in combination with a permanent reinforced concrete wall; (V3) Concrete secant piles; (V4) Permanent diaphragm wall/slurry wall. Figure 1a shows the variant with permanent sheet piling that encapsulates a 28 m × 28 m construction pit, accommodates the vertical loads of the 4-storey building above, and is designed for the entire service life of the structure. Like this, the retaining wall assures at the same time the need for a short-term construction pit and the long-term foundation wall.

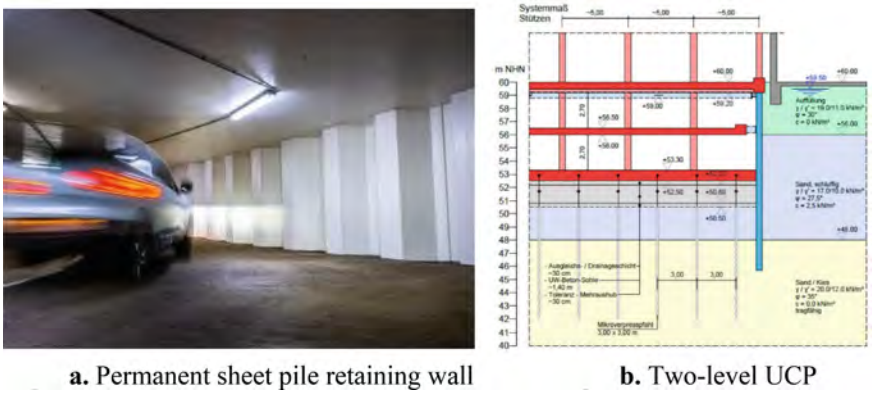

Fig. 1. **a.** Permanent sheet pile retaining wall. **b.** Two-level UCP

The LCA, verified by a panel of 3 independent experts, considers the entire retaining wall (blue on Fig. 1b) as a functional unit and follows the principles of ISO 14040/44 and EN 15978 [5]. Over the entire life cycle (modules A-D) the permanent sheet pile wall is 58% less impacting in CO_2e than the secant pile solution (see Fig. 2).

As the steel solutions, both temporary and permanent, come out cheaper than the concrete alternatives, the optimisation potential towards circularity and low-carbon construction is given. The LCA considers the quantity of construction materials and related transport emissions. Nevertheless, not included are social by-impacts that are caused by the transport of the materials, generally disturbing in inner city areas. Variant 1 only needs 704 t of materials (concrete, steel, etc), variant 2 1,290 t, while variant 3 consumes 5,113 t and variant 4 4,881 t. The study demonstrates that the use of low-carbon, modular and prefabricated construction solutions can accelerate the move towards circular economy, without suffering from drawbacks on a financial basis.

3.2 Optimised Design

For sheet pile retaining walls, the optimisation, hence the reduction of needed construction materials starts with efficiently designed sheet piles. As a consequence of continuous

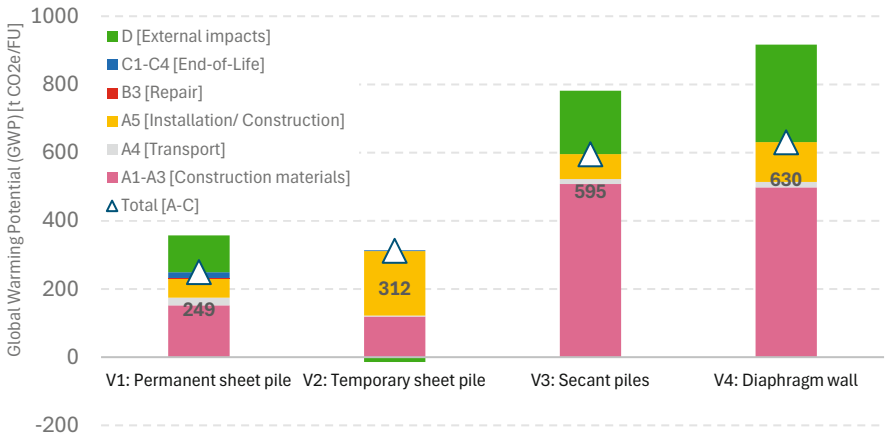

Fig. 2. Global Warming Potential caused by the retaining wall (FU/Functional unit)

improvements in production, profiles have become increasingly lighter while offering the same section modulus. New geometries, often wider, have enabled savings of up to 30% in steel mass over the last few decades. In terms of geometry, Z-shaped sheet piles are principally more efficient in surface mass (kg/m^2) than U-shaped profiles. In addition, Eurocode EN 1993-5 doesn't consider for a reduction factor (β_B) for Z-shaped profiles, as the interlocks are located far from the neutral axis, and are not subject to shear stresses. The second lever for optimising the sheet pile solution is the steel grade. The production standard for hot-rolled sheet piles EN 10248:2023 includes grades up to 500 MPa in yield strength. The rule of thumb says that the choice of a higher steel grade allows the choice of a lighter profile, leading to more economical solutions with reduced carbon footprint. A dyke reinforcement project in Dax, France, shows the potential of structural optimisation. The design study had foreseen a PU 18 profile. The contractor optimised towards a Z-shaped profile and installed an AZ 14-770. By avoiding the reduction factor β_B, the contractor was able to save 20% in steel mass, embodied emissions and cost, while still meeting the same safety level [6]. For permanent projects, Z-shaped profiles should be considered right from the beginning, leading to substantial savings in CO_2e in the projects. Still, U-shaped profiles remain the preferred choice for temporary projects. They are perfectly adapted to be reused several times (5–10×).

4 Reuse of Steel Sheet Piles: Operational and Business Model

Approximately 40 years ago, ArcelorMittal introduced the concept of sheet pile rental, further strengthening the competitive position of steel sheet piles in comparison with alternative construction methods, such as concrete. This rental-based business model was established for its steel sheet pile portfolio to generate benefits for both, customers and the environment. The rental model for steel sheet piles offers companies undertaking excavation projects a cost-efficient and logistically streamlined alternative to purchasing materials. By reducing capital immobilisation, and simplifying handling processes, the rental approach yields notably lower costs per square meter of retaining structures

compared with systems relying on other substitute materials. The repeated reuse of steel sheet piles across multiple construction projects exemplifies a practical and robust circular economy model within the infrastructure sector. This practice extends the service life of steel components, optimises material utilisation, and reduces demand for primary resources. ArcelorMittal operates a network of specialised service centres that function as logistical and operational hubs within its steel sheet pile rental system. These centres are responsible for the acquisition, assessment, refurbishment, inventory management, and redistribution of sheet piles, thereby ensuring a continuous and quality-assured material flow. Upon entry into the system, both new and previously used sheet piles undergo a structured evaluation process in which their condition is assessed and documented through an internal protocol. Subsequent cleaning, inspection, and repair activities restore the piles to the technical and performance standards required for redeployment. Once refurbishment is completed, the sheet piles are inventoried in batches characterised by profile, steel grade, and length. When a rental request is received, material from the corresponding batch is dispatched to the construction site. If existing stock does not fully satisfy the project specifications, additional piles from other batches are adapted to meet the order requirements. Rental fees are collected monthly, with a proportion allocated to covering operational and overhead costs of the service centre, while the remaining share contributes to the depreciation of the rented material. Following completion of the project, the sheet piles are returned to the service centre, where they undergo a renewed cycle of assessment, refurbishment, and reintegration into inventory. Depending on the extent of required maintenance, returned piles may be reassigned to a different batch. Costs associated with repairs, maintenance, or losses are charged to the customer. This closed-loop operational model (see Fig. 3) prolongs the effective service life of steel sheet piles and represents a practical implementation of circular economy principles within the construction sector.

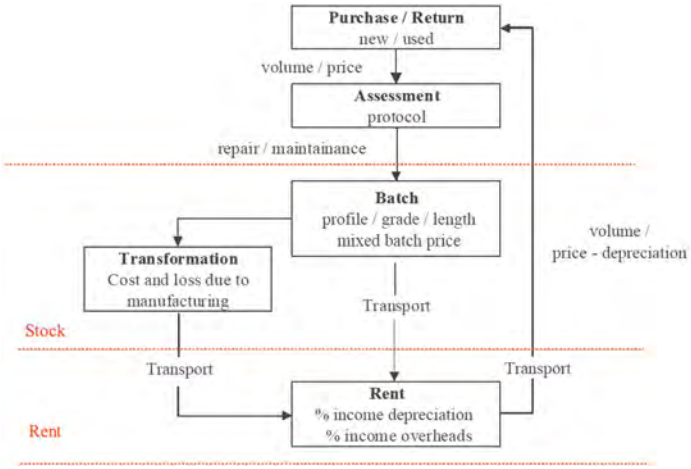

Fig. 3. Closed-loop operational model for sheet pile rental

The composition of the stock inventory is consistent to reflect region-specific geological conditions and the corresponding utilisation segments, which determine the expected loading and thus define required profile types and lengths. Only steel sheet piles from ArcelorMittal's product portfolio are held in stock, uniformly in steel grade S355GP. To guarantee the safe reuse of steel sheet piles, their conformity with the relevant product and manufacturing standards must be verified prior to re-introduction into the market. In the context of sheet piling works, structural design follows EN 1993-5, while steel sheet piles themselves are governed by the product standard EN 10248. Consequently, any reused sheet pile must undergo an assessment confirming compliance with EN 10248, and the resulting conformity documentation must be retained. This procedure provides the necessary assurance that reused elements meet the requisite mechanical and quality standard for safe employment in new construction projects. To ensure the reliable functioning of the sheet pile rental system, the company has implemented a structured quality-control procedure within its stocking facilities. Upon return of rented material or acquisition of used piles, a reception report is issued to the customer. The sheet piles are subsequently subjected to an initial cleaning process, during which surface contaminants are removed and the interlocks are thoroughly cleaned in order to allow for a precise visual assessment (see Fig. 4b). Thereafter, the geometric conformity of each pile is verified against the dimensions prescribed in EN 10248, enabling accurate classification of the returned elements with respect to profile and length. Any deviations from the standard geometry, as well as the repair measures required to restore compliance, are recorded in a reception protocol. This document incorporates photographic evidence of observed defects and provides an itemized overview of the refurbishment costs. Based on a cost-benefit evaluation, a decision is taken on whether a pile will be refurbished or scrapped.

Fig. 4. **a.** Sheet pile before washing. **b.** Sheet Pile after washing

Refurbishment tasks necessary to regain compliance with EN 10248 are executed in accordance with EN 12063, encompassing operations such as cutting, straightening, and welding. All interventions are documented and appended to the reception report, together with the corresponding invoicing information issued to the customer or job site. Following completion of the refurbishment process, the material is re-entered into inventory within the appropriate batch (see Fig. 5). Any customer inquiries or requests for inspection are addressed as part of the established procedure.

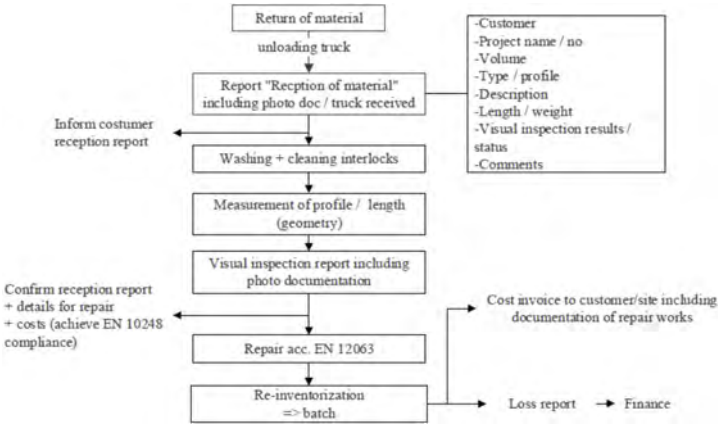

Fig. 5. Workflow for sheet pile rental business

This sheet pile rental model constitutes a utilisation-oriented business approach in which customer value is derived from access rather than ownership, enabling broader market reach and enhanced revenue generation from a single asset base.

To further decarbonise infrastructure projects, the rental stocks are composed of sheet piles made via the Electric Arc Furnace route, and use of renewable electricity (XCarb®). As an example, a construction pit in Germany used 798 t of rented sheet piles. Considering 5 reuse cycles with subsequent recycling of the steel, the allocated carbon footprint for this project is 104 t CO_2e, instead of 520 t CO_2e in modules A-D [7]. By reducing the need for new production, this model simultaneously alleviates environmental pressures and lowers resource consumption, thereby demonstrating that steel reuse is both technically feasible and commercially viable.

5 Recycling of Steel in Construction

Steel is the most recycled material in the world, mainly driven due to the inherent properties of steel enabling easy sorting. Especially the steel used in construction is nearly entirely recycled with recycling rates of 92% and a reuse rate of 4% for all construction steels (rebars, sections etc.) [8]. For sheet piling, surveys note around 60% of the initial tonnage recycled and 25% reused after the first use. Once collected at the end of the service life, the sheet piles, as well as other steel materials, are resources again, as every steel production route uses pre-consumer and post-consumer scrap. Especially the Electric Arc Furnace (EAF) route uses 100% scrap input. This recycling process does not rely on iron ore and/or coal to produce new steel products. Due to its properties, steel is recyclable without losing its characteristics. Moreover, steel production based on steel scrap allows for a drastic reduction of the carbon footprint of the new steel. Hereunder the average emissions (Modules A1-A3) of one ton of crude steel depending on the production route [9, 10]:

- Blast Furnace/Basic Oxygen route (BF/BOF): 2,300 kg CO_2e/t

- Direct Reduced Iron route (DRI): 1,100 kg CO_2e/t
- Electric Arc Furnace route (EAF): 400 kg CO_2e/t

An LCA study for a ferry terminal in Calais, France, inaugurated in 2021, showed that a HZ-M combi wall (EAF route) instead of a tube combi wall (partially BF/BOF route) saved 14,575 t of CO_2e in modules A1-A3 and 2,607 t of CO_2e in modules A-D [11]. The choice of the steel production route of the constituent steel members in a project is an important factor in reducing the overall environmental impact of infrastructure.

6 Conclusion

The application of selected R-strategies of the 9R circularity framework to infrastructure and deep foundation works reveals significant opportunities to enhance circularity and lower embodied carbon in retaining wall construction. Structural health monitoring evidence shows that extending service life effectively avoids carbon intensive new construction. Life Cycle Assessment results further demonstrate that optimised steel sheet pile walls markedly outperform conventional concrete alternatives. An established business model for reuse and refurbishment confirms that circular practices are technically mature and operational at scale, yielding measurable environmental benefits. Overall, steel sheet piling emerges as a proven and impactful pathway for advancing decarbonisation and circularity in global infrastructure projects.

Upfront Carbon and Circularity Assessment of a Modular UK Residential Building

Fabio Goncalves, Ana Bras, and Michaela Gkantou(✉)

BEST Research Institute, School of Engineering and Built Environment, Liverpool John Moores University, Liverpool, UK
m.gkantou@ljmu.ac.uk

Abstract. Modular construction is increasingly recognised as a low-carbon building approach due to its manufacturing efficiency, reduced waste generation, and potential to support circular material flows. This study evaluates the upfront embodied-carbon and circularity performance of a modular steel dwelling in Northwest England using an enhanced A0–A5 Upfront Carbon Tool developed by Liverpool John Moores University. Built based on the IStructE Structural Carbon Tool, the enhanced framework incorporates Low Energy Transformation Initiative (LETI)-aligned benchmarks, an expanded Environmental Product Declaration (EPD) database, whole-building assessment, and circularity metrics based on reusability and recyclability potential. A scenario-based analysis compares a baseline design with an optimised alternative using locally available low-carbon materials. The optimised scenario achieves a 28% reduction in upfront embodied carbon (A0–A5) while maintaining high circularity levels (≈72% reusability, 93% recyclability), demonstrating that carbon reduction and circularity can be achieved simultaneously through early-stage material substitution. The findings demonstrate that modular construction, when combined with early-stage material optimisation and whole-building carbon assessment, can simultaneously enhance circularity and reduce embodied impacts. The study highlights the need for standardised recyclability indicators within EPDs and improved reuse certification frameworks to further support circular-economy adoption in the construction sector.

Keywords: Low-carbon · circular economy · carbon tool · reusability · recyclability

1 Introduction

The construction sector is widely recognised as one of Europe's most resource-intensive and waste-generating industries, with the built environment accounting for around 50% of all extracted materials [1, 2] and almost 40% of annual waste [3, 4]. These figures highlight the growing urgency to minimise waste, improve material efficiency, and accelerate the transition to a more circular construction economy. In response to these challenges, modular construction and broader Modern Methods of Construction (MMC) have emerged as key approaches for increasing productivity and reducing environmental

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 537–544, 2026.
https://doi.org/10.1007/978-3-032-34930-9_63

impacts [5–7]. By shifting activities to controlled factory environments, MMC reduces construction errors, improves quality, streamlines supply chains, and significantly cuts waste compared with traditional on-site methods, positioning modular systems as a central component in European circularity strategies [6].

As operational emissions decline due to stricter energy standards, the relative importance of embodied carbon has increased, with construction materials and activities contributing nearly 40% of total greenhouse gas emissions [8, 9]. Life Cycle Assessment (LCA) therefore plays a vital role in quantifying environmental impacts and guiding low-carbon design choices. Improving material reuse and recycling—supported by selective demolition, standardised sorting, and greater confidence in recycled materials—can substantially reduce virgin material extraction and associated emissions. In parallel, design-for-disassembly and modular components enable buildings to function as material banks, extending material lifespans and reducing reliance on primary resources.

The present study applies LCA to a modular house in the UK to evaluate and optimise its environmental performance, while also evaluating its reuse and recycling potential in line with LETI [10] and EU targets [11]. The selected case study is presented in Sect. 2, the methodology and results in Sects. 3 and 4, respectively, and the final conclusions in Sect. 5.

2 Case Study

The case study building is a 99 m^2 semi-detached 3-storey dwelling located in Brooklands UK. It was designed and manufactured by the modular construction specialist Starship Group [12]. The dwelling contains 3 bedrooms, living area, kitchen and 2 bathrooms, representing a typical contemporary family home in the UK. Figure 1 presents some photos of the completed building.

The building perimeter walls are founded on reinforced concrete (RC) ground beams, which are supported on RC piles. On top of the RC ground beams sits a ground slab. The main superstructure is prefabricated Light Gauge Steel Framing (LGSF) including all

Fig. 1. Modular construction case study – Brooklands Building, Wirral Waters, UK [13].

walls, suspended slabs and roof. The core of the LGSF is infilled with thermal insulation (rockwool at internal face and Polyisocyanurate (PIR) at external face). Vapor barriers were installed on the inner faces of the façade walls as moisture control solution. The building's facade is protected by a brick slip system, and the roof is protected by cement thin flat tiles. The interior side of façade walls and ceilings are composed of plasterboard, and the floors finish is carpet. Internal walls consist of steel studs with optional mineral wool infill and plasterboard on both sides. The windows are triple-glazed plastic frames, and the interior staircases were made of wood. The floor layouts are presented in Fig. 2.

Fig. 2. Floor Plan Sketches – Brooklands Building, Wirral Waters, UK [13]

3 Methods

Liverpool John Moores University (LJMU) has developed an enhanced Microsoft Excel–based Upfront Carbon Tool to support construction professionals in estimating embodied carbon across stages A0–A5, covering all emissions before a building becomes operational, including A0 (pre-construction activities such as site preparation and temporary works) and A1–A5 (product manufacturing, transport, and construction). Built based on the IStructE Structural Carbon Tool [14], the LJMU tool adds LETI-aligned benchmark scoring, an expanded EPD database (with country of manufacture), and full structural and non-structural coverage. It introduces A5.4 worker-transport emissions and strengthens circularity through reusability and recyclability metrics. Carbon reporting is simplified to whole-building level, the Comparisons tab now includes 2030 full-building targets [15] with structural/non-structural separation for SCORS [16], and a new Future Homes Standard (FHS) Compliance Checklist [17] supports early-stage regulatory review. By quantifying upfront carbon and linking results to low-carbon and circular material options—including reclaimed content, bio-based choices, and high-recyclability products—the tool functions not only as a carbon calculator but also as a practical enabler of circular, net-zero-aligned design and procurement.

Using this tool, the environmental performance of the modular Brooklands housing project was assessed. Scenario 1 represents the baseline design, while Scenario

2 introduces targeted material substitutions intended to lower upfront embodied carbon and enhance circularity; the two scenarios are summarised in Table 1. In Scenario 2, conventional higher-carbon products are replaced with low-carbon, bio-based, or more recyclable alternatives, including increased Ground Granulated Blast-furnace Slag (GGBS) content in concrete, the use of anhydrite screed, and the selection of Electric Arc Furnace (EAF)-produced reinforcement steel. Further reductions are achieved by substituting several mineral-based materials—such as PIR insulation, particle boards, and brick slips—with bio-based options, including hemp insulation, cork panels, and brick slips made of near 100% recycled content, while already low-carbon components (e.g., plasterboard, cavity barriers, timber elements) remain unchanged.

4 Analysis and Results

Figure 3 presents the embodied-carbon results for the two scenarios, showing the distribution of emissions across the A0–A5 lifecycle (A0 not shown as it was assumed zero) stages, including embodied carbon, and their comparison against the 2030 upfront-carbon targets [15]. Scenario 2, which incorporates a set of low-carbon construction alternatives, demonstrates a 28% reduction in upfront embodied carbon relative to Scenario 1 and remains comfortably within the 2030 performance threshold. This highlights the considerable carbon-saving potential of substituting conventional materials with lower-impact options at early design stages.

Building on these carbon results, Fig. 4 illustrates the corresponding reusability and recyclability potentials derived from the proposed circularity metrics. The recyclability/reusability potential is defined as the percentage of the building's total embodied carbon that can be potentially recycled/reused at end-of-life. These metrics provide an indicative interpretation of LETI and EU recommendations by assessing whether each material can, in principle, be reused or recycled, and by weighing each material's contribution relative to its embodied-carbon share within the building. Using this method, both scenarios achieve nearly identical circularity outcomes—approximately 72% reusability and 93% recyclability—indicating that the adoption of low-carbon materials does not diminish the building's capacity to retain materials in circulation. Scenario 2 therefore delivers substantial carbon reductions while maintaining the same level of reusability and recyclability as Scenario 1, demonstrating that enhanced circularity and reduced embodied carbon can be achieved simultaneously without performance trade-offs.

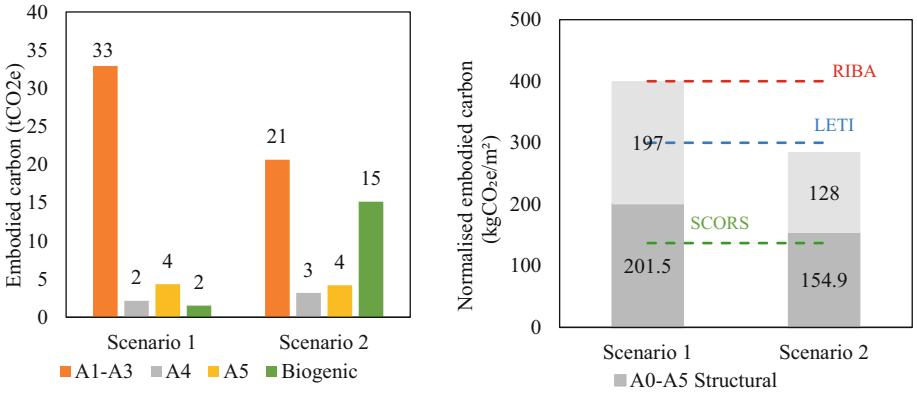

Fig. 3. Estimated embodied carbon (tCO_2e) by lifecycle stages (left) and comparison to 2030 targets ($kgCO_2e/m^2$) (right).

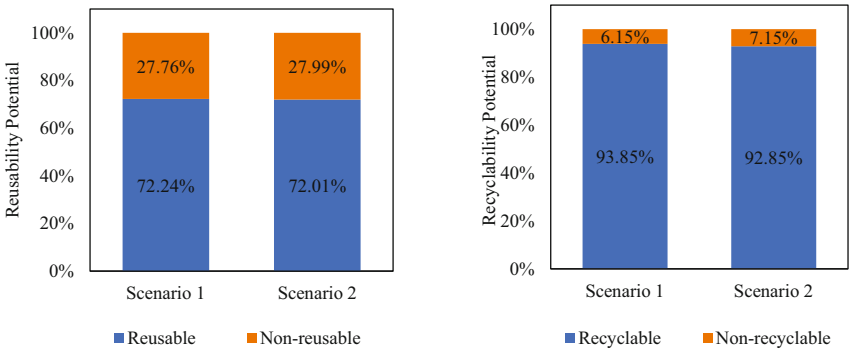

Fig. 4. Reusability (left) and recyclability (right) embodied carbon potential.

5 Conclusions

This study assessed the upfront embodied-carbon and circularity performance of a modular UK dwelling using the enhanced LJMU A0–A5 Upfront Carbon Tool. The scenario analysis showed that targeted material substitutions—such as higher GGBS content, anhydrite screed, EAF-produced steel, and bio-based alternatives—reduced upfront embodied carbon by 28% without affecting circularity, which remained at approximately 72% reusability and 93% recyclability. The circularity metrics used provide indicative alignment with LETI and EU objectives, though actual recyclability varies by product characteristics and available treatment pathways. Standardised recyclability indicators within EPDs, together with stronger domestic recycling infrastructure and clearer frameworks for certifying reusable materials, are needed to support more accurate assessments and wider adoption of circular practices. Overall, the findings demonstrate that modular construction, early material optimisation, and whole-building carbon assessment can jointly advance progress toward 2030 low-carbon and circular-economy targets.

Abstract. Modular steel buildings (MSBs) are increasingly recognised as a sustainable construction solution due to their ability to reduce construction time, material waste, and environmental impact compared with conventional building systems. Their prefabricated nature also supports circular construction through the potential reuse and reconfiguration of modular units and structural components. In such systems, inter-module connections (IMCs) play a critical role in ensuring structural stability, efficient load transfer, and rapid on-site assembly. Rotary-type IMCs are frequently adopted to accommodate construction tolerances, simplify installation, and facilitate efficient modular assembly. However, their influence on the axial global stability of sway frames in MSBs remains insufficiently understood. This study investigates the axial global stability of corner and interior sway frames assembled with rotary-type IMCs through experimental and numerical approaches. Five full-scale sub-assemblage specimens were tested under axial compression to evaluate load–displacement behaviour, failure modes, and stability mechanisms. A finite element model was developed and validated against the experimental results, followed by parametric analyses examining the effects of beam–column stiffness ratio, member gaps, discontinuities, and group configurations on axial capacity. The results indicate that axial instability is mainly governed by lateral sway, second-order effects, and local buckling of upper columns, while rotary-type IMCs effectively transfer forces without premature failure and support efficient modular assembly, enabling demountability and reuse of modular units across multiple lifecycle stages. These findings contribute to design considerations for resilient, reusable, and resource-efficient MSB systems aligned with circular and sustainable construction principles, promoting resource efficiency and lifecycle extension.

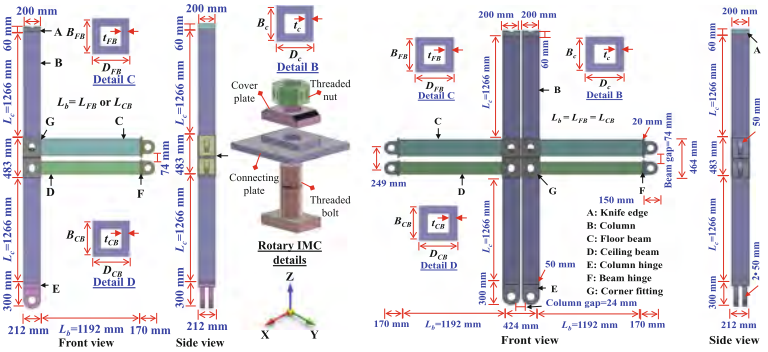
1 Introduction

Modular steel buildings (MSBs) use factory-produced modules that enable rapid assembly, disassembly, and reuse, offering a sustainable construction approach characterised by high prefabrication and reduced material waste, supporting circular construction principles [1]. In this context, design for disassembly is essential to enable lifecycle extension and resource efficiency in the built environment. Conventional welded inter-module connections (IMCs), although structurally efficient, hinder disassembly and limit reuse potential. In contrast, demountable systems such as rotary-type IMCs facilitate rapid assembly and disassembly while maintaining structural integrity, supporting repeated module reuse and reducing construction and demolition waste. In MSBs, IMCs between adjacent modules govern structural stability and load transfer but introduce discontinuities/groupings in structural members, significantly influencing global behaviour. Various IMC systems, including welded, bolted, shear-keyed, pre−/post-tensioned, self-locking, and rotary-type connections, have been investigated under different loading conditions [2–4]. However, unlike conventional steel frames, IMCs often behave as semi-rigid connections, altering stiffness distribution and effective column lengths, making direct application of traditional stability design methods uncertain [5]. Rotary-type IMCs are increasingly adopted due to their demountability, tolerance accommodation, and construction efficiency. Nevertheless, experimental studies on the axial global stability of rotary-connected modular frames under realistic boundary conditions remain limited, with most existing work focusing on grouped columns with idealised fixed conditions [6, 7]. Therefore, this study investigates the axial global stability of corner and interior modular sway frames with rotary-type IMCs through five full-scale experiments and refined finite element (FE) parametric modelling. The findings improve understanding of modular frame behaviour with demountable connections and support the design of reliable, adaptable, and resource-efficient MSB systems aligned with circular construction principles and lifecycle-oriented design strategies.

2 Experimental Investigation of Modular Sway Frames



2.1 Specimens and Test Setup

Three corner (RS1–RS3) and two interior (RDD-1 and RDD-2) frame specimens were fabricated using rotary-type IMCs based on a five-storey MSB prototype designed according to GB50017-2017 [8]. The corner frames had a height of 3375 mm and width of 1568 mm, while the interior frames had a width of 3160 mm. Columns were 200 × 200 × 8 mm, while the floor beam (FB) and ceiling beam (CB) had widths of 150 mm with depths of 200 mm and 150 mm, respectively (Table 1). To investigate the influence of the beam–column stiffness ratio, the thickness of the FB and CB was varied (6 mm and 8 mm), as shown in Fig. 1a, b. Material properties were obtained from tensile tests in accordance with GB/T228.1-2010 [9] and used in the subsequent FE modelling. The assembled frames were tested under axial compression applied to the top column using a hydraulic jack with a knife-edge hinge (Fig. 2a, b). A 20% preload was applied for alignment, followed by force-controlled loading to yielding and displacement control to

failure or 85% of ultimate load. Beam-end rollers allowed in-plane rotation and horizontal displacement while restraining out-of-plane movement, thereby simulating realistic sway boundary conditions in MSBs.

Table 1. Design details and capacity of sway modular corner and interior frames

Specimen	Floor beam (mm)	Ceiling beam (mm)	Column (mm)	Capacity (kN)
RS1	150 × 200 × 8 × 1192	150 × 150 × 6 × 1192	200 × 200 × 8 × 1266	1397
RS2	150 × 200 × 8 × 1192	150 × 150 × 8 × 1192	200 × 200 × 8 × 1266	1279
RS3	150 × 200 × 6 × 1192	150 × 150 × 6 × 1192	200 × 200 × 8 × 1266	1244
RDD-1	150 × 200 × 8 × 1192	150 × 150 × 6 × 1192	200 × 200 × 8 × 1266	3793
RDD-2	150 × 200 × 8 × 1192	150 × 150 × 8 × 1192	200 × 200 × 8 × 1266	3646

2.2 Failure Modes

All specimens exhibited similar instability mechanisms characterised by in-plane lateral sway, local column buckling, and rotation at the IMCs (Fig. 4 a–e). As axial load increased, horizontal displacements of the FB and CB governed global sway, strongly influenced by the beam–column stiffness ratio. In corner frames, thinner FBs resulted in larger sway responses, whereas thicker beams enhanced stiffness and reduced lateral displacement. At ultimate load, local buckling occurred primarily in the upper columns

(a) Test setup for modular corner frame (b) Test setup for modular interior frame

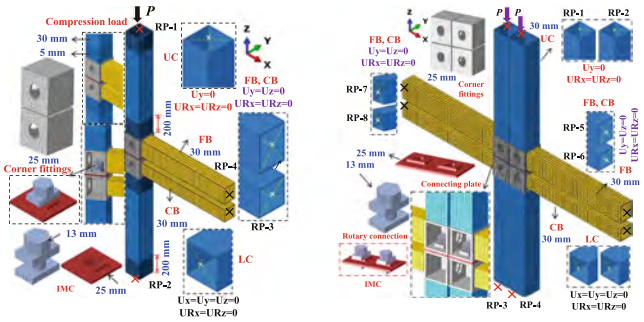
Fig. 2. General compression testing setup of sub-assembled rotary-connected frames

near the connection zones, typically within 50–200 mm of the column ends, forming a characteristic S-shaped deformation pattern. The lower columns generally remained elastic. Rotary IMCs effectively transferred forces without local failure, maintaining overall structural integrity. Interior frames exhibited similar behaviour; however, specimen RDD-2 showed greater lateral deformation and earlier instability due to its lower beam stiffness compared with RDD-1.

2.3 Load–Displacement Behaviour

All specimens exhibited three response stages: elastic, inelastic, and post-peak softening (Fig. 5 a–e). In the elastic stage, load increased approximately linearly with displacement until yielding. During the inelastic stage, stiffness progressively decreased due to local buckling in the upper columns. Beyond the ultimate load, the response entered a descending branch characterised by increasing sway and rapid strength degradation. Specimens with higher beam stiffness showed greater capacity and initial stiffness, whereas frames with more flexible beams exhibited enhanced ductility and larger post-peak deformation. These results highlight the critical role of the beam–column stiffness ratio and the semi-rigid behaviour of IMCs in governing the global stability and ductility of modular sway frames.

3 Numerical Modelling and Parametric Analysis



3.1 Finite Element Modelling

A nonlinear FE model was developed in ABAQUS to investigate the stability behaviour of the frames, using C3D8R solid elements with mesh refinement near the column roots (or top) to capture local buckling (Fig. 3 a, b). Linear eigenvalue buckling analysis identified critical modes, followed by nonlinear Riks analysis to simulate post-buckling behaviour. Material properties were derived from tensile tests, assuming Poisson's ratio of 0.3. Boundary and loading conditions were applied using reference points: lower columns permitted in-plane rotation, beams restrained vertical movement, and upper columns allowed both rotation and translation. Beam–column joints were modelled

using tie constraints, while rotary IMCs were defined through surface-to-surface contact with a friction coefficient of 0.3. Initial geometric imperfections, based on the lowest buckling mode, were introduced to capture global sway, local buckling, and second-order effects observed experimentally, with amplitudes taken as $H/600$ or $0.64t_c$ (where H is the specimen height and t_c is the column wall thickness) for local imperfections, and eccentricities of $e = 3.35D_c/7$ (corner) and $e = 3.35D_c/100$ or $7D_c/500$ (inner frame), where e is the eccentricity and D_c is the column cross-section dimension.

3.2 FE Model Validations

The FE model was validated by comparing predicted load–displacement responses and global/local failure modes with experimental results (Figs. 4 a–e and 5 a–e). For RS1–RS3, the average differences were 0.3% in capacity, 9.1% in stiffness, and 8.5% in ductility. For RDD-1 and RDD-2, the predicted values differed from the tests by approximately 1%, 3.2%, and 7.9%, respectively. The model accurately reproduced the observed S-shaped local buckling of upper columns and sway deformation, confirming its capability to capture the mechanical behaviour of modular frames with rotary-type IMCs.

(a) FE model of modular corner frame (b) FE model of modular interior frame

Fig. 3. Verified FE model details of the rotary-connected modular frames

3.3 Parametric Analysis

A parametric study examined the influence of beam and column cross-sectional dimensions, member lengths, connection plate thickness, gaps, and member grouping on frame stability (Fig. 6 a–h). Increasing beam thickness or depth enhanced capacity and stiffness, whereas more flexible beams improved ductility and deformation capacity. Similarly, increasing column size and thickness significantly improved capacity and stiffness by reducing slenderness. In contrast, increasing member length reduced buckling resistance due to higher slenderness, although greater deformation capacity developed prior to failure. Parameters such as beam–column gaps and connection plate thickness had only minor influence. However, increasing the number of columns significantly enhanced load-carrying capacity (up to 482%) and stiffness (approximately 384%) due to load

redistribution, demonstrating a strong grouping effect. Beam–column stiffness ratio, member grouping, and slenderness were identified as the dominant factors governing frame stability, while rotary-type IMCs effectively transferred forces without failure, supporting structural reliability and reusability.

4 Implications for Circular Modular Construction

The results demonstrate that modular sway frames with rotary-type IMCs achieve stable structural performance under compression while enabling demountable and reusable systems. From a circular construction perspective, their ability to facilitate assembly and disassembly without compromising structural integrity offers a clear advantage over conventional welded or grouted connections, which restrict reuse, require additional working space, and often lead to material downcycling at end of life. Rotary IMCs enable modular units to be disassembled, relocated, and reconfigured for multiple use cycles, extending the service life of structural components. This supports design-for-disassembly principles and reduces construction and demolition waste, while improving material efficiency and lowering demand for new structural steel. From a lifecycle perspective, the reusability and adaptability of such systems indicate strong potential for reducing embodied carbon associated with material production and end-of-life processes. Compared with conventional monolithic construction, modular systems with reusable connections can support closed-loop material cycles, retaining components at higher value across multiple reuse stages. The observed structural reliability and absence of premature connection failure confirm that rotary-connected systems are suitable for practical implementation. Their compatibility with rapid assembly, disassembly, and transportation aligns with industrialised construction practices emphasising off-site manufacturing, reduced labour, and increased productivity.

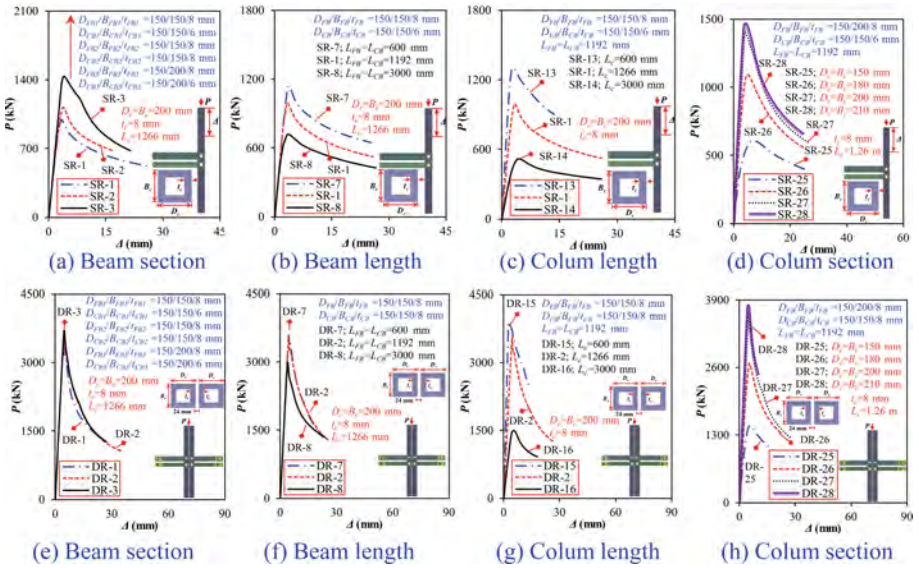

Fig. 6. Parametric study outcomes on the load-shortening curves of modular frames

5 Conclusions

This study investigated the axial global stability of rotary-connected modular corner and interior sway frames through five sub-assemblage experiments and FE parametric modelling. All specimens exhibited typical elastic, inelastic, and post-peak softening responses, with failure governed by in-plane sway instability and local S-shaped buckling of upper columns at the column top or near the IMC regions. The FE model accurately reproduced the experimental responses, including load–displacement behaviour, capacity, stiffness, ductility, and failure modes. Parametric analysis identified the beam–column stiffness ratio, member grouping, and slenderness as the dominant factors influencing stability, while connection plate thickness and module gaps had minor effects. Increasing the number of columns significantly enhanced capacity (up to 482%) and stiffness (approximately 384%) due to load redistribution. Rotary-type IMCs demonstrated

reliable force transfer and structural integrity, enabling demountable and adaptable modular systems. These findings support the development of resource-efficient MSBs with extended service life, aligned with circular construction principles.

Abstract. Modular construction is increasingly positioned as a pathway to circular economy goals through off-site manufacture, standardisation, and reductions in construction waste. However, these benefits do not necessarily translate into whole life carbon reductions for timber and steel modular building systems, where site waste forms a limited share of embodied emissions. This paper examines whether modular construction can support higher value circular strategies, specifically adaptability, deconstruction, and reuse at both module and sub assembly levels, rather than relying on waste minimisation claims alone. It combines a concise review of timber and steel volumetric modular systems with practitioner survey evidence, focusing on design approaches and connection strategies that influence disassembly and reuse. The results indicate that multi-cycle reuse is technically feasible when systems are explicitly designed for reuse, although current evidence more often reflects intended reuse or technical potential than verified repeated redeployment in practice. Prevailing industry practices such as irreversible interfaces, tightly integrated building services, and limited documentation continue to constrain adaptability and recovery in mainstream projects. The review also suggests that circular modular construction is unlikely to follow a single reuse model across all sectors, and that hybrid approaches may often be more realistic than full module redeployment in permanent applications. Across both materials, the enabling conditions that would enable modular reuse at scale are reversible joints, standardised interfaces, and digital documentation that supports traceability and consistent assessment.

1 Introduction

Modular construction is increasingly presented as a pathway to circular economy goals in the built environment because off-site manufacture, standardisation, and controlled production can reduce construction waste and improve delivery efficiency [1–4]. However, these advantages do not necessarily translate into meaningful whole-life carbon reductions for timber and steel modular building systems, where site waste represents only a limited share of embodied emissions [5]. This raises a more important question than waste minimisation alone, namely whether modular systems can support higher-value circularity such as adaptability, deconstruction, and reuse.

This paper examines circular modular construction through a concise review of policy and design themes supported by practitioner survey evidence. It focuses on timber and steel volumetric modular systems, since both are widely associated with circularity but present different technical and practical constraints for reuse. Particular attention is given to demountable connections, standardised interfaces, and digital documentation, as these influence whether modules and sub-assemblies can be disassembled, reassessed, and redeployed in practice. The paper therefore considers not whether modular construction is circular in principle, but under what conditions it can support credible multi-cycle reuse.

2 Circularity, Demountability, and Reuse in Modular Systems

2.1 Regulatory Context

Current policy and industry guidance increasingly frame circularity in construction in terms of whole-life carbon, adaptability, durability, reuse, and traceability rather than waste diversion alone. This is reflected in recent European and UK frameworks, including the Circular Economy Action Plan, the recast Energy Performance of Buildings Directive, PAS 2080, and the UKGBC Whole Life Carbon Roadmap, all of which place emphasis on retaining material value through longer service life, recovery, and reuse [6–9]. Within this context, modular construction is often presented as a favourable delivery model because standardisation, off-site manufacture, and kit-of-parts logic may support disassembly and future redeployment. However, the policy direction does not imply that modular construction is circular by default. For both timber and steel modular systems, the relevance of modularity to circular construction depends on whether systems are designed and documented in a way that supports adaptability, disassembly, and reuse across more than one life cycle.

2.2 Demountability and Reuse in Timber and Steel Modular Systems

At system level, the circular potential of modular construction depends on whether buildings, modules, or sub-assemblies can be disassembled and reused without disproportionate technical, logistical, or regulatory difficulty. In timber modular systems, this potential is evident across several project types, but case studies also show that intended reuse through relocation is not always realised. Volumetric timber projects such as

PLACE/Ladywell and Y:Cube (London, UK) were both conceived around demountable modular housing, yet their reuse trajectories remain shaped by condition, regulation, and redeployment constraints. Other projects, including HASLE TRE (Oslo, Norway) and Krokodil (Winterthur, Switzerland), embed circularity more explicitly through demountable timber connections and design strategies intended to support future recovery, even where second-life reuse has not yet been demonstrated. Evidence from reusable panelised systems further shows that timber demountability depends not only on structural concept, but also on controlled disassembly, grading, storage, transport, and the ability to adapt future design to recovered material [10–12].

Steel modular systems present a somewhat different picture because repeated redeployment is already more established in parts of practice, particularly in relocatable buildings and commercial modular supply chains. Demonstrator projects such as the Legacy Living Lab and M-Box 1.0, as well as supplier-based systems such as Portakabin and Algeco, show that repeated relocation is feasible when module typology, lifting strategy, and service integration are compatible with reuse. However, system-level reuse remains constrained by factors beyond the primary structure, including cavity barriers, integrated services, acoustic and fire layers, tolerance accumulation, and the effort required to reassess recovered modules [13–16].

Across both timber and steel systems, demountability is therefore shaped not only by the structural frame, but by the extent to which the wider building system supports separation, handling, reconfiguration, and future compliance. The case evidence is uneven and often reflects intended or potential reuse rather than verified multi-cycle redeployment, so a distinction is needed between nominal demountability, recovery after a single disassembly event, and verified reuse across repeated cycles. Verified redeployment is more evident in portable and relocatable sectors than in permanent modular schemes, where service integration, procurement, financing, and long-term occupation create different constraints.

2.3 Connection-Level Demountability in Timber and Steel Modular Systems

While system strategy determines the overall possibility of reuse, practical demountability is governed to a large extent by connection design. In timber modular systems, connection detailing strongly affects whether structural elements can be separated without local damage that reduces reuse potential. Reviews of reversible timber connections show that dry mechanical systems are generally more compatible with adaptability, disassembly, and reuse than adhesive or heavily invasive fixing methods, particularly where inelastic demand can be concentrated in replaceable steel components rather than in the timber itself [17, 18]. This direction is illustrated in Fig. 1, where Fig. 1a shows a practical dry timber connection designed for reversible assembly, while Fig. 1b shows the MOD-IT connection, which more explicitly addresses disassembly and reuse at the interface level.

In steel modular systems, a similar distinction arises between connections developed primarily for erection efficiency and those developed with demountability and repeated use more directly in mind. Inter-module connections for hot-rolled steel modular buildings include a wide range of mechanical, interlocking, and hybrid arrangements, but their design is often governed by alignment, force transfer, and assembly requirements in first

use rather than by multi-cycle reuse [19]. This contrast is reflected in Fig. 2, where Fig. 2a shows a practical steel inter-module connection for modular assembly, while Fig. 2b shows the interlocking concept proposed by Corfar and Tsavdaridis [20], developed more directly around demountability and reuse. For both materials, the comparison highlights that connection design determines whether modules and sub-assemblies can be dismantled, inspected, and redeployed with acceptable effort and damage.

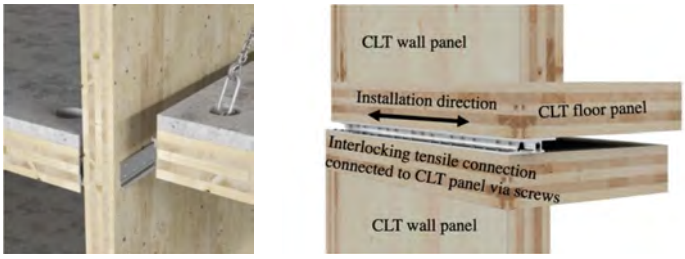

Fig. 1. Examples of demountable timber connection systems: (a) Rothoblaas LOCK FLOOR connector [19] and (b) MOD-IT connection [18].

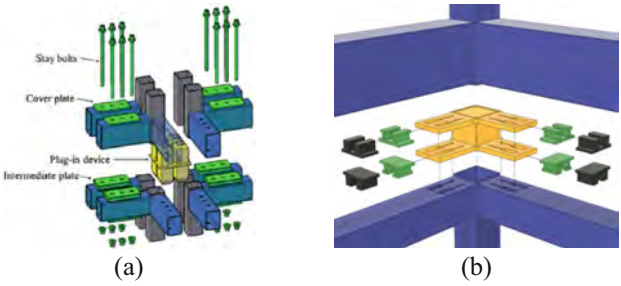

Fig. 2. Examples of demountable steel inter-module connection systems: (a) plug-in bolted connection and (b) interlocking connection [21].

3 Questionnaire Survey Method

To complement the review, an international questionnaire survey was conducted to capture practitioner perspectives on modular construction in relation to circularity, with particular attention to barriers, reuse pathways, and enabling measures. The questionnaire was developed by the authors, refined through internal review, and administered online between September and November 2025 using purposive sampling through professional networks and project partners. A total of 33 respondents participated, including structural engineers, architects, manufacturers, contractors, researchers, and clients from

the UK, Northern Europe, Italy, Canada, and Australia. The survey combined closed-ended questions, including Likert-scale and multiple-choice items, with optional open-text responses addressing industry attitudes, barriers to adoption, adaptability, reuse, disassembly of different connection types, and the adequacy of current standards and documentation approaches. Results are reported using descriptive statistics and thematic reading of open comments. Given the modest sample size, the survey is treated as exploratory and indicative rather than statistically generalisable and is used to triangulate themes identified in the literature.

4 Survey Findings and Discussion

Within the survey sample, practitioner responses indicate that modular construction is generally viewed positively and is strongly associated with circular economy objectives, particularly adaptability, ease of deconstruction, and reuse. However, respondents linked circular value not to off-site manufacture alone, but to whether systems can be disassembled, reconfigured, and redeployed in practice. As shown in Fig. 3, respondents rated modular construction as highly relevant to adaptability, deconstruction, and reuse, indicating that these higher-value circular strategies are already central to how modularity is understood in practice.

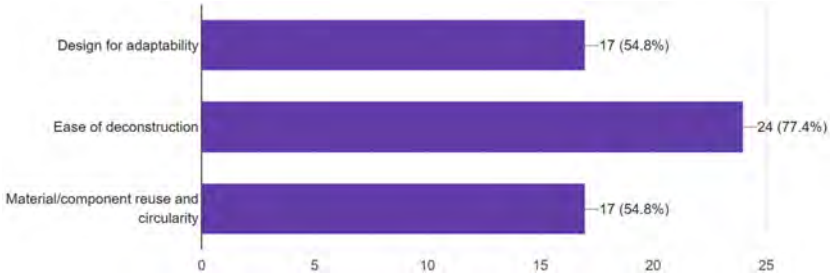

Fig. 3. Practitioner appraisal of the relevance of modular construction to (1) design for adaptability, (2) ease of deconstruction, and (3) material or component reuse and circularity.

The survey also shows that the main barriers to circular modular construction are not only technical. Respondents most frequently identified lack of standardisation, high initial cost, regulatory and approval challenges, and market perception or customer acceptance. This suggests that even where modular systems are physically recoverable, reuse may remain limited if there is no clear pathway for assessment, compliance, and acceptance in subsequent applications.

The survey also highlighted the importance of connection design as a technical issue. Respondents viewed bolted steel connections more consistently favourably in relation to disassembly, with responses clustered toward the lower end of the difficulty scale, whereas timber connections using steel plate interfaces were also viewed relatively favourably but with a broader spread of responses. As shown in Fig. 4 a, b, bolted steel connections were more clearly associated with lower perceived disassembly difficulty,

while timber connections using steel plate interfaces received a more mixed, though still generally favourable, assessment. This is consistent with the review evidence, which indicates that practical reuse depends on whether interfaces allow controlled disassembly, limited local damage, and subsequent reassessment.

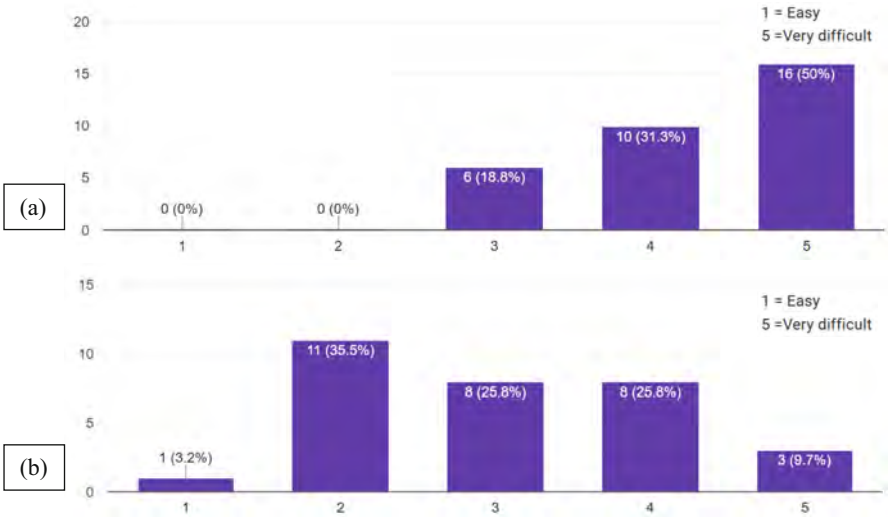

Fig. 4. Practitioner appraisal of the perceived disassembly difficulty of selected connection types in modular systems: (a) bolted steel connections and (b) timber connections using steel plate interfaces.

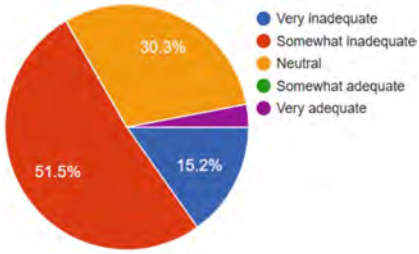

Fig. 5. Practitioner appraisal of the perceived adequacy of current design codes and guidelines in addressing modular construction and connection design.

A final theme concerns standards, guidance, and digital documentation. Respondents expressed limited confidence that current codes and guidelines adequately address modular construction and connection design in relation to circularity, as shown in Fig. 5. They also placed high value on digital documentation, particularly product or module passports, standardised structural assessment procedures, deconstruction manuals, and as-built BIM information. The survey therefore indicates that reuse at scale depends not

only on reversible technical design, but also on traceability, assessment protocols, and clearer approval routes.

5 Conclusions

This paper examined circular modular construction through a concise review of policy and design issues supported by practitioner survey evidence focused on timber and steel modular systems. The results indicate that modular construction is viewed as relevant to circular economy goals but also show that modularity alone is insufficient to deliver higher-value circular outcomes. Across both the review and the survey, circularity was shown to depend less on waste reduction than on whether systems are designed and documented to support adaptability, disassembly, reassessment, and potential reuse across multiple life cycles.

The reviewed evidence also suggest that circular modular construction is unlikely to follow a single reuse model across all sectors. In traditional permanent modular applications, demountability may remain central, but higher-value reuse may depend less on relocating whole modules (for social mobility and economic reasons) than on enabling adaptation, reconfiguration, and flexibility over time. Hybrid (combined) approaches may therefore be more realistic than assuming full module redeployment for all modular systems.

In both timber and steel modular systems, this depends strongly on connection strategy and interface design. Reversible joints, accessible detailing, and standardised interfaces are therefore central conditions for practical reuse. At the same time, the survey shows that the barriers to circular modularity are not only structural or material related. Practitioners identified standardisation gaps, regulatory uncertainty, and limited documentation for reuse as major constraints, while digital product or module passports, standardised reassessment procedures, and clearer approval workflows were consistently identified as important enablers.

Overall, circular modular construction should be understood as a design, documentation, and governance-dependent pathway rather than as an automatic consequence of off-site manufacture. The key issue is no longer whether modular systems can support reuse in principle, but how to make reuse reliable in practice. Future work should develop frameworks to assess damage, material degradation, overall condition, and thus reuse potential across repeated disassembly and redeployment cycles.

Abstract. Reusing structural steel can deliver substantial embodied carbon savings (up to 98% versus "new" steel, and 88% vs. recycled), yet barriers remain to scaling. The UK provides an early policy-led signal, with reuse concentrated in London commercial developments where circular economy statements and pre-demolition audits are required for referable planning applications. This paper synthesises 4 years of industry-embedded research across six Innovate UK-funded projects: over 60 semi-structured interviews, nine supply chain site visits spanning production, stockholding/processing, fabrication, construction, and demolition, and a database of 35 UK steel reuse projects delivered in 2022–2025 (15 analysed in depth). UK practice is predominantly member-level reuse (beams and columns) rather than whole-frame relocation, increasing the need for early identification, matching, verification, and logistics. Evidence from the project database (21/35 projects in London; 16/35 commercial) and stakeholder accounts points to three recurring constraints: (1) high-stakes selection decisions under uncertainty in member condition and provenance; (2) limited visibility of forthcoming donor buildings and weak mechanisms to share reuse-relevant information across organisations; (3) misaligned end-of-life incentives, with demolition contractors carrying programme and liability risks while receiving limited incentives for recovered material; and (4) commercial sensitivity to steel price volatility. The paper identifies a focused set of scale-up interventions: strengthening selection capability for donor buildings and members, improving donor-building visibility and traceability infrastructure, aligning incentives through procurement and fiscal mechanisms, and recognising donor-side recovery through clearer reporting and reward structures. These findings provide practical insights for scaling circular steel markets.

1 Introduction

Steel reuse avoids remelting, retains component value, and can deliver substantial embodied carbon savings [1]. The UK is currently the leading market for structural steel reuse, with a large number of implemented projects and an expanding body of industry guidance, and provides an informative early market for understanding how reuse can move from isolated pilots towards repeatable practice, particularly in commercial developments in large cities where planning requirements and whole-life carbon narratives have created a clearer demand signal [2]. Yet uptake remains uneven and difficult to scale, particularly where donor-side recovery is commercially risky and where information on forthcoming donor buildings and reusable inventories is limited [1, 3–5].

Drawing on 4 years of industry-embedded research across six Innovate UK-funded projects (DISRUPT [1], DISRUPT II [6], ARMOUR [7], E-TRACS [8], RE-CELL [9], and HARNESS [10]), we synthesise evidence from 60+ interviews, nine site visits, and a database of 35 UK steel reuse projects delivered in 2022–2025, including 15 analysed in depth [1, 6, 11].

Three questions are addressed:

RQ1: What characterises the UK steel reuse market in 2022–2025?
RQ2: What constraints limit scaling-up?
RQ3: What interventions are most plausible for unlocking bottlenecks?

The paper contributes an empirical profile of recent UK activity, evidence on how policy, incentives, and information shape donor-side supply, and a focused set of scale-up interventions grounded in current delivery conditions.

2 Background

In the UK, around 50,000 buildings are demolished annually [12], releasing large volumes of high-quality structural steel. Most of these (93%) are routed to recycling rather than reuse [13]. At the same time, around 80% of UK scrap is exported for processing overseas, reflecting constraints in domestic recycling capacity [14]. Based on published A1–A3 EPDs and benchmark data, reusable steel is reported as 69.5 $kgCO_2e/t$ [15], compared with 560 $kgCO_2e/t$ for recycled structural steel sections [16], and 1,850 $kgCO_2e/t$ for global average primary steel [17], highlighting the substantial embodied-carbon advantage of reuse. Reuse, therefore, offers both embodied carbon reduction and domestic material value retention.

Previous UK-focused work shows that the main barriers to structural steel reuse are systemic rather than purely technical. Reported constraints include cost, availability and storage, limited client demand, traceability, and supply chain gaps and lack of integration. The latter relates to incentives and coordination: unless there is visible demand and a clear financial upside, there is limited motivation to invest in the additional capability required for deconstruction, storage, and testing/verification, so reuse remains opportunistic rather than routine [3]. Another study [4] analysed how cost and risk are distributed across the UK construction value chain, noting that viability depends strongly on where marginal costs sit and who carries programme exposure. Key issues include the additional labour

and time associated with deconstruction and reconditioning (relative to demolition and new fabrication), as well as opportunity costs under tight fabrication programmes. The study highlights the value of intermediaries (for example, specialised stockists) that can take on sourcing, storage, reconditioning, and assurance, thereby reducing transaction costs and perceived risk for design and delivery teams. More recent synthesis work frames barriers at the ecosystem level, including limited material availability from demolition, challenges in maximising reusable outputs, gaps in design rules and standards, and high upfront costs. It also draws attention to decision-critical early choices (whether to deconstruct, what to target, and what evidence to capture) because these shape the downstream burden of testing, reconditioning, and redesign [5]. Given the rapid recent market development, updated evidence from delivered projects is needed.

3 Methodology

This study adopted an embedded qualitative research design, combining longitudinal engagement across applied research projects with interviews, site observations, and structured project documentation. This multi-method qualitative approach enabled triangulation between practitioner perspectives, observed practices, and evidence from implemented projects to detect patterns shaping the emerging steel-reuse market.

Interviews (n = 60+). Semi-structured interviews were conducted over 4 years across the steel reuse value chain. Participants included developers, structural engineers, architects, main contractors, steel contractors/fabricators, steel stockholders, demolition contractors, and pre-demolition auditors. Interviews explored decision drivers and criteria, practical constraints and opportunities, approaches used to manage verification and risk, and perceived intervention needs.

Site visits (n = 9). Site visits were undertaken to observe practices and operational constraints in context. These included demolition or deconstruction sites (2), fabrication facilities (3), steel stockholding and processing yards (2), and construction sites incorporating reused structural steel (2). Observations focused on decision points, logistical constraints, and information handovers between actors.

Project database (n = 35). A structured database of UK projects delivered between 2022 and 2025 with reclaimed structural steel was compiled. Inclusion criteria were: (i) projects located in the UK; (ii) reuse involving the removal and reuse of structural steel members (excluding adaptive reuse or retention in situ); and (iii) verification through public documentation and/or stakeholder confirmation. For 15 in-depth case studies, additional information on drivers, procurement routes, challenges, and lessons learned was triangulated through interviews and documentary sources [1, 6, 11].

Data analysis. Interview transcripts, case study notes, and site observations were analysed using thematic analysis. The material was systematically reviewed and categorised into key themes, including drivers of reuse, procurement models and risk allocation, information and traceability, cost and price sensitivity, and potential intervention mechanisms. Case studies were analysed using a structured template capturing procurement routes, relationships between donor and recipient buildings, reuse types, verification approaches, constraints, and lessons learned. Findings were refined through cross-case comparison and triangulation (validating observations and opinions) between interviews, site observations, and documentary evidence.

4 Findings and Discussion

4.1 Market Evolution, Profile, and Procurement Models

UK experience indicates a shift from earlier portal frame relocation in industrial buildings towards member-level reuse within commercial sector. Earlier documented activity (2004–2014) involved relocating whole frames or large assemblies, where matching and verification were comparatively straightforward [4]. Since 2022, projects have involved the reuse of individual beams and columns in new structures. This is more demanding because viability depends on early member selection, timely design matching, and decisions under uncertainty around coatings, damages, usable lengths, attachments, and provenance. London's policy context has been important in shaping this shift. Circular Economy Statements and stronger expectations for pre-demolition audits have helped to drive reuse consideration in major commercial schemes and encouraged the earlier generation of reuse-relevant information [2]. However, these demand-side signals alone do not mobilise donor-side supply.

Table 1 summarises UK projects with steel reuse completed in 2022–2025 (noting that projects to be completed in 2026 are excluded). Across the current dataset of 35 projects, reuse activity is concentrated in London (21/35) and in commercial developments (15/35), followed by industrial projects (8/35), 5 art/public realm, 4 residential, and 2 bridges. Industrial projects are more regionally distributed and mostly involve reclaimed tubulars reused as piling or foundation elements. Reuse of tubulars for piling has been established for some time, whereas reuse in commercial building projects has only gained momentum since 2022.

Reuse is predominantly member-level rather than whole-frame, increasing reliance on early identification of reusable members in donor buildings, matching to recipient design and programme, and verification pathways where provenance is uncertain.

Five procurement models were identified. In stockholder-driven open-market reuse, stockholders source, process, and sell recovered steel, broadening access but often increasing uncertainty around provenance and reconditioning scope. In client-driven portfolio reuse, a developer retains steel from a donor asset for use in a new project, simplifying provenance and verification but limiting wider market pooling. Hybrid procurement combines a known donor asset with reclaimed stock sourced from the market. Two further models were observed: demolition-contractor-led reuse, in which contractors recover steel for sale into reuse markets rather than scrap, and fabricator-led reuse, in which surplus or unused sections are retained for future use, typically with reconditioning and testing undertaken by specialist intermediaries. This latter model is not reported in Table 1, as although the steel was reclaimed, it has not been reported as reused, i.e. incorporated into a new structure. This suggests that a wider set of actors is beginning to capture value from reclaimed steel.

Within commercial projects, stockholder-led reuse (7 projects) and hybrid procurement (5 projects) dominate, with fewer pure client-led examples (2 projects). However, project counts alone may not reflect the scale of reuse. Hybrid projects often rely primarily on steel sourced from the client's own portfolio, supplemented by smaller quantities from stockholders. For example, at 30 Duke Street, the largest steel reuse commercial

project as of March 2026, most of the steel was reused from the client's portfolio, with only a smaller proportion sourced from stockholders.

4.2 Constraints and Scale-Up Priorities

Compared with earlier UK literature, some enabling conditions have improved. Interviewees reported greater awareness, stronger familiarity with design approaches, and the role of stockholders, capable of sourcing, storing, reprocessing, and managing testing of reclaimed steel. Storage remains a practical issue, but it is increasingly managed within stockholder yards and, in some demolition-led and fabricator-led cases, within existing operational space.

Four constraints nevertheless remain influential. First, demand is stronger but localised – London's planning regime provides a clearer compliance and reporting context, while incentives outside London yet remain weaker and less consistent. Second, donor-side incentives remain weak – demolition contractors face additional planning, handling, sequencing, and perceived liability risks when recovering steel for reuse, while carbon and circularity credit is captured in the recipient project narrative. Third, information gaps persist; limited visibility of forthcoming donor buildings and inconsistent member-level information increase the cost and uncertainty of verification and reconditioning. Fourth, reuse economics remain highly sensitive to steel price volatility and to uncertainty in member condition and reprocessing.

These findings suggest that scaling depends on improving the conditions for predictable delivery. Four priorities emerge. First, member- and building-level selection capability should be strengthened, because coatings, attachments, composite interfaces, connection details, and usable length directly affect reconditioning scope, testing needs, and programme risk. Second, donor-building visibility and interoperable information infrastructure should be improved by linking pre-demolition audits to standardised

member inventories and design requirements. Third, incentives should be better aligned through procurement and fiscal mechanisms, particularly where public procurement can create steadier demand. Fourth, donor-side recovery should be explicitly recognised through clearer reporting of recovered tonnes and routes to reuse, alongside contractual or fiscal mechanisms that reward deconstruction effort.

5 Conclusions

This paper provides an empirical profile of the UK structural steel reuse market in 2022–2025. Recent activity is dominated by member-level reuse in London commercial developments, reflecting stronger policy signals and carbon reporting requirements, but also increasing reliance on early selection, verification, and logistics. Market awareness and intermediary capability have improved, yet scaling remains limited by weak donor-side incentives, persistent information gaps, and cost sensitivity. To move from repeatable pilots to a broader circular steel market, interventions should focus on stronger selection capability, better donor-building information, more effective procurement and fiscal incentives, as well as clearer recognition of donor-side recovery. These lessons offer useful insights for other markets with structural steel reuse activity.

Abstract. Within the broader framework of the circular economy and sustainable construction practices, the reuse of structural components or systems offers a promising strategy for reducing the carbon footprint of new buildings. To enable the integration of existing elements into subsequent life cycles, it is essential to assess their condition and structural performance at the end of their initial service life. For trusses made from structural hollow-sections the reuse pathways could consider the use of the original truss or through cutting and subsequent welding of truss elements. Regardless of the chosen approach, a detailed evaluation of geometric imperfections accumulated during the first life cycle is required to ensure safe and reliable reuse. The study examines geometric imperfections in RHS steel truss members in two conditions: (1) immediately after fabrication, representing the baseline state, prior to the first service life and (2) after a first life cycle involving loading histories representative of serviceability and ultimate limit states from dead and snow loads. The tested elements correspond to top-chord members under eccentric compression, scaled for laboratory constraints. Imperfections were quantified using industrial laser scanning and dedicated processing software, enabling high-resolution assessment of geometric deviations. The measured values were compared with standard tolerance limits to evaluate compliance and detect potential degradation. Particular attention is given to the residual imperfections over the service life, as these may affect structural reliability for reuse.

Keywords: Truss Elements · Imperfections · Reuse · Tolerances

1 Constrains and Challenges in Reuse of Steel Elements

One of the main advantages of steel structural systems is their capacity to be reintegrated into new buildings at the end-of-life cycle. The residual value of steel becomes thus an important advantage as this reduces the ecological footprint of manufacturing compared to producing "virgin" steel. However, the reuse process bypasses the energy-intensive processes of recycling (by shredding, melting, and reforming) steel as shown by Yeung et al. [1]. While recycling plays a significant role in reducing the demand for primary raw materials, the direct reuse of steel components represents a substantially more effective strategy for lowering the environmental impact and conserving material and energy

resources. Currently, only about 11% of steel in Europe is reused, whereas approximately 88% undergo recycling [2]. Empirical assessments indicate that the reuse of steel elements can reduce environmental impacts by up to 95% compared with the production of new steel, underscoring its relevance for circular economic practices and sustainable construction [3]. However, in the process of deconstruction for reuse, several barriers could be encountered, as mentioned by Bartsch [4], such as material quality, integration in new design projects, lack of costumer interest or important costs for reconstruction.

Among the barriers to reusing steel elements, the importance of member imperfections could be considered as a challenge as these could affect the further reuse of elements, especially if stability of elements is among the design criteria of elements. The structural and geometrical imperfections could arise in manufacturing of the structure, its assembly and during the use of the structure. As shown by Smak and Straka, various reasons could lead to increased imperfections during the life cycle of structures, such as removal of elements or manufacturing [5]. Radwan and Kövesdi [6] proposed special buckling reduction factors for reclaimed steel members considering the increased imperfections accumulated during service life.

2 Experimental Tests

Fundamentally, the typical reuse of truss structures could be done in two ways: (i) either by the reuse of the entire truss roof structure or (ii) by reclaiming of individual elements by considering the structural disassembly and re-fabrication in new truss or individual members. While the first option is restricted by geometric limitation in transportation and careful disassembly of the full structure, the second possibility should integrate the cut-and-refabrication methodology. As shown by Brutting et al. [7], the re-fabricated elements could be re-integrated in new original truss members, steel masts or secondary structural members, such as purlins or girts in new buildings.

However, the new buildings should fulfil the actual normative conditions including strength, stiffness, material requirements and imperfections. If the firsts are common for usual design, the evaluation of imperfections should be carefully made as the elements could possess increased imperfections from previous life-cycle.

2.1 Selection of Testing Specimens

The study focuses on analysing a top-chord member from an industrial truss beam originally designed with a 30 m span and a 6 m bay, subjected to eccentric compression as described in [8], and subsequently scaled for laboratory testing. The scaling process preserved key similarity parameters, including the buckling resistance ratio, the width-to-thickness (c/t) ratio, and the non-dimensional slenderness, ensuring consistency between the original and scaled sections. Thus, the original top-chord member RHS200 $\times$ 120 $\times$ 80 of a 4 m length was scaled- down for laboratory testing RHS100 $\times$ 60 $\times$ 4 (S500) and a length of 1.5 m.

Ten testing specimens were conceived for testing as shown in Table 1 from which two were tested to buckling failure (MC-A-F), four to serviceability loading conditions

(MC-A-SLS) and the other four (MC-A-ULS) to ultimate loading conditions. The serviceability and ultimate limit state conditions were simulated using a hypothetical cyclic loading protocol. In the first stage, the permanent load (G_k) was applied, followed by a second stage involving progressively increasing cyclic loads to represent the design snow load (S_k) according to serviceability and respectively ultimate limit states acting on the truss structure [8].

Table 1. Description of MC-A experimental specimens.

Type of test	Specimen label	Type of load	Loading protocol	No. of specimens
Members in eccentric compression RHS 100 × 60 × 4	MC-A-SLS	SLS loading	Cyclic	4
	MC-A-ULS	ULS loading	Cyclic	4
	MC-A-F	Failure	Monotonic	2
	MC-A-SLS-F*	Failure after SLS	Monotonic	2
	MC-A-ULS-F*	Failure after ULS	Monotonic	2

*selected from the MC-A-SLS/ULS specimens, after initial SLS/ULS testing

2.2 Test Set-Up

Figure 1 shows the test set-up, which consists of specimens fixed at their ends by two pinned supports into a universal testing machine that applied the load in load control for SLS and ULS loading and displacement control specimens tested to for failure. The applied eccentricity was of 22.68 mm, in order to produce the similar moment to the non-scaled element (having an eccentricity of 58.22 mm).

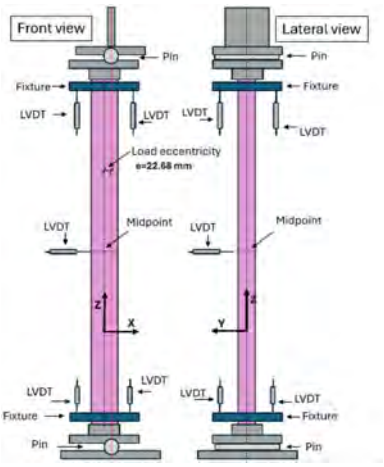

Fig. 1. Testing set-up for eccentric MC-A specimens.

To record deformations during testing, ten displacement transducers were used: eight LVDTs measured axial deformations and end rotations, while two additional LVDTs monitored mid-section deformation along the major axes.

2.3 Experimental Results: Cyclic Loading

Figure 2 presents the recorded transversal deformations for specimens MC-A-SLS-04 and MC-A-ULS-04, loaded in cyclic SLS and respectively ULS conditions.

As expected, for both specimens, the in-plane deformations (X-axis) are greater than the out-of-plane (Y axis) deformations due to the imposed axial eccentricity. For in-plane deformations, the maximum transient (7.2 mm) and the residual (2 mm) transversal deformations are more important in case of ULS loading than the values recorded in SLS conditions of 2.8 and 0.1 mm respectively. The recorded values show that a residual imperfection is recorded after loading.

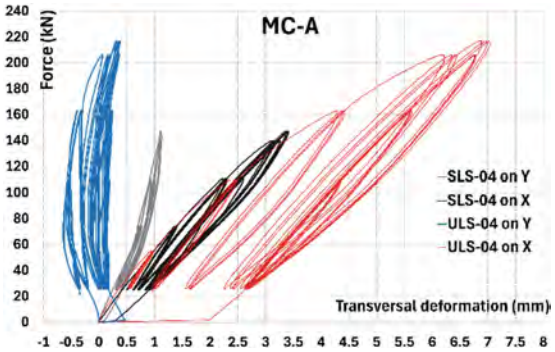

Fig. 2. Force – lateral deformation of the central cross-section response curves for specimens MC-A-SLS-04 and MC-A-ULS-04 under cyclic SLS/ULS loading.

3 Evaluation of Imperfections for RHS Truss Elements

Table 2. Values of initial and residual member imperfections after SLS/ULS tests.

Specimen	Initial imp. on *Y* (mm)	Residual imp. on *Y* (mm)	Initial imp. on *X* (mm)	Residual imp. on *X* (mm)
MC-A-F-01	0.059	–	0.053	–
MC-A-F-02	0.151	–	0.076	–
Average (F)	**0.105**	–	**0.065**	–
MC-A-SLS-01	0.173	0.250	0.023	0.335
MC-A-SLS-02	0.157	0.189	0.020	0.456

(*continued*)

Table 2. (*continued*)

Specimen	Initial imp. on Y (mm)	Residual imp. on Y (mm)	Initial imp. on X (mm)	Residual imp. on X (mm)
MC-A-SLS-03	0.105	0.183	0.009	0.508
MC-A-SLS-04	0.158	0.622	0.010	0.482
Average (SLS)	**0.148**	**0.311**	**0.016**	**0.445**
MC-A-ULS-01	0.088	0.446	0.023	1.417
MC-A-ULS-02	0.102	0.668	0.098	1.302
MC-A-ULS-03	0.103	0.433	0.077	1.442
MC-A-ULS-04	0.109	0.687	0.043	1.476
Average (ULS)	**0.101**	**0.559**	**0.060**	**1.409**

To capture the exact outer geometry of the elements, blue-ray laser scans were performed before and after cyclic testing. The resulting surface maps represented total imperfections, combining both local effects – such as thickness variations and surface waviness – and global member imperfections. Member imperfections were extracted by fitting a second-order polynomial to the measured surface profile, constrained to pass through the centroids of the end cross-sections and some nine equally spaced intermediate centroids as explained elsewhere [8]. Imperfections were evaluated along the two principal axes, X (in-plane) and Y (out-of-plane).

The full scanning of the elements can offer a difference between the local (sectional) and member imperfections. However, generally, the local imperfections can influence both the shape and magnitude of the resulting member imperfections.

Table 2 presents the values of maximum member (bow) imperfections obtained from scanning of specimens before and after cyclic loading at SLS/SLU conditions.

3.1 Initial Imperfections

Figure 3 shows as example the measured initial total imperfections for specimen MC-A-SLS-02 on X and Y axes, as well as the bow (member) imperfections obtained by polynomial fitting. The values are within the allowable tolerances specified in EN 1090-2:2008 [9] of 6 mm or $L/750$ (here 2 mm) for truss members. As observed in Table 2 similar values were obtained for all tested specimens. Considering the measured specimens, it can be observed that the largest initial imperfections are recorded in the direction of the weakest cross-section dimension (Y axis or out-of-plane direction).

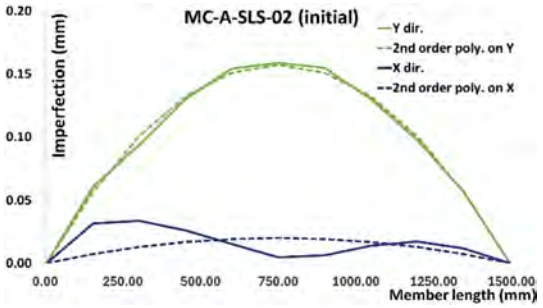

Fig. 3. Initial imperfections for MC-A-SLS-02 specimen.

3.2 Increased Imperfections After SLS/SLU Loading

Figure 4 shows the equivalent total in-plane (*X* axis) residual imperfections resulted on MC-A specimens after cyclic SLS (left) /ULS (right) conditions, in comparison to the initial imperfections. For both loading conditions, the residual imperfections after loading are much larger than the initial imperfections, as shown also in Table 2:

– average values of imperfections: 0.016 mm initial/0.445 mm after SLS loading;
– average values of imperfections: 0.006 mm initial/1.409 mm after ULS loading.

It could be mentioned that increased imperfections were recorded also in the Y direction (along the weaker cross-section dimension), but the differences are smaller. The obtained values are consistent with the recorded residual imperfections presented in Sect. 2.3.

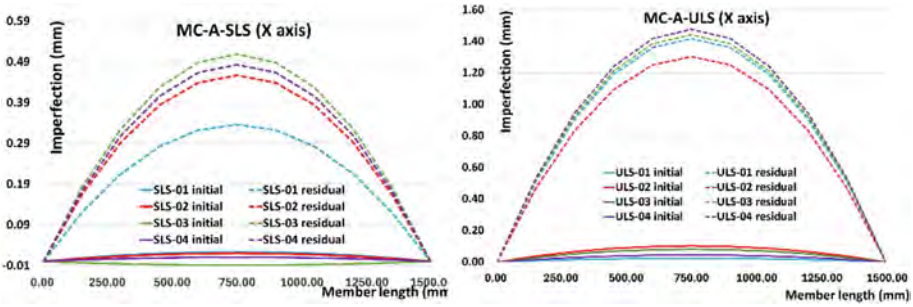

Fig. 4. Initial vs. increased residual total member imperfections after cyclic SLS/SLU loading.

4 Influence of Imperfections at Ultimate Loading

Figure 5 shows the resulting force – transversal deformation for the specimens loaded to failure: two virgin specimens (F-01 and F-02), two after SLS loading (SLS-01-F and SLS-01-F) and respectively two after ULS loading (SLU-01-F and SLU-01-F). Table 3

presents the synthetic values recorded during testing, as the maximum load, deformation at maximum load and axial shortening as well as the imperfections at the starting of loading.

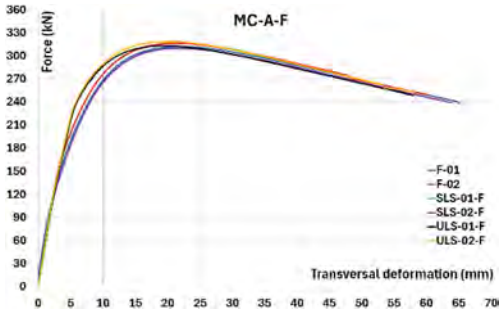

Fig. 5. Force – transversal deformation curves for MC-A-F specimens.

The specimens exhibit comparable responses, with similar maximum loads (F_{max}) and only minor amplitude variations of about 2.2%. The deformations recorded at F_{max} are within a narrow range of 20–23 mm. Comparable initial stiffness and stiffness in the unloading branches are observed as well. However, the ULS specimens display a noticeably stiffer behaviour in the pre-peak region up to F_{max}. The axial shortening recorded during loading is a direct consequence of the buckling deformation of the specimens.

Table 3. Synthetic values resulted from failure tests.

Specimen	Axial shortening (mm)	Maximum load F_{max} (kN)	Deformation at F_{max} Y axis (mm)	Initial imp. Y axis (mm)
MC-A-F-01	3.12	312.95	21.28	0.059
MC-A-F-02	2.71	310.22	22.89	0.151
MC-A-SLS-01-F	2.87	316.76	21.08	0.335
MC-A-SLS-02-F	3.12	317.35	20.86	0.456
MC-A-ULS-01-F	2.80	313.64	19.73	1.417
MC-A-ULS-02-F	2.89	319.72	20.25	1.302

All specimens failed by flexural buckling about the major inertial axis (X-axis), as illustrated in Fig. 6. This failure mode is consistent with the applied eccentricity. In a few specimens, however, minor deformations were also observed about the minor axis (Y-axis). The recorded results indicate that no intuitive correlation exists between the maximum forces achieved during testing and the initial geometric imperfections measured before the application of the failure load. This suggests a key conclusion: for RHS elements subjected to eccentric compression, the ultimate failure behaviour is

not significantly influenced by initial imperfections, provided these remain within the allowable limits prescribed by design standards.

Fig. 6. Failure by lateral flexural buckling of F-01 and ULS-01-F specimens.

5 Conclusions

The paper investigates the influence of geometric imperfections in reclaimed RHS steel truss elements subjected to eccentric axial loading, representing typical SLS and ULS life-cycle conditions with consideration for future reuse. Imperfections were quantified through 3D scanning of the specimens before and after testing Their significance was assessed by correlating the measurements with the ultimate load-bearing performance of the elements.

The geometric scans revealed that the total initial imperfections of the specimens were minimal, with average deviations of 0.12 mm about the minor inertial axis—substantially below the normative limit of 2 mm. Under eccentric axial compression, the mid-length transient deformations increased from roughly 3.2 mm (0.2% of the element length) under SLS loading conditions to 7.2 mm (0.48%) under ULS loading. A similar trend was observed for the residual member imperfections, idealized as a polynomial: mean values increased from 0.445 mm for SLS to 1.445 mm for ULS loading conditions.

Both the initial imperfections and the residual imperfections measured after SLS and ULS loading remained within the allowable limits prescribed by current design standards. Consequently, the reclaimed RHS elements satisfy the geometric criteria for reuse in a subsequent service life. Moreover, the experimental results indicate that the ultimate failure behaviour of RHS members subjected to eccentric compression is not significantly affected by prior SLS or ULS loading.

Sustainable Buildings, Infrastructures and Cities: Sustainability Assessment Frameworks, Sustainable Design, Construction, Operation and Management; Synergies Across Scales

Advancing Regenerative and Circular Building Practices in Kosovo: Pathways to Net-Zero and Low-Carbon Urban Development

Bahri Prebreza(✉)

University of Prishtina, Prishtina, Kosovo
bahri.prebreza@uni-pr.edu

Abstract. The transformation of Kosovo's built environment toward a regenerative and circular model represents an urgent step in aligning national development with European sustainability frameworks. The country's building sector, characterized by outdated construction practices, low energy efficiency, and limited integration of renewable energy, contributes significantly to greenhouse gas emissions and resource inefficiency. This study aims to explore transformative pathways for achieving net-zero and carbon-neutral buildings in Kosovo, emphasizing systemic change across design, policy, and practice.

This research adopts a qualitative policy-analysis and comparative literature review approach, supported by synthesis of secondary quantitative energy performance data derived from existing studies, institutional reports, and national energy strategies.

The study proposes a framework for accelerating the circular transition of Kosovo's building sector through three core strategies: mainstreaming renewable energy technologies in urban planning, promoting adaptive reuse and energy-retrofitting of existing buildings, and establishing participatory governance models that integrate scientific, industrial, and community expertise.

The research highlights Kosovo's potential to contribute meaningfully to a regenerative and low-carbon built environment in Southeast Europe.

Keywords: Circular Economy · Net-Zero Buildings · Renewable Energy Integration · Regenerative Architecture · Energy Efficiency · Sustainable Urban Development

1 Introduction

Kosovo's transition toward a regenerative and circular built environment is increasingly recognized as a strategic priority for aligning national development with European sustainability agendas and climate commitments. The building sector in Kosovo remains one of the largest consumers of energy and a significant contributor to greenhouse gas emissions, largely due to aging building stock, insufficient thermal insulation, inefficient heating systems, and the continued reliance on fossil-fuel-based electricity. In addition, conventional linear construction practices - characterized by high material consumption, limited recycling, and short building life cycles - further intensify environmental pressures and resource depletion.

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 583–590, 2026.
https://doi.org/10.1007/978-3-032-34930-9_68

Recent European policy frameworks, including the EU Green Deal, the Energy Performance of Buildings Directive (EPBD) recast, and circular economy action plans, provide a reference model for transforming the built environment toward climate neutrality. For Kosovo, adopting similar principles requires a systemic shift that integrates energy efficiency, renewable energy technologies, and circular material flows throughout the entire building life cycle - from design and construction to operation, renovation, and end-of-life recovery. The building sector plays a crucial role in global efforts to mitigate climate change and improve energy sustainability. Buildings account for nearly 40% of global energy consumption and approximately 36% of energy-related greenhouse gas emissions, making them one of the most critical sectors for decarbonization strategies. Similar trends are evident in Southeast Europe, including Kosovo. The majority of the building stock was constructed during periods when energy performance standards were minimal or nonexistent. Consequently, many residential and public buildings suffer from poor insulation, inefficient heating systems, and outdated construction materials [1].

Kosovo faces major challenges in achieving a sustainable energy future while addressing climate change and reducing carbon emissions. With its current reliance on lignite, the country must shift toward renewable sources like solar, wind, hydropower and other renewable sources [2].

Recent studies highlight the critical role of the building sector in Kosovo's energy and climate transition. According to a national energy efficiency assessment supported by the World Bank [1], buildings account for approximately 47–48% of Kosovo's final energy consumption, making them the largest energy-consuming sector in the country. In addition, the total building stock is estimated at around 45 million m^2 of floor area, of which nearly 75% consists of residential buildings, reflecting the dominance of household energy demand in the overall energy system [3]. Energy intensity in Kosovo's residential sector is estimated at about 278 kWh/m^2 per year, significantly higher than the EU average and approximately 25% above the Western Balkan average, largely due to inadequate insulation, inefficient heating systems, and outdated construction practices [4, 8].

Energy efficiency interventions in public buildings alone could achieve 30–50% reductions in energy consumption, demonstrating the large impact of building retrofits and technological upgrades [5, 9]. At the same time, Kosovo's energy system remains heavily dependent on fossil fuels, with roughly 90% of energy production derived from fossil sources, which significantly increases the carbon intensity of buildings that rely on grid electricity for heating and cooling.

Research analyzing apartment blocks in Kosovo demonstrates that optimal combinations of retrofit measures can significantly reduce heating energy consumption while lowering environmental impacts [6]. Another important aspect of sustainable building development involves passive architectural design strategies. Research on natural ventilation in Kosovo demonstrates that passive cooling and ventilation techniques can significantly reduce electricity consumption in buildings while improving indoor comfort [7].

2 Kosovo's Current Energy Landscape

Kosovo's energy sector relies heavily on lignite, which causes significant pollution and emissions. Its aging coal plants, Kosovo A and B, are inefficient and contribute to unreliable power supply, resulting in frequent shortages and imports. (see Table 1.) Renewables like hydropower, wind, and solar remain limited, though expansion efforts are in progress. The Energy Strategy of the Republic of Kosovo 2022–2031 is a key policy document that outlines Kosovo's vision for a sustainable, secure, and integrated energy sector. Key reforms include alignment with the EU Clean Energy Package, the Energy Efficiency Directive, and climate-related frameworks. The Strategy also supports the National Energy and Climate Plan (NECP) and Kosovo's commitments under the Sofia Declaration to achieve carbon neutrality by 2050 [2].

Table 1. Capacity mix in Kosovo, 2021. (Source: Energy Strategy of the Republic of Kosovo 2022–2031)

Fuel	Name	Year of commissioning	Installed capacity, MW	Available capacity, MW
Lignite	Kosovo A3	1970	200	135
	Kosovo A4	1971	200	135
	Kosovo A5	1975	210	135
	Kosovo B1	1983	339	260
	Kosovo B2	1984	339	260
Wind	–	–	137	–
Hydro	–	–	110–132	–
PV	–	–	10	–
Biomass	–	–	1.2	–
Total:	–	–	**1546–1568**	–

Larger investments are needed, alongside efforts to address high energy use in homes and industry caused by poor insulation and inefficient heating.

3 Methodology

This research adopts a mixed-methods approach that combines qualitative and quantitative analysis. The methodology consists of three main components: **1. Policy analysis:** Evaluation of national energy strategies, climate policies, and building regulations relevant to energy efficiency and renewable energy integration; **2. Literature-based energy performance modeling:** Analysis of published research examining building energy consumption, retrofit strategies, and emission reduction potential and **3. Stakeholder and institutional analysis:** Review of existing reports and studies assessing barriers to implementation, including financial constraints, institutional fragmentation, and technological limitations.

This multidisciplinary approach enables the identification of both technical solutions and governance challenges affecting the transformation of Kosovo's building sector.

4 Energy Consumption in Kosovo's Building Sector, Energy Efficiency Potential and Emerging Opportunities

The study identifies three interconnected dimensions shaping Kosovo's transition toward regenerative and circular buildings: technological, regulatory, and socio-economic drivers. The proposed framework is not presented as a predictive engineering model, but as a strategic analytical framework derived from comparative policy analysis and synthesis of existing empirical studies. This framework links renewable energy integration, energy retrofitting, governance coordination, and circular construction principles into a coherent transition pathway for Kosovo's built environment.

By combining these drivers, the framework connects design innovation, technological solutions, and policy measures to enable systemic change in Kosovo's building sector. The ultimate goal is to reduce operational energy demand, lower greenhouse gas emissions, enhance resource efficiency, and create a regenerative built environment that is resilient, sustainable, and aligned with European climate and sustainability objectives: **1. Technological drivers** that include building-integrated photovoltaics; High-performance thermal insulation materials; Heat pumps and efficient HVAC systems; Smart energy management systems; Building energy modelling and digital monitoring technologies. **2. Regulatory drivers** that include energy performance of buildings directive alignment; National energy efficiency regulations; Building energy certification schemes; Financial incentives for renewable energy and building renovation; Carbon reduction targets and climate policies and **3. Socio-economic drivers** that include investment mechanisms and green financing; Capacity building for architects, engineers, and construction professionals; Public awareness on energy-efficient buildings; Energy cost reduction for households, and job creation in the green construction sector.

Existing research confirms that buildings dominate Kosovo's energy demand. In addition to high energy consumption, Kosovo's energy system is still largely dependent on fossil fuels, particularly lignite-based electricity generation. Consequently, reducing building energy demand would significantly decrease greenhouse gas emissions and improve energy security.

Figure 1 illustrates the electricity demand and supply in Kosovo. The data indicates a steady increase in energy demand over the past decade, reflecting economic development, urbanization, and growth in the building sector. This trend highlights the urgent need for improving energy efficiency in buildings and integrating renewable energy technologies. Reducing energy demand in the built environment is therefore a critical step toward achieving net-zero and carbon-neutral buildings in Kosovo.

Studies consistently indicate substantial opportunities for improving building energy performance. The results suggest that energy-efficiency measures could reduce building energy demand by approximately 44%.

These savings could be achieved through a combination of strategies including: thermal insulation upgrades; energy-efficient windows and building envelopes; heat pumps and advanced HVAC systems and integration of solar photovoltaic systems.

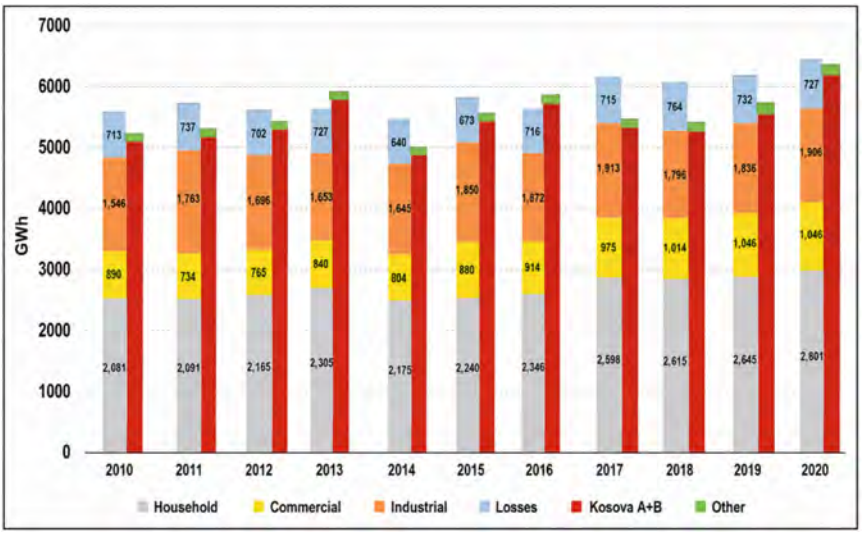

Fig. 1. Elements of electricity demand and supply, 2010–2020, GWh (Source: KOSTT, ERO)

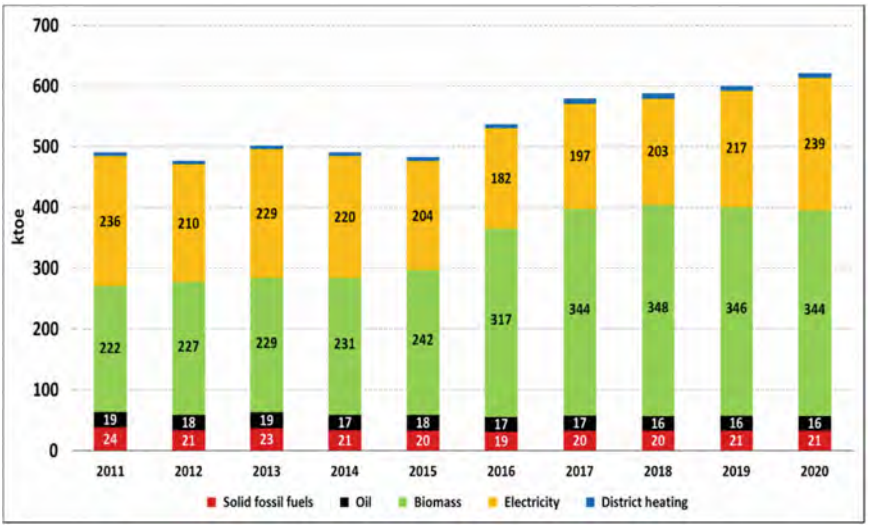

Fig. 2. Energy consumption in the household sector, ktoe (Source: Eurostat)

In Kosovo, demand for electricity varies by month, and in several categories this difference is quite significant. Household consumption is highest during the winter season, largely due to use of electricity for space heating. Recently, the Kosovo power system has faced significant pressure due to the increase in electricity demand resulting in the

need for expensive imports of electricity, especially during the heating season (October–March), when many household customers switched to heating their homes with electricity, instead of using the more expensive wood pellets (Fig. 2).

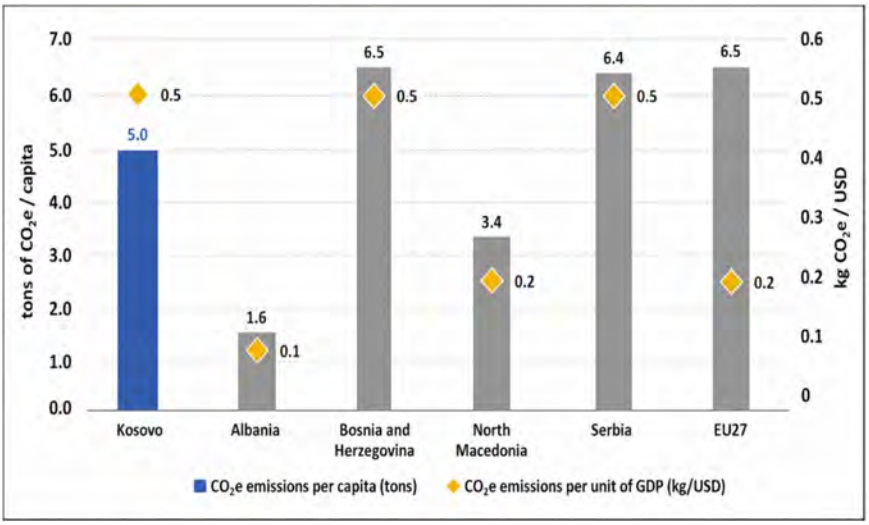

Fig. 3. GHG intensity and GHG emissions per capita in the region (Source: Kosovo Environment 2020 Report of environmental indicators)

According to the latest greenhouse gas (GHG) inventory of Kosovo, annual emissions amounted to 9.613 million tons CO_2eq in 2019. The share of fuel combustion was 86%, to which the power and heating sectors contributed with 66% (6.316 million CO_2eq). Whereas pollution from transport and heating is distributed across the country, the power sector's impact is concentrated in one area (in and around the capital, Prishtina). The overall emission trend shows some fluctuation, but the level has not changed significantly over the years for which data are available, ranging between 8.8 and 10.5 million tons CO_2eq. As shown in Fig. 3. the per capita emissions were below the EU average in 2019, but the GHG emission intensity of the economy is more than twice as much as the EU average.

The forecast of economic growth (GDP) is an important factor for the forecast of electricity demand in Kosovo. Table 2 presents the indicators of development of GDP based on the Economic Reforms Program of the Government of the Republic of Kosovo.

Energy efficiency policies are distributed across multiple governmental institutions, which often leads to **Coordination difficulties**; **Limited financial incentives** that include high upfront costs of building renovation and renewable energy systems discourage widespread adoption and **Lack of stakeholder collaboration** that include insufficient collaboration between academia, industry, and government institutions that slows innovation and knowledge transfer.

Despite these challenges, several initiatives demonstrate the potential for sustainable transformation. Examples include: pilot solar photovoltaic installations in public

Table 2. Projections of economic growth according to the document (Source: The Economic Reforms Program).

GDP real growth	2020–2028
Low scenario	2.2%
Baseline scenario	4.3%
High scenario	5.4%

buildings; municipal climate and green action plans and international energy-efficiency programs funded by development institutions. These initiatives indicate a growing awareness of sustainability issues and provide a foundation for further policy and technological development.

5 Pathways Toward Regenerative and Circular Buildings

Circular economy principles in construction involve recycling building materials, designing for disassembly, and promoting resource-efficient construction techniques. In the Kosovo context, opportunities also exist for revitalizing traditional materials and techniques such as local stone construction, timber elements, lime-based finishes, and adaptive reuse of masonry structures. These practices can reduce embodied carbon, support local supply chains, and preserve regional architectural identity while con-tributing to a modern circular economy.

6 Conclusion

The transformation of Kosovo's building sector represents a critical component of the country's transition toward a sustainable and low-carbon economy. Buildings account for a significant share of national energy consumption and greenhouse gas emissions, making them a priority for climate mitigation efforts.

The findings of this study demonstrate that substantial improvements in energy efficiency and carbon reduction can be achieved through integrated approaches combining technological innovation, policy reform, and stakeholder collaboration. By implementing strategies such as renewable energy integration, building retrofitting, and participatory governance, Kosovo can move toward a regenerative and circular built environment aligned with European sustainability objectives.

Furthermore, achieving a sustainable transformation of Kosovo's built environment requires stronger institutional coordination and long-term investment frameworks. Policy instruments that support large-scale building renovation, renewable energy integration, and energy-efficient urban planning will be essential to accelerate decarbonization in the building sector. In particular, targeted financial incentives, green financing mechanisms, and regulatory alignment with European energy and climate policies can stimulate both public and private investments in sustainable construction practices.

Strengthening collaboration between universities, research institutions, industry stakeholders, and public authorities will be crucial for advancing innovation and knowledge transfer. Such collaborative efforts can help position Kosovo as an emerging contributor to sustainable and regenerative urban development in Southeast Europe.

A House for the Body

Miguel Veríssimo(✉)

Solar Trap – Architecture, Porto, Portugal
solartrap.arch@gmail.com

Abstract. In the transition from linear Cartesian models to systemic regenerative thinking, humanity is increasingly contextualized within "A Web of Life". In this paradigm, where the shelter constitutes a technological externalization of the human niche, buildings operate as primitive somatic extensions governed by identical physical and biological laws; their organization mirrors the functional logic of human physiology and global ecological constraints. Because humans evolved to prioritize competitive survival via ecosystem modification rather than steady-state sustainability, modern buildings function as metabolic mediators that physically manifest our contemporary evolutionary mismatch. By processing multi-scalar flows of energy, mass, and information—from the individual to the biosphere—buildings primitive-grade analogues of human anatomy, physiology, and homeostatic feedback loops, either exacerbating biospheric entropy through open-loop resource depletion or operating as active thermodynamic nodes within an interconnected reality. Although the house is the primary mediator of human adaptation, architectural treatises neglect the complexity of the building's biological essence reducing the BODY<>HOUSE<>NATURE triad to mere anthropometric, ergonomic, or cultural abstractions. This reductionism overlooks our bodies as active biological, psychological, and social agents whose metabolic needs act as catalysts for technological evolution and ecosystem service appropriation. Addressing this conceptual neglect, the study 'A HOME FOR THE BODY' reframes the house not as an industrial product or a 'machine for living,' but as a complex bio-entity intrinsically linked to human anatomical, physiological, metabolic, and neurological functions. Grounded in recent advances in systems biology, this research proposes a framework based on dissipative, low-entropy processes to reformulate BODY<>HOUSE interfaces across nested scales - from cellular tissues to the biosphere - utilizing systemic design-thinking to reshape habitats by mimicking life's low-impact principles."

in architecture, as in other disciplines, the logics of biological systems from intellectual and scientific production, elevating an anthropocentric view of Humans<>Nature relationship. Within this mechanical framework, architecture optimized mass production to accommodate urban population surges, forcing the body—our primary perceptual interface—to adapt to rigid industrial constraints. This linear path-dependency is historically understandable given capital-intensive life-cycles, yet it reveals an evolutionary mismatch: our opportunistic 'Stone Age hardware' used industrial technology to amplify ancestral instincts of resource dominance, scarcity consumption, and hyperbolic discounting ('now' bias), rather than managing abstract, slow-moving threats like climate change or the "tragedy of the commons" . This paradigm, epitomized by Le Corbusier's technocratic metaphor of the 'house as a machine for living,' reduced human activity to measurable anthropometric and ergonomic parameters, instrumentalizing the body while ignoring its physiological, metabolic, and neurological biocomplexity. However, contemporary systems ecology—rooted in Ludwig von Bertalanffy's Systems Theory, Fritjof Capra's web of life, and Gregory Bateson's relational cognition—challenges this view. Intertwined with Alan Turing's morphogenesis and Maturana and Varela's autopoiesis, living systems are redefined as self-producing, open thermodynamic networks. Similarly, Victor Olgyay's bioclimatic principles and Luis Fernández-Galiano's energy histories proved that buildings are dynamic thermal couplers, a relational understanding reinforced by James J. Gibson's ecological psychology and Paul Rodaway's multisensory geographies. As Manuel Damásio notes, consciousness transforms humans into active agents of homeostatic control. Guided by culture—acting as an ethical software update to override biological shortsightedness and redefine social prestige away from extraction—the home transcends its industrial definition to become a bio-entity: an exosomatic prosthesis following Georgescu-Roegen in 1971, and extended nervous system where technology like - sensors, AI, mobile phones, etc., provides a potential real-time ecological sight that blind evolution omitted increasing entropy. Modern biophysics, biochemistry, and thermodynamics reinforce these body-environment feedback loops, shifting our trajectory toward conscious, directed co-evolution. Adrian Bejan's Constructal Law unifies biological, inanimate, and technological patterns as flow architectures that optimize current access to minimize irreversibility and reduce entropy. This thermodynamic determinism is mirrored in Nick Lane's bioenergetics, where metabolic networks mitigate entropy decay, and Martin Picard's psychobiology, which links cross-scalar cellular energy dynamics directly to macro-level behavior. Furthermore, Michael Levin's work on bioelectricity highlights how distributed information networks coordinate physical form. Together, these breakthroughs demand that the house be reframed as a low-entropy, life-mimicking dissipative structure. By embedding these systems design-thinking variables into architectural layers—from cells to the biosphere—the built environment achieves thermodynamic decoupling, evolving from a predatory mechanism of ecological degradation into an active, reciprocal node of a wider, interconnected planetary reality. Together, these perspectives challenge the conceptual separation between biological processes and architectural environments. If living organisms are defined by continuous exchanges of energy, matter, and information with their surroundings, then the built environment must also be understood as part of these wider interactions. This takes the Biosphere and the Laws of Physics as a matrix to redefine a new perspective

from the Body to the House, moving toward a more ecological shelter/habitat within the "Web of Life."

2 Why a "House For The Body"

The study 'A HOME FOR THE BODY' is an ongoing research project hypothesizing that architectural design-thinking and construction workflows informed by the human body's anatomical, physiological, metabolical (energy and matter processing), and neuro-cognitive interconnection and information flows, can generate negenentrophyc built environments across nested multi-scalar layers that optimize exergy and minimize localized entropy production compared to conventional designs. The question is, if architectural systems were synthesized through these isomorphic biophysical principles - operationalizing buildings and built environments as open, far-from-equilibrium thermodynamic subsystems structurally coupled with the biosphere, could the house achieve higher standards of thermodynamic efficiency, homeostatic adaptability and autopoietic regenerative capacity, like the self-organizing principles observed in living systems?

3 How to Address the House For The Body

To investigate the proposed hypothesis, this research employs a transdisciplinary comparative analysis between human body biological systems and the architectural design elements of a house (defined as the elementary dwelling unit) taking the following method of analysis:

3.1 Definitions

The Biological Substrate: The Body The human body is a decentralized, self-producing (autopoietic) organism characterized by a 20-year ontogenetic development phase (construction time span) and an 80-year operational lifecycle. Operating across nested biophysical scales—from microscopic eukaryotic cells to macroscopic biosphere networks—the organism maintains metabolic homeostatic stability through eleven synergistic physiological systems. At the cellular foundation, decentralized metabolic networks, such as the mitochondrial Krebs Cycle, process continuous cross-scalar fluxes of energy, mass, and information to generate cellular bioelectricity and fuel systemic functions (thermoregulation, respiration, and waste elimination). Governed by non-equilibrium thermodynamics, the body acts as a highly optimized dissipative structure; it actively minimizes internal entropy production and sustains localized states of high organization (negentropy) by continuously converting environmental exergy into physiological maintenance, somatic repair, and cognitive, collaborative, cooperative, and adaptive performance. The human body's precise phase distribution—dominated by a dynamic liquid matrix (~60–65%) suspended within a minimal, optimized solid tensegrity framework (~30–35%)—is an evolutionary jewel in balancing gravitational resistance with entropy dissipation under the planet physical constraints. Operating across nested biophysical scales, from microscopic eukaryotic cells to macroscopic biosphere networks,

this biological laboratory maintains metabolic homeostatic stability through eleven synergistic physiological systems: the Tegumentary, Skeletal, and Muscular Systems (form the structural, protective, and kinematic matrix); the Nervous, Endocrine, and Immune Systems: Orchestrate real-time information processing and regulatory feedback loops; the Cardiovascular, Lymphatic, Respiratory, Digestive, and Urinary Systems: Act as closed-loop mass, fluid, and resource transport infrastructures. At the cellular foundation, decentralized metabolic networks, such as the mitochondrial Krebs Cycle, process continuous cross-scalar fluxes of energy, mass, and information to generate cellular bioelectricity and fuel systemic functions like respiration, thermoregulation, and waste elimination. Governed by non-equilibrium thermodynamics, the body acts as a highly optimized dissipative structure; it actively minimizes internal entropy production and sustains localized states of high organization (negentropy) by continuously converting environmental exergy into physiological maintenance, somatic repair, and cognitive, collaborative, cooperative, and adaptive performance. This laboratory environment is materially optimized by a precise phase distribution—a dynamic liquid matrix (~60–65%) suspended within a minimal, optimized solid tensegrity framework (~30–35%)—which serves as an evolutionary jewel in balancing gravitational resistance with convective entropy dissipation under terrestrial physical constraints.

THE HOUSE can be understood as an extension of human bodies. Just as cells, tissues, and physiological systems organize the body to maintain life, the house mirrors aspects of bodily physiology and functions as an external regulatory layer that helps stabilize the environmental conditions required for human survival. Through walls, roofs, and envelopes, it acts similarly to bones, muscles, and the integumentary system, providing structure and space while protecting inhabitants from climatic variations, pathogens, and external disturbances, and maintaining controlled exchanges with the surrounding environment. Systems within the house- such as electrical networks, air and water supply, ventilation and thermal control, and liquid and solid waste disposal- operate as infrastructural analogues of physiological systems. In this sense, the house becomes part of the larger logistical network that supports human metabolism and mediates human interactions with the planet. It transforms, distributes, consumes, and stores energy and resources, while facilitating physiological and sociocultural interactions with the environment. By regulating temperature, humidity, light, and air quality, the house reduces the energetic burden placed on the human body to maintain homeostasis, although it externalizes environmental impacts as a consequence of fulfilling human needs. It therefore acts as a technological and spatial prosthesis that extends the body's capacity to resist environmental fluctuations and maintain states of order. Like the body, the house also operates within broader ecological and social systems. Individual dwellings connect to urban infrastructures, communities, and environmental cycles, forming networks that resemble the organization of bodies within the biosphere. Through this perspective, the house can be understood not simply as shelter, but as an adaptive interface between human biological systems and the external world- an architectural extension that supports the continuous flows of energy, matter, and information necessary for human life.

3.2 The Method for a Design Manual

This approach establishes a framework to compare analogous functions across both biological and architectural domains. The proposed methodology is divided into three distinct phases:

Phase 1: Mapping and Measuring
This phase involves an anatomical and physiological mapping quantification and functional categorization of the eleven human body systems equivalent to architectural elements of a house. Acknowledging that the human body operates as a continuous construction site, the study aligns the 80-year life cycle of a building with that of a human body. However, it distinguishes the initial 20 year growth phase (body construction) from the subsequent operational cycle. For the purpose of this comparison, basal metabolic energy associated with physical movement is excluded. Mass and total mass weight is a subject of study.

Phase 2: Biomimetic Translation and Design Parameters
This stage involves the translation of identified biological functions into technical architectural parameters. Biological logics are converted into specific design solutions, where physiological processes- such as metabolic cycles or homeostatic regulation- serve as blueprints for building systems. The goal is to bridge the gap between organic efficiency and tectonic implementation.

Phase 3: Comparative Performance Simulation
A performance simulation will be executed to compare a "biologically-informed" case study against a conventional building model. The analysis focuses on critical indicators such as energy flux, entropy reduction, and resource circularity, evaluating the regenerative capacity and ecological efficiency of the proposed metabolic architectural framework.

Under this proposed framework, architectural design and construction processes that emulate the physiological and metabolic logic of the human body - specifically its regulation of embodied energy and matter flows, and organizational/functional feedback loops, serve as the foundation a low-entropy design manual. A direct analogy is established between the basal metabolic outflows of the human body and the operational and embodied energy management of buildings. Just as basal metabolic processes define the minimum energy required to sustain life-supporting critical functions such as thermoregulation, circulation, and neural activity-buildings necessitate a baseline operational metabolism. This baseline is essential to maintain environmental quality, structural integrity, and technological functionality throughout their 80-year life cycle. By quantifying these parallels, the study evaluates how ´living architectural systems can optimize resource consumption and enhance eco-efficiency.

4 Discussion/Confrontation

4.1 The Metabolic Divergence of Body (Living) and House (Inert)

This research suggests a necessary shift beyond purely metaphorical comparisons between architecture and physiology. By transitioning toward a thermodynamic and entropic analysis of BODY<>HOUSE as a continuous, we reveal critical pathways for a more accurate design approach. Framing the house as an 'inert' structure versus the body as a 'living' one exposes the fundamental tension between Embodied Energy and Metabolic Flux across an 80-year lifecycle.

In this Chapter, the following identified systems that share similar functions in both human physiology and architectural design are studied separately, quantified, and analyzed. It aims to generate conclusions capable of providing further insights for the design manual, as proposed in Phase 2 of the Methodology.

Considering that a HOUSE serves as an external apparatus of the human body, the 'A HOUSE FOR THE BODY' research adopts a model where physiological functions find direct parallels in architectural design and operation. The hypothesis and methodology aim to deepen this principle of engagement. Consequently, the following biological dimensions are particularly relevant, as they follow a logic analogous to building elements, functional operations, and the exchange of energy and mass shared by both the BODY and a HOUSE, allowing a possible comparison:

- **Structural System** (Mass, Structure, Support, and Muscles): The skeletal system provides the rigid framework (load-bearing structure) that protects vital internal components, while the muscular system manages stability, tension (analogous to tensile structures), and kinetic capabilities.
- **Circulatory System** (Flows of Energy, Water, and Air): The cardiovascular system acts as the primary "pumping" and "piping" network responsible for transporting nutrients, gases, and thermal energy. The endocrine system functions as a long-distance chemical signaling network that regulates system-wide processes through the bloodstream.
- **Integumentary System** (Envelope, Int/Ext Interface and Protection): The integumentary system (skin, hair, and gland) operates as a selective barrier - analogous to a building façade -managing thermoregulation, waterproofing, and sensory interaction with the environment.
- **Respiration** (Gas, Water and Thermal exchanges): The respiratory system regulates the intake of O_2 and the expulsion of CO_2, mirroring the ventilation processes and "breathing" capacity of a building's internal volume.
- **Waste Management** (Solid and Liquid Waste flows): The urinary (renal) system functions as a filtration unit that maintains chemical and fluid balance, while digestive system processes raw matter and manages nutrient absorption and waste elimination.
- **Neurological System** (Communication and Cognition, Management, and Energy flows): The nervous system functions as both the "central processing unit" (the brain) and the communication network (the nerves), coordinating physiological processes through real-time responses to stimuli via electrochemical signaling. Brain energy.
- **Regeneration and Autopoiesis** (Protection, Maintenance, and Replication/Growth): The lymphatic and immune systems provide defense and internal "cleaning," which

are essential for maintaining systemic integrity and biological self-maintenance. In addition, cellular and tissue regeneration, together with reproductive processes, provide the biological basis for growth, repair, and generation of new biological units (Table 1).

4.2 Human Body vs Building Systems: A Systemic Mapping

Table 1. Systemic Mapping

Building system	Building components	Body equivalent	Body mass	Body energy
Structure	Concrete, steel, slabs 65–75%, energy 40–60%	Bones + muscles mass	~50–60%	~20–25%
Envelope	Facades, windows 15–20%, energy 20–30%	Skin + fat + hair mass	~15–20%	~5–10%
Distribution+ networks	Pipes, wiring 2–5%, energy 10–15%	Vessels + nerves mass	~5–8%	~10–15%
Thermal + air regul.	hvac, ventilation 1–3%, energy 5–10%	Lungs + thermal reg. mass	~1–2%	~20–30%
Information + organization	Sensors, automation, domotics 0,1–0,3%, energy 1–3%	Brain + nervous mass	~2%	~20%
Energy transform.	Energy generation + storage 1–4%, energy 5–15%	Digestion, cells + mitochondria mass	~2%	~20%
Waste management	Drainage systems 1–2%, energy 1–4%	Kidneys, bladder, intestines mass	~2–3%	~5%

5 Conclusion

In conclusion, this study establishes the BODY<>HOUSE paradigm as a rigorous biophysical and interdisciplinary framework for rethinking architectural design, construction, management, and long-term environmental performance. By neutralizing kinetic locomotion, both the dwelling and the biological body it shelters are analyzed as stationary laboratory environments governed by identical non-equilibrium thermodynamic laws. The comparative metabolic balance reveals that while contemporary buildings rely on fragmented, carbon-intensive, and energy-intensive mechanical systems, the human body operates as a highly optimized, autopoietic dissipative structure characterized by vastly superior exergy efficiency, systemic adaptability, and homeostatic self-regulation through minimal energy expenditure. Through a strict functional analysis of anatomical morphology, physiological feedback, and metabolic networks, this research

isolates comparable mechanisms governing cross-scalar material circulation, fluid thermoregulation, and biochemical waste remediation. This comparative assessment highlights the systemic limitations of conventional architectural and construction models when confronted with contemporary ecological and energetic challenges. Translating the body's highly optimized, low-entropy processes and integrated feedback loops into architectural practice provides a solid scientific and technological foundation for systemic design manuals. By translating biological principles—such as adaptive regulation, circular resource flows, multifunctionality, and resilience—into practical architectural organization, it becomes possible to replace static, carbon-intensive mass with active hydronic networks, closed-loop resource cascading, and sensor-driven envelopes. Consequently, this framework redefines housing not as an industrial product or a passive shield, but as an intelligent, life-mimicking, and environmentally responsive bio-entity, advancing eco-efficient housing models capable of reducing material waste, minimizing localized entropy production, and achieving long-term thermodynamic and biospheric regeneration.

Urban Solar Carver: A GPU-Accelerated Framework for Solar-Driven Urban Form Finding

Aristotelis Vartholomaios(✉)

University of Thessaly, Volos 383 34, Greece
avartholomaios@uth.gr

Abstract. From early zoning codes to contemporary environmental standards, building volume regulation has served as a primary mechanism for guiding urban form and protecting access to sun and light. The study presents the Urban Solar Carver (USC), a computational framework for generating maximum developable building volumes that protect solar and daylight access. USC builds upon earlier works on solar voxel-based form-finding methods, embedding them into a unified, transparent and reproducible framework. Its main advantage is the integration of GPU-accelerated geometry voxelization, raytracing and solar and sky radiation modelling to evaluate millions of ray–surface–voxel interactions at near real-time speeds. USC is currently under development as a standalone Python library with its own command line interface and connectors to Grasshopper for Rhinoceros 3d. It can generate conventional daylight and time-based solar envelopes but can also perform advanced volume carving using performance-based criteria such as cumulative solar irradiation, passive solar benefit, daylighting benefit, outdoor comfort and even radiative cooling benefit. Some of these features are stable while others are still experimental and require further validation. USC utilizes multiple thresholding techniques, moving beyond fixed-rule envelopes and toward performance-responsive form finding. This level of interaction lets designers and planners experiment with different constraints and immediately see how these choices shape the final massing.

Keywords: solar access · urban planning · urban form · building volume · performance-based design

1 Introduction

Access to sunlight and daylight has long influenced the regulation of urban form [1, 2]. Geometric constraints such as setbacks, height-to-street-width ratios, cut-off planes, and solar access rules are frequently employed to limit overshadowing and maintain adequate environmental conditions for buildings and public space [3]. Interest in solar access has increased in the context of climate-responsive urbanism, where solar exposure affects daylight availability, passive heating, outdoor comfort, and local renewable energy use [4].

L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 600–607, 2026.
https://doi.org/10.1007/978-3-032-34930-9_70

Urban solar-access regulation has gradually evolved from simple geometric rules toward solar-informed volumetric controls. Early approaches relied on setbacks, height-to-street-width ratios, and later sky-exposure planes, as in New York's 1916 zoning framework, to limit building mass [2]. The solar envelope concept introduced in the 1970s marked a shift from fixed angular restrictions to buildable volumes derived from sun-path geometry and protected periods of solar access [5]. Subsequent work expanded this lineage through methods such as solar fans [6], the Residential Solar Block envelope [7], iso-solar surfaces [8], reverse or subtractive solar envelopes [9], and solar-collection envelopes [10]. Digital envelope generation methods have been developed since the 1990s ranging from raster and point-grid approximations [6, 11] to Boolean solid operations [7] and voxel-based approaches [9, 12, 13], each involving trade-offs in precision, robustness, speed, and usability. Some tools implement only a single envelope logic, while others are tied to proprietary software environments or narrow workflows [6]. As solar-access ambitions expand, practical tools for planners and designers remain limited.

This paper introduces the Urban Solar Carver (USC), a computational framework for producing maximum developable urban volumes. USC follows a subtractive logic: a theoretical maximum volume is progressively carved to satisfy environmental constraints. The framework integrates GPU-accelerated voxelization, ray-based volumetric carving, solar and sky radiation modelling, and threshold-based filtering within a single workflow.

2 Tool Description

USC is implemented as a standalone Python library with a command line interface and connectors to Grasshopper for Rhinoceros 3D, enabling both reproducible analysis and interactive design use. A user-defined maximum candidate volume is first discretized into a three-dimensional voxel grid representing potential built mass at any scale (building, block, or neighborhood). The user also defines test surfaces requiring solar or sky access, such as windows, PV arrays, or entire façades. Surface normals must face outward. Rays are traced from sampled points on these surfaces toward multiple directions. Depending on the evaluation mode, these directions correspond to fixed angles, sun positions, or sky patches. Voxels intersected by the rays accumulate either violation counts or weighted obstruction scores. A user-defined threshold is then applied to the resulting voxel score field to determine which voxels are retained.

The workflow consists of three stages: preprocessing, thresholding, and exporting. Preprocessing includes geometry loading, voxelization of the candidate volume, sampling of test surfaces, generation of directional vectors, and per-voxel score computation. Thresholding converts the score field into a binary retention mask using fixed or automatic criteria. Exporting reconstructs the retained voxels into a polygonal mesh with optional cleanup or smoothing (Fig. 1). Parameters are controlled through a YAML configuration file, with optional runtime overrides for batch studies. The framework requires three minimum inputs: a maximum volume mesh, a test-surface mesh, and for climate-based analyses an EPW weather file. The candidate mass is voxelized at a user-defined resolution and test surfaces are sampled into point–normal pairs, controlling the trade-off between geometric fidelity and computational cost.

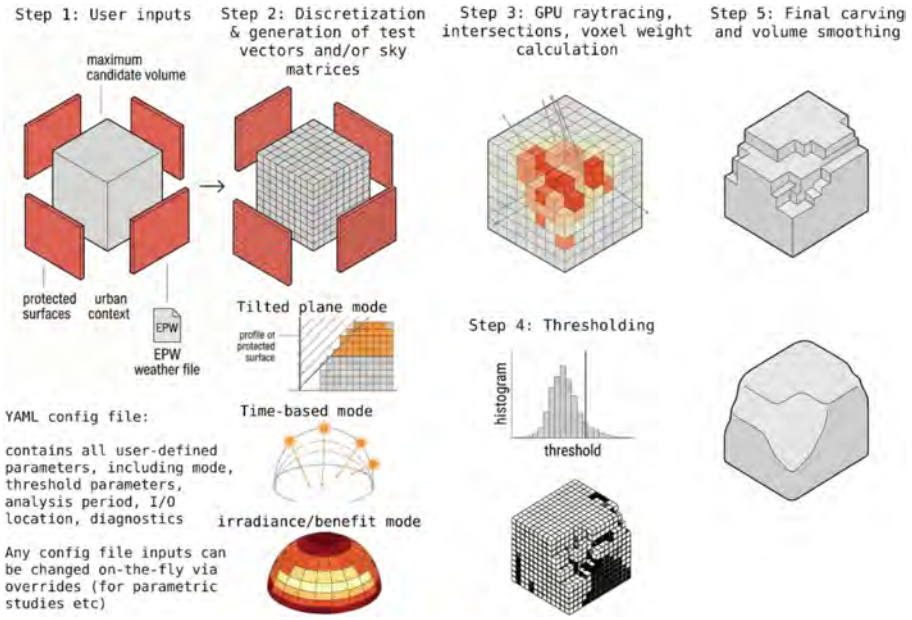

Fig. 1 Overview of USC inputs, modes and execution steps.

Directional data are derived in two ways. For time-explicit analyses, Ladybug generates sun vectors for specified dates and hours. For climate-based analyses, USC uses weighted sky patches derived from annual weather data mapped onto the Tregenza sky subdivision. These create two analysis families: sun-vector methods, which evaluate obstruction at specific times, and sky-patch methods, which evaluate cumulative environmental opportunity over the sky hemisphere. In this study the demonstrated modes are tilted plane, time-based, irradiance, daylight, and benefit.

In *tilted plane* mode, USC applies an angular plane restriction defined by user-specified angles, optionally varying by orientation. Rays cast from sampled surfaces accumulate voxel violation counts according to this directional field. In *time-based* mode, sun vectors for a specified analysis period are generated and rays are cast toward these positions. Intersected voxels accumulate solar-access violations. With a zero-tolerance threshold the resulting mass approximates a conventional solar envelope. In *irradiance mode*, sky directions are weighted by cumulative annual radiation derived from EPW data. Voxels blocking directions with higher radiation receive higher scores and are preferentially removed. In *daylight mode*, sky directions are weighted using a CIE overcast sky luminance distribution. Voxels obstructing brighter sky regions accumulate higher scores. The *benefit mode* weights sky patches according to passive solar usefulness rather than radiation magnitude alone.

Weights are derived from the Ladybug *benefit sky matrix*, generated using Radiance's gendaymtx, which assigns a positive or negative weight to each Tregenza sky patch depending on whether radiation from that direction offsets heating loads or increases cooling loads, given temperature data from the EPW file [14]. The balance temperature

and balance offset parameters control these assumptions and can be refined through building energy simulation.

The computational core of USC evaluates large numbers of ray–voxel intersections. For each sampled surface point, a ray is cast toward each direction in the active set (sky-patch centre or sun position); the total ray count equals the product of test points and directional vectors. USC relies on NVIDIA Warp [15] for sparse voxel representation and ray tracing and on Ladybug Tools [14] for sun-position calculation and climate-based environmental weighting from EPW data. The framework can run on CPU or CUDA-enabled GPUs. Warp provides voxel and raytracing operations while USC handles carving logic, score accumulation, and data flow.

Preprocessing produces either a violation-count field (tilted plane, time-based) or a weighted obstruction field (irradiance, daylight, benefit). During thresholding, weighted fields may be normalized and converted into retention masks using user-defined thresholds or automatic methods such as Otsu or head/tail classification. A retained-fraction strategy can also be used to preserve a specified share of the score distribution. After thresholding, the retained voxel mask is reconstructed into a polygonal mesh with optional smoothing. Intermediate score fields and metadata are stored to enable selective reruns without repeating the full computation.

3 Methodology

USC is applied to a real neighborhood to test its capability to generate and compare alternative solar-driven urban volume controls within the same urban setting. The case study site is in western Thessaloniki, Greece which has Mediterranean climate (40°40′33.4″N, 22°54′47.9″E). This 15 ha neighborhood comprises mainly multifamily apartment buildings.

Building footprints and height data were extracted from OpenStreetMap and used to reconstruct the existing built fabric as a three-dimensional urban geometry (reference case). The same footprints were extruded to a common upper height limit to generate candidate redevelopment masses, retaining the parcel structure while providing a shared geometric basis for comparison. All vertical facade surfaces of the existing buildings were used as test surfaces.

Three USC modes were tested: (i) a fixed-plane scenario using a 45° angular restriction, (ii) a time-based solar-envelope scenario for the winter solstice from 10:00 to 14:00. And (iii) a benefit-based scenario guided by a threshold of 80% useful insolation. Climatic data were provided in EPW format from the IWEC database. For the benefit scenario balance temperature was set to 20 °C with a range of ±2 °C. The value was determined through a simple shoebox simulation of a residential mid-floor apartment using EnergyPlus [16] with construction and occupancy matching the Greek building energy code (KEvAK) specifications. Heating period according to the code for the respective climatic zone (Γ') is from 15th of October to 30th of April. For each scenario, USC carved the candidate masses and generated a final urban volume. These were compared with the existing built form, resulting in four examined cases: existing, fixed plane, time-based, and benefit. All four cases were then subjected to the same ex-post heating period solar simulation.

The comparison used two groups of indicators. Development intensity was described through total built volume, volume per site area, and an estimated mixed Floor Area Ratio (FAR) proxy, assuming an average floor-to-floor height of 3.5 m. Heating period solar performance was described through: (i) total cumulative insolation across all building envelopes and (ii) mean cumulative insolation in kWh/m^2, calculated as the average cumulative energy received per evaluated surface over the examined period. The latter was used as the main solar-performance indicator.

4 Results

Table 1 summarizes volumetric and solar-performance results for the four cases while Fig. 2 visualizes them. The existing neighborhood has a total built volume of 780,400 m^3, corresponding to a volumetric density of 5.08 m^3/m^2 and a mixed FAR of 1.45. Mean cumulative winter insolation is 214.76 kWh/m^2. Calculation time was 47 s per run on a workstation with 64 GB RAM and a GeForce RTX 3060 (12 GB VRAM) for 223 volumes and 1338 test surfaces at a voxel and grid resolution of 0.5 m (over 99 million voxels and 532,581 test points). With 145 Tregenza sky patches the total ray workload exceeded 77 million patch-test point queries per run.

The 45° fixed-plane scenario produced the largest envelope volume (Table 1), representing a 12.1% increase relative to the existing built volume. Mean cumulative insolation increased by +10.9% relative to existing. This scenario also yielded the highest total cumulative insolation due to its larger exposed surface area. The time-based scenario was the most restrictive, reducing total volume approximately 25.7% below the existing built volume (Table 1). Despite this reduction, mean cumulative insolation increased to about 23.5% above the existing condition. The benefit-based scenario nearly matched the volume of the fixed-plane case while achieving the highest mean cumulative winter insolation (Table 1). This represents increases of 34.7% relative to the existing neighborhood, 21.4% relative to the fixed-plane scenario, and 9.0% relative to the time-based case.

The three scenarios reveal clear density–solar trade-offs. The fixed-plane rule retains the largest buildable volume, the time-based envelope secures stronger winter solar

Table 1. Volumetric and winter solar performance comparison of the examined cases

Scenario	Volume (m^3)	Volume/site area (m^3/m^2)	Mixed FAR	Mean cumulative winter insolation (kWh/m^2)	Total cumulative insolation (GWh)
Existing	780,400	5.0	1.4	214	57.15
Fixed plane	874,687	5.7	1.6	238	62.54
Time-based	579,806	3.8	1.0	265	56.01
Benefit	869,904	5.7	1.6	289	60.58

access at the cost of density, and the benefit-based method achieves the highest mean solar performance while maintaining a volume comparable to the fixed-plane case.

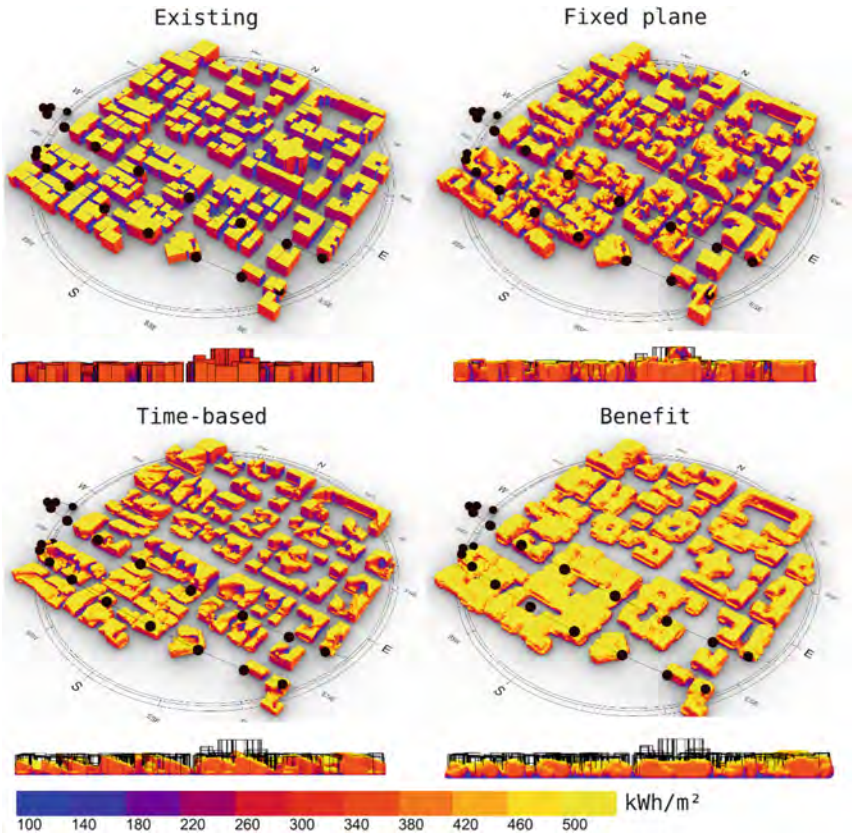

Fig. 2. Average cumulative insolation for the heating period for the four examined cases. Indicative cross-sections illustrate the volumetric differences between the current built form and the three generated envelopes. Sun positions for start and end dates shown as black dots.

5 Conclusions

This paper presented USC, a voxel-based GPU-accelerated framework for solar-driven urban form finding. The framework integrates different volumetric control logics within a common computational pipeline and generates redevelopment envelopes in a reproducible manner. In the neighborhood-scale experiment, three control modes were tested: a 45° fixed-plane rule, a winter-solstice time-based solar envelope, and a benefit-weighted solar criterion. The scenarios produced markedly different density–solar outcomes with the benefit-based scenario retaining nearly the same volume as the fixed-plane case while producing the highest mean cumulative winter insolation among all tested cases.

The analysis is exploratory and limited to a single neighborhood, while the benefit mode relies on simplified assumptions regarding passive-solar usefulness. Despite these limitations, USC can serve as a general computational basis for subtractive urban form finding, allowing different environmental constraints to be compared within the same framework and supporting future research on climate-responsive volumetric controls.

Abstract. The retrofit of vernacular building stock is essential for sustainability, yet standardised solutions often fail to address the typological diversity of mountain regions. Rather than proposing novel designs, this research provides an empirical evaluation of two prevalent, real-world intervention archetypes compared to a baseline scenario corresponding to a building with its original solutions in the Montesinho Natural Park: a non-retrofitted vernacular dwelling (Pathway A), a modern reconstruction using industrial materials (Pathway B), and a sensitive thermal adaptation (Pathway C). Thermal comfort was assessed using the Portuguese adaptive model, contextualised by long-term hygrothermal monitoring and occupancy profiles. Results reveal a critical divergence: the non-retrofitted baseline confirms severe winter discomfort; however, improving this comfort is vital to prevent building abandonment and ensure long-term maintenance. The modern reconstruction (Pathway B)—utilising an internal XPS and plasterboard lining—achieves a rapid thermal response suitable for intermittent use, but represents a "linear substitution". By discarding the original structural solutions, it fails to extend their lifespan and instead generates construction and demolition waste. Conversely, the sensitive rehabilitation (Pathway C) preserves the granite shell (structural circularity), successfully extending the amortisation of the building's existing embodied impacts. However, it risks summer overheating as the non-reversible internal insulation thermally decouples the envelope from the dwelling volume. The findings highlight that sustainable interventions must balance occupant comfort with respect for heritage, prioritising the maintenance of differentiating characteristics and the reversibility of construction works over standardised replacements

1 Introduction

The EU's "Renovation Wave" effectively targets urban centres, but its application to rural vernacular heritage creates a complex "sustainability paradox" [1]. Standardised energy efficiency metrics frequently conflict with heritage preservation, compromising cultural integrity [2].

In Portugal's Montesinho Natural Park (MNP), this conflict is acute. Local granite and schist masonry represent inherently circular, "resource-conscious construction" with near-zero embodied carbon [3]. Despite these ecological benefits, the vernacular shell's failure to meet modern winter comfort standards—evidenced by regional monitoring [4–6]—often drives homeowners to replace circular stone shells with linear, industrial materials. The core challenge is negotiating the trade-off between operational comfort, material circularity, and embodied impacts [2].

While previous research characterises MNP's bioclimatic typologies [3, 7], a gap remains regarding occupant interaction. Adaptive behaviours (e.g., adjusting ventilation [8] or clothing [9]) significantly alter energy demand, particularly during intermittent "weekend" occupancy. Addressing this gap, this study correlates long-term hygrothermal monitoring with occupancy profiles across three real-world MNP archetypes. Rather than proposing novel designs, this research provides an empirical evaluation of these actual intervention archetypes, assessing their success in balancing heritage conservation and occupant comfort.

2 Methodology: Defining the Intervention Archetypes

Beyond theoretical abstraction, the study analyses three real-world archetypes located in Pinheiro Novo and Montesinho villages. These cases are not theoretical design proposals, but rather empirical archetypes documenting the divergent physical interventions already executed by homeowners in the region.

2.1 The Case Studies as Strategic Prototypes

The case studies were selected to represent the "Compact Cluster" and "2-Storey" typologies, identified as the most prevalent vernacular forms in the region [3]. Table 1 summarises their characteristics through the lens of circularity and intervention intensity. Crucially, because these are real-world occupied dwellings rather than controlled laboratories, the monitored spaces possess differing geometries and orientations. Consequently, this study does not attempt a direct 1:1 quantitative comparison of identical spaces. Rather, these archetypes are evaluated as representative 'extremes' of the current intervention spectrum—ranging from absolute non-intervention to total structural replacement. They serve as indicative boundaries to expose the real-world trade-offs between thermal standardisation and heritage circularity.

(a) Pathway A (Case 1) Pinheiro Novo. The Non-Intervention Baseline: Representing the "Do Nothing" approach, this dwelling retains its original vernacular configuration: 60–80 cm double-leaf dry granite masonry walls with a hybrid roof (clay and slate). Monitoring focused on a "sandwiched" first-floor bedroom (13.5 m^3) located

beneath the slate roof section. The room has a 0% external Wall-to-Window Ratio (WWR), relying solely on indirect light borrowed from the adjacent kitchen's roof skylights. Consequently, this approach embodies maximum circularity (100% local lithological materials, zero embodied carbon intervention) but relies entirely on the building's original passive capacity to mitigate the climate.

Table 1. Comparative Profile of the three Intervention Pathways

Feature	Pathway A (case 1)	Pathway B (case 2)	Pathway C (case 3)
Intervention logic	Non-Intervention Baseline (Vernacular)	Modern Reconstruction	Adaptation (Sensitive retrofit)
Wall structure	60–80 cm Granite masonry	Reinforced Concrete frame with infilled with thermal clay blocks	Granite masonry (Retained shell)
Insulation	None (Relies on high thermal inertia)	Internal lining system: XPS insulation + Laminated plasterboard	Internal thermal plaster with EPS aggregate
Window ratio (WWR)	0% (Internal/ Indirect light only)	High (> 40% glazed façade)	Low (< 5%)
Circularity profile	Indigenous (100% circular/zero embodied carbon)	Linear substitution (high waste/industrial)	Structural circularity (retains shell/compromised by synthetic plaster)
Heating strategy	Indirect radiant (borrowed heat from adjacent kitchen wood stove)	Mobile convective (electrical unit – on/off demand)	Centralised hydronic (radiators – intermittent use)
Occupancy profile	Continuous (an elderly resident)	Intermittent (2 weeks per month)	Transient (short-term stays)
Thermal goal	Passive survivability	Instant convective comfort (low inertia)	Standardised comfort

(b) Pathway B (Case 2) Montesinho: Modern Reconstruction. Monitoring targeted a rear SE-facing bedroom (38.5 m^3) characterised by high solar exposure (WWR > 40%) and intermittent weekend occupancy. Representing the "Linear" approach, this building is a contemporary reconstruction of a collapsed vernacular ruin. In compliance with strict modern thermal regulations (REH), the original stone load-bearing structure was substituted by a reinforced concrete frame infilled with thermal clay blocks and fitted with double-glazed PVC frames. Crucially, the thermal envelope utilises an

internal lining system of Extruded Polystyrene (XPS) followed by plasterboard. This "box-in-a-box" strategy creates a low-inertia inner surface that thermally decouples the living space from the heavy structure, prioritising rapid convective response over passive stability. While thermally efficient, it represents a "Linear Material Substitution": replacing a monolithic, reusable stone shell with a composite, multi-layered industrial assembly that is difficult to separate or recycle at end of life.

(c) Pathway C (Case 3) Montesinho: Data was collected from a 50.7 m^3 bedroom (SE orientation) located on the upper residential floor. The room features a sloped ceiling that follows the roof pitch, placing the occupant directly beneath the thermal envelope without an attic buffer. Representing the 'Hybrid' approach, this case involves the adaptive reuse of a vernacular two-storey granite dwelling to meet modern habitability standards. The strategy employed a sensitive internal retrofit intervention: the original granite walls were preserved (Structural Circularity), but thermal performance was upgraded using a layer of insulating thermal plaster with EPS beads that is applied internally. This pathway negotiates a trade-off: it saves the embodied carbon of the heavy shell but introduces a synthetic, non-reversible industrial layer to achieve habitability. Crucially, the direct exposure to the roof (lacking a buffer zone) exacerbates summer overheating, as the internal insulation traps solar gain entering through the unbuffered slate roof envelope, creating a ´thermos effect´ during summer.

2.2 Assessment Metric: The Adaptation Gap

The study evaluates thermal resilience using the Portuguese Adaptive Comfort Model [10], specifically calibrated for the local climate. Unlike static ISO 7730 standards, this model defines comfort boundaries based on the 7-day running mean outdoor temperature (Θ_{rm}), acknowledging the occupant's ability to adapt in naturally ventilated spaces.

Consistent with ISO 7726 [11], indoor air temperature (Θ_{int}) serves as a robust proxy for operative temperature (Θ_{op}). In Case 1, high inertia and indirect heating minimise radiant asymmetry. In Case 2, the use of a mobile electrical heater provides direct convective heating which, combined with the low inertia plasterboard lining and internal insulation, ensures rapid air-surface equilibrium. Similarly, Case 3's internal insulating thermal plaster decouples the surface temperature from the structural mass, preventing radiant cooling during intermittent occupancy.

The comfort limits for Category II (Normal Expectation) are calculated using the algorithm calibrated by Matias 2010 [10]:

$$\Theta_c = 0.43 \cdot \Theta_{rm} + 15.6 \left(\pm 3.0^{\circ}\mathrm{C}\right) \tag{1}$$

where Θ_c is the operative comfort temperature. For the heated/intermittent cases (Cases 2 and 3), the ASHRAE 55-based adaptive coefficient [12] (cited by [10]) is applied to account for higher user expectations:

$$\Theta_c = 0.31 \cdot \Theta_{rm} + 17.8 \left(\pm 3.5^{\circ}\mathrm{C}\right) \tag{2}$$

Performance is reported as Comfort Compliance (%), defined as the percentage of hours in which the indoor operative temperature falls within the calculated bandwidths.

2.3 Monitoring Protocol

Hygrothermal monitoring utilised Testo 174H dataloggers (accuracy: ±0.5 °C/±3% RH). Data was recorded at 30-min intervals over a continuous annual cycle (Feb 2024–Feb 2025) to capture seasonal inertia lags.

To prevent occupant interference and to comply with owners´ requirements, sensor heights are varied: Case 1 was monitored at the sleeping plane (0.7 m), while Cases 2 and 3 were monitored at elevated positions (2.0–2.5 m). While thermal stratification implies these elevated sensors record temperatures slightly higher than the occupied zone, this methodology ensures a conservative assessment of winter discomfort (actual conditions are colder) and captures worst-case heat accumulation risks during summer.

3 Results: The Comfort Cost of Intervention

3.1 Winter: The Survivability Deficit

During the heating season, all three pathways struggle to meet Category II comfort standards (18 °C–25 °C) without active energy (Table 2), but their failure modes differ significantly:

(a) Pathway A (Non-Intervention): Records 0% comfort compliance, with indoor temperatures anchoring to the ground temperature (~8–11 °C). While the massive granite walls dampen daily fluctuations, the lack of insulation results in a steady-state thermal crypt. For the continuous elderly occupant, survival depends entirely on personal adaptation (heavy wool clothing) and a localised radiant heat source (wood stove), confirming that the vernacular shell fails modern static comfort metrics.
(b) Pathway B (Heavy Reconstruction): Despite deep renovation (concrete/XPS), the unheated baseline is only marginally better (13.9% compliance). However, the *responsivity* is the key differentiator. The low-inertia internal lining allows the intermittent occupant to heat the space rapidly using the mobile electrical heater. This rapid thermal response suits the intermittent occupancy profile but renders the building rapidly uncomfortable during power outages, lacking the passive survivability of the high-mass vernacular.
(c) Pathway C (Sensitive Rehabilitation): The sensitive retrofit performs poorly in winter (7.8% compliance). The internal EPS thermal plaster isolates the room from the granite mass. Without a continuous heat source to "charge" the stone, the room cools rapidly, behaving more like a lightweight tent than a massive cave.

3.2 Summer: The Maladaptation Risk

Summer highlights critical pathway trade-offs (Table 2):

(a) The Thermos Effect (Pathway C): Case 3 exhibits the lowest summer compliance (53.0%), frequently overheating above 27 °C. The internal EPS thermal plaster layer traps solar gain inside, preventing the massive granite wall from acting as a heat sink. Consequently, occupants face a stifling environment that cannot passively cool down at night. While this thermally decoupled, low-inertia space would respond rapidly if active air-conditioning were installed, its inability to manage heat passively represents a fundamental bioclimatic failure for a vernacular structure.

(b) The Ventilation Paradox (Pathway B): Surprisingly, the concrete box achieves the highest summer comfort (94.3%). This is not due to materials, but operability. The high Window-to-Wall Ratio (WWR) allows the weekend user to induce rapid cross-ventilation, dumping heat instantly.
(c) The Inertial Drag (Pathway A): The vernacular baseline achieves moderate success (59.5%) but suffers from "Cold Lag" in spring and "Heat Retention" in late summer, as the massive walls are slow to adjust to seasonal shifts

Table 2. Annual Portuguese Adaptive Comfort Compliance (Category II EN 16798–1) [10, 13]. Table format and methodology adapted from [14].

Season	Case 1 (Baseline)	Case 2 (Reconstruction)	Case 3 (Rehabilitation)
Winter	0.0%	13.9%	7.8%
Spring	0.0%	21.9%	73.0%
Summer	59.5%	94.3%	53.0%
Autumn	0.1%	14.3%	35.2%

4 Discussion: Negotiating Circularity and Comfort

The results highlight a fundamental conflict: the intervention that delivers the best *instant* comfort (Pathway B) is the most destructive to circularity, while the most circular option (Pathway A) is thermally obsolete.

4.1 Structural vs. Material Circularity

In order to evaluate the circularity implications of each intervention, defined here as the strategy's success in extending the lifespan of existing materials and avoiding the introduction of non-reversible industrial waste, this study defines a two-tier assessment:

(a) Pathway B (Case 2) represents a Linear Substitution. While this intervention successfully achieves the highest summer comfort compliance (94.3%) and provides rapid operational responsivity for intermittent winter use (as detailed in Sect. 3), this operational success comes at the severe cost of structural circularity. Rather than sourcing local granite to complete the structural shell, the deficit was bridged using non-reversible industrial materials (reinforced concrete, thermal clay blocks, and XPS). By discarding the durable vernacular shell, this pathway represents a missed opportunity for lifespan extension and generates unnecessary construction and demolition waste, prioritising short-term thermal standardisation over long-term material reuse.
(b) Pathway C (Case 3) represents Structural Circularity. By retaining the granite shell, it successfully extends the amortisation of the building's existing materials [2]. However, as evidenced by the severe summer overheating (53.0% compliance) detailed

in Sect. 3, the application of a non-reversible EPS-based thermal plaster creates a maladaptive thermal environment. The internal insulation thermally decouples the envelope from the dwelling volume, trapping solar gain and negating the passive heat-sink potential of the granite. Furthermore, unlike traditional earth mortars, the synthetic plaster contaminates the stone rubble, compromising future material circularity. True circularity in this context requires substituting non-reversible synthetic layers with bio-based, reversible alternatives (e.g. cork or hemp) that respect the building's passive physics.

4.2 Occupancy-Aligned Interventions

The failure of Pathway C and Pathway A suggests that one standard intervention cannot serve all users. We propose an Occupancy-Based Framework:

(a) For Intermittent Use (e.g. holiday houses): High-mass interventions are inefficient because they take too long to heat. A box-in-a-box lightweight strategy (similar to Pathway B but reversible) is more energy-efficient for 2-day stays.
(b) For Continuous Use (e.g. permanent dwellings): The Non-Intervention approach (Pathway A) is insufficient. However, deep encapsulation (Pathway C) risks overheating. The optimal circular strategy is Selective Insulation: insulating only the roof (major heat loss) and the north façade, while leaving the south granite internally exposed to take advantage from the thermal inertia and act as a heat sink, preserving the lithological inertia that stabilises the home.

5 Conclusion

This study compared three intervention archetypes in the Montesinho Natural Park (MNP) to evaluate the trade-off between material circularity, comfort, and heritage. The results confirm that heavy reconstruction (Pathway B) achieves a rapid thermal response suitable for intermittent use but constitutes a circularity failure; by discarding the durable vernacular shell, it fails to extend the lifespan of original materials and generates unnecessary construction and demolition waste. Conversely, sensitive retrofits (Pathway C) preserve the granite structure, successfully extending the amortisation of the building's existing embodied impacts, but risk maladaptation (summer overheating) if non-reversible synthetic insulation interferes with the building's passive physics.

Ultimately, sustainable renovation in MNP cannot be a binary choice between preservation and modernisation. It requires a negotiated intervention strategy that aligns the intervention intensity with the Occupancy Profile. Furthermore, the extreme archetypes evaluated here highlight that the optimal solution does not lie at the boundaries of total preservation or total replacement, but rather in intermediate, hybrid approaches. These findings have critical implications for the circularity of the wider built environment: they demonstrate that sustainable interventions must balance occupant comfort with respect for heritage, prioritising the maintenance of differentiating characteristics and the reversibility of construction works over standardised replacements. For the region's dominant stone masonry typology, the most circular future lies not in replacing the granite, but in surgically enhancing it—using bio-based materials to fix the winter gap without destroying the summer resilience that this geology has provided for centuries.

Monitoring the Advance of Light Pollution Through Remote Sensing Data: Case Study in a Brazilian City

Ricardo Nacari Maioli(✉), Ludmila Brunow Orlandi, Izabela Uliana Pellegrini, Victor Moura Bussolotti, and Cristina Engel de Alvarez

Programa de Pós-Graduação em Arquitetura e Urbanismo, Universidade Federal do Espírito Santo, Vitória, Brazil
ricardo.maioli@ufes.br

Abstract. Light pollution is a growing global issue that interferes in the life cycle of humans, fauna, and flora, so it's necessary to identify and understand its causes to propose mitigation strategies. This research aims to analyze the evolution of the radiance using remote sensing data in Serra, a Brazilian city of approximately 520,000 inhabitants, the most populous municipality in the state of Espírito Santo, in the southeastern Brazil. Serra had one of the highest growth rates in the state, requiring light pollution monitoring due to its potential impact. The research was based on annual remote sensing images acquired from the Visible Infra-red Imaging Radiometer Suite (VIIRS). Light pollution in the area analyzed was monitored using maps with radiance emission records generated from 2012 to 2024. These data were cross-referenced with population urban indicators. The methodology used made it possible to identify areas of the city with higher levels of light pollution, which can assist government officials and urban planners in creating control policies or other mitigation actions. The results show a significant increase in light pollution during the period analyzed, higher than expected due to population growth. The lighting of public squares and main avenues is responsible for high levels of radiation, and the urbanized area of the city, which concentrates 99% of the population, is subject to high levels of light pollution, affecting the health of its inhabitants.

Keywords: Artificial Light at Night · Night-time Light · Radiance · VIIRS · Artificial Lit Surface

1 Introduction

Light pollution is a growing problem on Earth and comes with negative consequences for fauna, flora, and human-being [1–3]. This problem has been known for several decades [4], but new discoveries are being made regarding the loss of darkness or the impact of Artificial Light at Night (ALAN) on living beings [3, 5]. Studies indicate that ALAN can cause a decrease in melatonin production at virtually any exposure intensity and, consequently, disrupt the human circadian cycle, for example [6]. The increasing use of artificial light at night is potentialized by the new lighting technologies with higher efficacy and lower cost of light, creating a rebound effect [1, 7].

Remote sensing of night lights is an important tool to observe human activities from space and, more recently, to monitor the light pollution of a region [8, 9]. Despite limitations such as low resolution and the impact of weather conditions, the use of satellite images of night-time lights can provide important information for urban management and planning [10]. This kind of investigation is used in other studies around the world [10–12].

Monitoring nighttime lights in growing cities can provide important information for urban management and planning. This study analyzes light pollution in the city of Serra, state of Espírito Santo, on the coast of Brazil (Fig. 1), which has experienced continuous population growth in recent years.

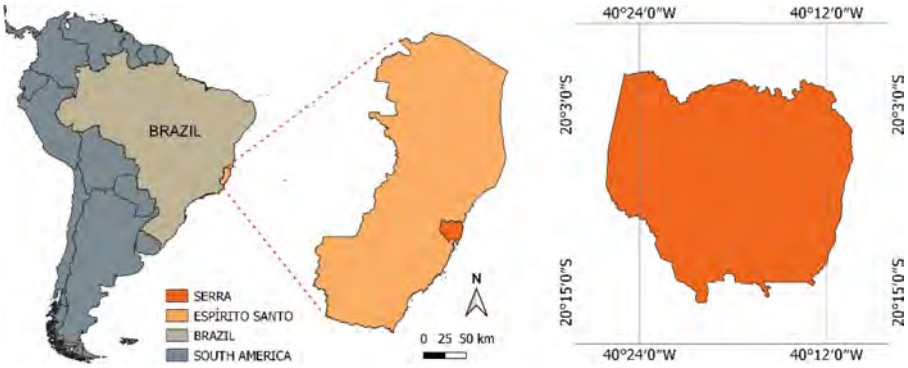

Fig. 1. Location of the municipality in relation to the state and the country.

The main objective of this study is to analyze the light pollution from 2012 to 2024 in Serra (Brazil) using remote sensing data to identify the main sources, changes and trends. This investigation uses maps to highlight the levels of radiance present in the analyzed area over this period and compares them with the type of land occupation. Thus, it is expected that it can be helpful in urban management.

2 Method

2.1 Research Area

Serra has an area of 547,631 km^2 and a population of 520,653 inhabitants. It is the most populous municipality in the state of Espírito Santo and has a population density of 950.74 inhabitants per km^2. It has the sixth highest Gross Domestic Product (GDP) *per capita* in the state and ranks among the top 10% in the country. Its urbanized area corresponds to just over 17% of the territory [13], but the municipality's urbanization rate is over 99.5% and less than 0.5% of the population is rural.

The municipality has industrial areas distributed in specific points of its territory, which concentrate a large part of the region's industries. This is due to the creation of industrial centers, a process that began in the 1970s to meet the growing demand of

the metropolitan region, culminating in the largest industrial hub in the state. Consequently, in the following decades, the municipality experienced robust demographic and economic growth [14] and now accounts for 13.6% of the state's population [13]. It should be noted that industrial, demographic, and economic growth can be indicative of increased light pollution [15], which makes Serra an interesting case study.

2.2 Extraction and Organization of Radiance Data

Light pollution data were extracted from a portal that provides annual maps of nighttime lights (www.lightpollutionmap.info), used by other studies [5, 10, 16]. At the time of writing, global maps containing radiance emissions ($nWcm^{-2}\ sr^{-1}$) were available for the years 2012 to 2024. These maps, in GeoTIFF format, were inserted into QGIS software for georeferenced spatial representation and contained radiance data for each pixel in the image. The software was used for visualization, creation, and editing of maps, as well as data analysis (https://qgis.org/). The radiance data contained in the pixels were divided into value ranges, with each range represented by a specific color in a predefined gradient, facilitating the analysis and comparison of the data obtained. A spreadsheet with radiance data was also generated from the maps produced in the software. The data for each year was then compiled and organized for analysis of the evolution of light pollution over the period evaluated.

2.3 Selection of Methodology

Light pollution was analyzed using statistical indicators such as the sum of radiance values (Rad. Sum), radiance per unit area (Rad. Mean), and radiance per 1000 inhabitants (Rad./1 k Pop.) [5], to compare the data obtained with other studies and to analyze its evolution over time.

Another way of evaluating light pollution, proposed by Górniak-Zimroz *et al*. [10], is to organize its levels into five classes, from No pollution to Very High pollution. In the present study, an adaptation of the last class was proposed, since the values found may exceed the originally proposed limit, resulting in the following scale: 0–1.5–3.0–15.0–higher ($nWcm^{-2}\ sr^{-1}$). This methodology can help identify social and environmental elements that emit light or are subject to it [10]. Here, this methodology was used to analyze the spatial coverage of each class and the land use and occupation subject to it. However, this method restricts the possibilities for analyzing radiance data, so a complementary analysis was proposed in the sequence.

Therefore, another method used in the research was the spatialization of radiance levels divided into more bands, including higher values, proposed to facilitate the identification of areas that record radiance peaks in the city. A similar method was used in the research by Maioli *et al.* [16] for the analysis of annual maps, however, with another scale of radiance levels. Thus, this study proposed a scale of radiance levels divided into 10 bands, each band being limited to twice the value of previous one (0–0.5–1.0–2.0–4.0–8.0–16.0–32.0–64.0–128.0 $nWcm^{-2}\ sr^{-1}$). With the production of maps using this new classification, areas with higher radiance levels became visually prominent. Next, the type of land use present in these brighter regions was verified, an important analysis to assist public authorities in taking mitigating measures.

3 Results and Analysis

The number of inhabitants of Serra growth 27,2% in 12 years (2010–2022) [13], observed in Fig. 2a, but the sum of total radiance observed in this city increased 65,4% (2012–2024). This means that the amount of radiance emitted per inhabitant is growing rapidly, reflected in an increase in *per capita* emissions in the range of 30%. Contrary to what is observed in most developed countries, developing countries show a growing trend in nighttime light pollution mean and *per capita* [11]. The *per capita* radiance of the municipality reached 99.5 nWcm^{-2} sr^{-1} for every 1,000 inhabitants, which is higher than the national mean of 45.2 nWcm^{-2} sr^{-1} [17].

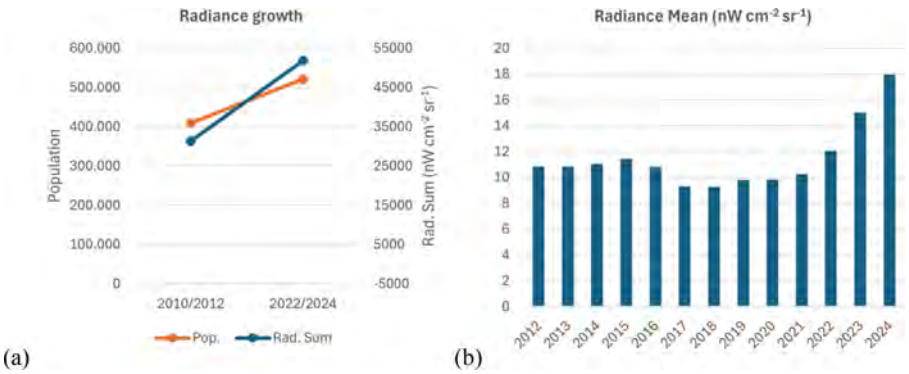

Fig. 2. Population growth and total radiance emissions over a 12-year period (a). Evolution of mean radiance between 2012 and 2024 (b).

In the middle of the period analyzed, it was possible to identify a decrease in radiance levels, which may be caused by different reasons [9, 11, 12]. However, an alarming increase in emissions was observed in sequence. The last three years have presented a continuous elevation of radiance levels (Fig. 2b). This fact matches with the gradual replacement of the street lighting system. The transition of streetlamps technology to LED in the city started in 2020 and was completed in 2024, and the amount points of light grows caused by the expansion of urban areas and the number of luminaires. The municipality reported that the new lights installed were 5000 K in color temperature. It should be noted that the sensitivity limitation of VIIRS DNB for wavelengths below 500 nm may suggest a false reduction in light pollution in cities that have transitioned to LED lighting [18].

In contrast to what was observed in the neighboring municipality, the state capital, which reached an average of 32.74 nWcm^{-2} sr^{-1} in the period [16], the mean radiance levels Serra between 2012 and 2024 was 11.43 nWcm^{-2} sr^{-1}, exceeding the national mean by 47 times. It is worth noting that the city's average radiance is on the rise and reached an average of 17.97 nWcm^{-2} sr^{-1} in the last year analyzed, close to the level recorded in Hong Kong [12], while the average for Brazil is 0.24nWcm^{-2} sr^{-1}.

In this study, the light pollution classification method based on Górniak-Zimroz *et al.* [10] was used, divided into five classes, to analyze the coverage of each class in

the territory. As a result, the areas corresponding to Very High Pollution increased by 21.3% in comparison between 2012 (Fig. 3a) and 2024 (Fig. 3b), reaching a portion corresponding to 29% of the territory. Another class that increased significantly in the period was the area covered by Medium Pollution, registering a growth of 41,8%.

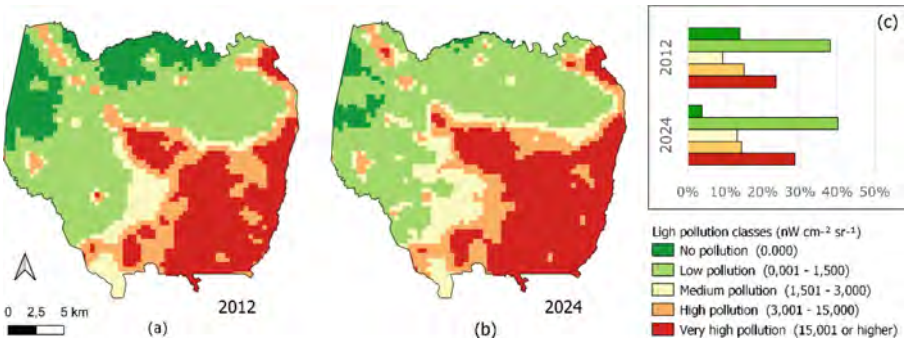

Fig. 3. Maps of the study area drawn up from light pollution classes, based on Górniak-Zimroz *et al.* [10] for the years 2012 (a) and 2024 (b), with a comparative graph between them (c).

One of the aggravating factors of light pollution in the region, observed in the study, is a 72.6% decline in areas identified as No Pollution, which was limited to only 4% of the territory in the last year analyzed (Fig. 3b). This indicates an increase in light pollution in non-urbanized areas of the city, which can have negative impacts on the ecosystems of these regions. The other classes of light pollution registered a variation of approximately 5% in the total quantity, that is, less significant, but with a partial shift in the areas covered by them (Fig. 3c).

Next, the social and environmental elements in each class were identified by analyzing land use and occupation. It was observed, therefore, that the area covered by the Very High Pollution class on the 2024 map corresponds to the urbanized area. Thus, it is estimated that approximately 99% of the municipality's population lives in a region classified as Very High Pollution (Fig. 4b). Some buildings were found outside this zone, but subject to some level of light pollution.

Considering only its urbanized land, it was possible to highlight in the analysis the presence of urban environmental protection zones [19] close to the city's residential and industrial areas located in regions with Very High Pollution in 2024 (Fig. 4a). This fact can have a negative impact on local fauna and flora, as they are influenced by ALAN from urban lighting [1], which remains on throughout the night.

Nevertheless, this approach to radiant classification has some limitations, such as the absence of highlighting of the brightest pixels in the study area. To address this, a 10-class scale was used to facilitate identification. This made it possible to identify the pixels in the municipality with the highest radiance levels and the type of land use and occupation present in the region with the most intense brightness (Fig. 5).

Despite the large presence of industries in the municipality, some of them operating 24 h a day, among the areas responsible for the highest emissions, some had little or no industrial activity. The areas that stood out with the highest radiance indices are

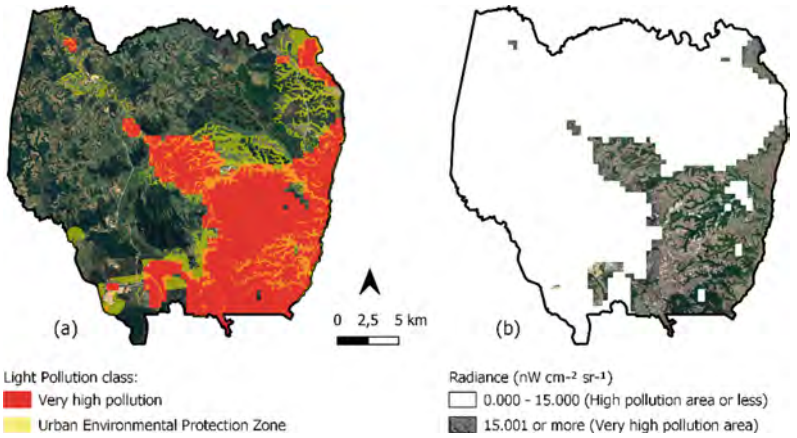

Fig. 4. Maps of Serra with satellite images recorded using QGIS software. (a) Very High Pollution area (in red) covering Environmental Protection Zones [19] (in soft yellow). (b) Urbanized portion of the territory corresponding to the Very High Pollution class.

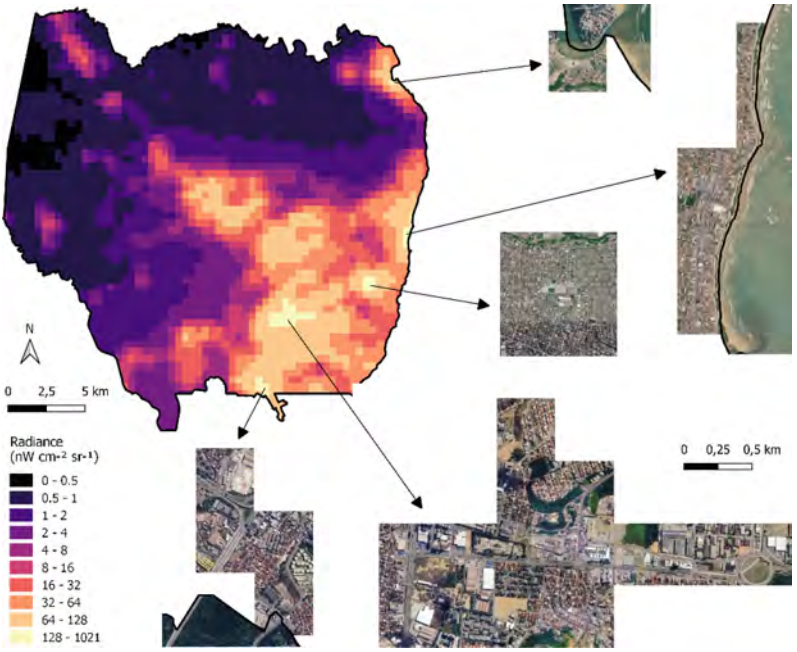

Fig. 5. 2024 light pollution map highlighting the areas with the highest radiance levels.

beachfront regions, public squares, and major avenues, characterized by the presence of commercial establishments and few industries. Among the highlighted sections, two public squares appear to be responsible for excessive light emissions into space. It should be emphasized that, in 2024, the municipality expanded the lighting system on some of

the main avenues, which may have contributed to an increase in emissions that year in certain sections of the city.

Similar results were found in research conducted in China, where residential and commercial areas achieved higher mean radiance values, with 48 $nWcm^{-2}$ sr^{-1} and 54 $nWcm^{-2}$ sr^{-1}, respectively, than industrial regions, which recorded 38 $nWcm^{-2}$ sr^{-1} [12].

4 Conclusions

The research aimed to analyze the evolution of light pollution in the city of Serra (Brazil) from 2012 to 2024 based on satellite data, a process carried out through the classification and subsequent identification of areas with recorded levels of radiance. The method used proved to be effective in identifying the spread of light pollution and the brightest areas of the city. 99% of the municipality's population is subject to high levels of light pollution, which can be harmful to the health of its residents, while environmental preservation areas located near urbanized regions are also impacted by this level of pollution, probably affecting the ecosystems present there. The municipality recorded an increase in *per capita* light emitted into space, as well as an increase in total light emitted over the last three years of the analysis, and the problem may be even more serious due to limitations of the nighttime light sensor.

A survey closer than satellite data, such as local measurements or drone analysis, can provide more accurate data on the main sources of local light pollution. However, conducting the first approximation through the evaluation of satellite data has proven to be an interesting strategy for assessing the evolution of light pollution and that can be reproduced in similar situations.

Acknowledgments. This study was conducted with support from the Fundação de Amparo à Pesquisa e Inovação do Espírito Santo (FAPES).

A Regenerative Framework for the Renovation of Existing Buildings

Cristina Jiménez-Pulido(✉), Ana Jiménez-Rivero, and Justo García-Navarro

Universidad Politécnica de Madrid, 28040 Madrid, Spain
cristinajpulido@gmail.com

Abstract. Regenerative development offers a promising pathway to address the transformation required in the building stock to meet climate commitments. However, its application to existing buildings remains largely unexplored. Supporting this transition requires instruments aligned with regenerative ambitions. This study proposes a regenerative framework for existing buildings to support decision-making from the evaluation phase onward. The framework adopts a hierarchical structure based on three pillars—Place-based (Pb), System-based (Sb) and Positive-oriented (Po)—that represent the core ambitions. These pillars are articulated through nine attributes: Building pre-conditions, Site usage patterns, and Location sensitivity (Pb-1,2,3); Long-term vision, Closed-looped systems, and Lasting value (Sb-1,2,3); Empathy with occupants, Responsible and nature-based elements, and Creativity and Innovation (Po-1,2,3). Together, these elements provide a structured basis for advancing the regenerative transformation of existing buildings. By organising regenerative ambitions into a hierarchical and assessment-oriented structure, the framework provides a coherent basis for supporting the integration of regenerative principles into evaluation processes for building maintenance and renovation. In a prospective manner, the study explores the integration potential of the framework with current evaluation instruments—institutional initiatives, Sustainability Certification Systems and pioneering assessment tools—highlighting their potential role in supporting regenerative approaches to building renovation.

Keywords: Regenerative framework · Evaluation instruments · Sustainability certification systems · Existing building renovation · Regenerative approach

1 Introduction

Cities and buildings are key to reducing environmental impacts and to mitigating climate change. The renovation of the building stock represents both a challenge and an opportunity for long-term sustainable development. Regenerative development is increasingly considered necessary to redefine sustainability (e.g., [1, 2]). It challenges traditional building-centric approaches to maintenance and renovation [2], and moves beyond a conservative impact-reduction vision towards buildings capable of generating economic, social, environmental, and intangible benefits. Therefore, the regenerative approach is particularly well-suited to the transformation required in the building stock.

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 625–633, 2026.
https://doi.org/10.1007/978-3-032-34930-9_73

This shift in perspective also calls for updated instruments to make decisive progress. Although regenerative principles are increasingly explored in relation to buildings and urban environments, studies developing these principles, and proposing operative processes remain scarce [3], especially for existing buildings. Early attempts to incorporate regenerative principles into instruments have been noted [4], but overall advancement remains moderate. Instruments grounded in regenerative principles could support both planning and implementation of regenerative actions, with assessment tools being particularly relevant for practical application. To obtain regenerative outcomes, assessment procedures for existing buildings must align with the goals envisioned by the regenerative paradigm. However, current tools—with Sustainability Certification Systems (SCSs) playing a leading role—rarely focus on either existing buildings or regenerative sustainability [5].

To address this gap and promote regenerative decision-making, this study aims to lay the foundations for integrating the regenerative perspective in practice-oriented instruments for existing buildings. Specifically, our objective is to identify the regenerative elements subject to be integrated into assessment processes for existing buildings and to outline a framework to support future implementation. The contribution of this work lies in reorganising existing concepts and formalising regenerative ambitions into a hierarchical and assessment-oriented structure tailored to building stock transformation.

The following section provides the methodological approach adopted, analyses the regenerative sustainability paradigm in relation to existing buildings and presents the proposed framework. Section 3 examines links between the regenerative framework and current evaluation instruments to explore pathways for application. The final section presents the conclusions of the study.

2 Conceptual Development of the Regenerative Framework

2.1 Methodological Approach

Structuring the shift towards regenerative sustainability into an operational framework is challenging [6], specifically for buildings in use given their multidimensional nature. A literature-informed conceptual analysis was conducted to examine both the regenerative sustainability theory and evaluation instruments, with a focus on their applicability to existing buildings, their structures and sustainability approaches. Regarding the study of regenerative theory to identify regenerative ambitions applicable to existing buildings, a literature specifically addressing this paradigm was first reviewed. The review was expanded to include related literature areas, namely circularity, resilience, and traditional sustainability, based on conceptual linkages identified.

Regarding evaluation instruments, literature was collected with a focus on pioneering regenerative-oriented tools and emerging instruments aligned with regenerative thinking. Additionally, literature on Sustainability Certification Systems (SCSs), complemented by previous review work [5], and institutional assessment initiatives were analysed. Evaluation instruments can help bridge theory and professional practice, and SCSs, because of their widespread use, can provide useful insights and may support the integration of regenerative approaches into practice. Furthermore, given the relevance of regenerative

approaches to global and European challenges, examining their links with institutional instruments was also considered essential.

For regenerative sustainability to succeed in existing buildings, it is essential to understand the implications of adopting a regenerative approach and to translate regenerative principles into assessment-oriented elements. Rather than proposing new regenerative concepts, the study reorganises existing ones into an assessment-oriented framework tailored to existing buildings, capable of systematically structuring the particular regenerative ambitions. Based on the review conducted, key regenerative features and recurring themes were identified and, through an iterative process, synthesised into the main regenerative ambitions for existing buildings (see Fig. 1). These elements were grouped around conceptual pillars, organised into attributes for building evaluation purposes. This process enabled the development of a hierarchical regenerative framework intended to support regenerative evaluation and renovation for existing buildings.

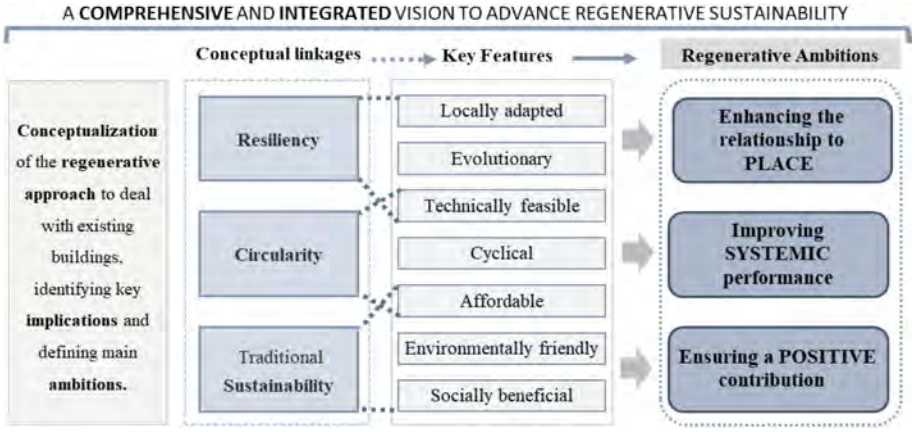

Fig. 1. Conceptual analysis conducted to examine the regenerative sustainability paradigm.

2.2 Identifying the Regenerative Ambitions to Be Pursued for Building Stock

The regenerative sustainability linked to the built environment emphasises two key concepts, as Orova & Reith [1] highlighted: (a) the co-evolution between people and nature; (b) a proactive vision aimed at reversing environmental degradation by generating benefits. Instead of "doing less harm" as in traditional sustainable buildings [6], regenerative buildings aim to produce net-positive impacts. In practice, this involves adapting decisions to the particular circumstances of each building, restoring technical, social, and natural systems as a first step towards generating positive outcomes (that is, regeneration).

The change of vision implied by the regenerative paradigm foregrounds place as a generator of social and natural capital [4, 7]. To transform existing buildings into regenerative ones, a systems-based approach is paramount, as the building stock forms a complex socio-technical-natural structure with multiple interconnected dimensions and stakeholders. This highlights the need to reconsider the notion of place in existing

buildings. The history and potential of the living environment must be acknowledged, together with the functioning dynamics among existing buildings, to understand context, preconditions, and priority needs.

Closing loops during building operation is essential. Lifecycle thinking must therefore be applied to guide decisions, considering the building's lifespan [8] as well as the functionality and maintainability of its components. Long-term resource efficiency, to save energy and material sources, requires extending building use while improving performance, highlighting the relevance of regenerative approaches to buildings maintenance. Successful regenerative interventions must involve strengthening vital relationships [3], in partnership with nature. This requires a long-term vision to account for overall impacts and complex interactions with context. Tailored regenerative roadmaps for each building could reduce negative impacts and generate positive contributions at multiple scales, enhancing cultural identity and supporting environmental health and biodiversity.

2.3 Proposed Regenerative Framework for Existing Buildings

Pursuing regenerative results when dealing with existing buildings requires considering all regenerative ambitions as pillars underpinning decisions, and adopting a broader, holistic, and integrated approach. Three Regenerative pillars—Place-based (Pb), System-based (Sb), and Positive-oriented (Po)—form the backbone of the proposed framework, providing its first hierarchical level. These pillars directly relate to the categories proposed by Kamari et al. [9] for renovation processes ("Functionality", "Feasibility", and "Accountability"). A second hierarchical level is defined through three attributes for each pillar, which intends to support the framework applicability and decision-making. These elements together, pillars and attributes, shape the regenerative framework (see Fig. 2), intended to provide guidance for action in existing buildings.

The **Place-based pillar** is shaped by: Building pre-conditions (Pb-1); Site usage patterns (Pb-2), focused on physical dynamics and geographical characteristics; Location sensitivity (Pb-3), related to intangible values of the place. Regenerative decisions should be adapted to the building's existing physical pre-conditions, usage patterns, and local context, seeking harmony with place and co-evolution [2]. However, buildings and urban areas are often treated separately [10]. Given that existing buildings are at some point in their lifespan, a comprehensive assessment of their physical and functional condition is paramount to ensure feasibility and anticipate impacts of solutions.

The **System-based pillar** comprises: Long-term vision (Sb-1); Closed-looped systems (Sb-2); Lasting value (Sb-3). A systemic approach is fundamental because existing buildings are embedded in complex and evolutionary socio-technical-natural systems [7]. Regenerative interventions must not only consider multiple scales, scenarios and long-term implications, but also identify circular flows. Closing loops depend on stakeholder engagement, particularly those involved in resource and service provision. A holistic view permits identifying interrelationships among the different facets—where human factors are key—and enables the evaluation of multiple impacts of decisions. Economic considerations are also essential to ensure feasibility of measures and to spread the benefits. Ultimately, regenerative solutions should produce lasting improvements.

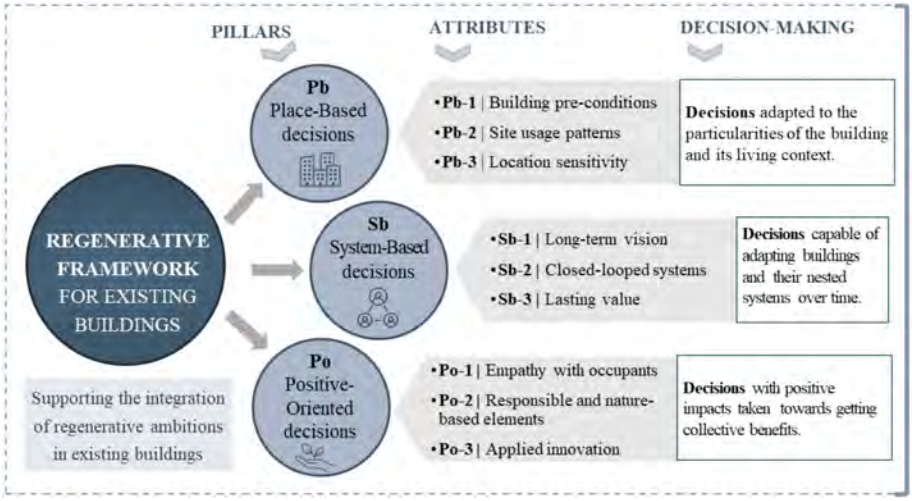

Fig. 2. Proposed Regenerative framework for dealing with existing buildings.

The **Positive-oriented pillar** comprises: Empathy with occupants (Po-1); Responsible and nature-based elements (Po-2); Creativity and Innovation (Po-3). Positive-oriented measures enhance human wellbeing and strengthen natural systems. Suitable materials and products, and designing with nature, support occupant comfort and reduce environmental harm. Creativity and innovation can contribute to achieving regenerative ambitions, enabling resource-efficient solutions. Monitoring performance and controlling users' satisfaction is also advisable, ensuring operational transparency.

Although presented as separate regenerative elements, the pillars and attributes function interdependently. System-based considerations reinforce place-based attributes, and human-factor elements appear in both System-based and Positive-oriented pillars, stressing the need for a holistic vision. The framework can help define criteria for regenerative action on existing buildings, acting as a structured basis for integrating regenerative ambitions in evaluations, through integration within instruments used by practitioners for assessments. Once the right elements are identified, for implementation in practice, suitable metrics and indicators must be developed [7] to assess the attributes and support decision-making.

3 Instruments Supporting the Practical Application of the Regenerative Framework

3.1 Institutional Instruments for Sustainability Evaluation

Institutional instruments such as codes, standards, regulations, and strategies have enormous influence because they set minimum requirements and shape practice. They hold significant potential for incorporating more ambitious targets toward a regenerative built environment. European standards developed by CEN/TC 350, such as prEN 15978 [11],

have developed building sustainability assessment methodologies from a life-cycle perspective. Standards such as ISO 15392:2019 [12] adopted closely aligned restorative and regenerative concepts to support sustainability targets. Reed et al. [13] highlighted the relevance of a widely accepted certification system, which draws attention to the tool Level(s), linked with the EN standards and with the support of EU policymakers.

Level(s) is a voluntary reporting tool that promotes harmonisation to set a common sustainability language [14], offering guidance for assessing and improving buildings. Level(s) encourages staged building renovation through three levels of detail [15]. It also promotes life cycle performance thinking compatible with regenerative approaches. Given its institutional status and its integration of sustainability, circularity, and quality-of-life aspects, Level(s) may become a driver of regenerative practice. However, since Level(s) does not distinguish between new and existing buildings, it may replicate limitations noted in SCSs [5] when it is applied in buildings in use. Developing a specific scheme for existing buildings, aligned with the regenerative framework here proposed, could address this gap.

3.2 Sustainability Certification Systems and Regenerative-Oriented Tools

Sustainability Certification Systems (SCSs) stand out as the most mature and recognised assessment instruments. BREEAM and LEED certification, launched in 1990 and 2000 respectively, remain the most internationally widespread [16]. The number of SCSs and scheme updates is still growing, some of them specifically directed to existing buildings, to certificate their operation or renovation. However, the schemes adaptation from new buildings to the specific features of existing ones is still limited [5]. Consequently, SCSs in existing buildings, whose performance evaluations are more complex, remain underutilised.

SCSs have been instrumental in mainstreaming sustainable building practices [6] but their focus on reducing negative impacts rather than generating positive ones [7] limits alignment with regenerative approaches. At present, the Living Building Challenge (LBC), launched in 2006 by the International Living Future Institute, is considered the SCS closest to a regenerative perspective [17]. Still, circularity issues remain at an early stage of integration [18] in SCSs as does a deeper understanding of interactions between buildings in use and their surrounding environment. Besides, some emerging instruments adopt promising approaches to regenerative sustainability. Apart from the well-known WELL Building Standard, these include The Natural Step, One Planet Living, and Planet Mark [19], and more regenerative-oriented tools, such as REGEN, Eco-Balance planning and design, Perkins + Will's framework, and LENSES framework [4]. More recently, RELi rating system has been developed for assessing and planning buildings to be resilient.

While these methods embed regenerative ideas to varying degrees, none fully assess the regenerative capacity of buildings, let alone that of existing ones. Moreover, most of them are quite experimental or are not widely applied in practice. The LENSES framework appears to be the initiative that most clearly incorporates regenerative principles. It was developed for practitioners to guide decision-making, rather than to certify the final product, promoting design measures that enhance system interconnections to create regenerative places [20]. The REGEN tool and RELi certification are remarkable for

being promoted by the USGBC (LEED certification administrator). REGEN sought to complement LEED by guiding the attainment of positive outcomes [4], but its limited metrics hindered adoption. RELi rating system [21], adopted later (in 2017) by USGBC, builds on LEED to promote resilience to climate-related impacts, expecting to become a leading system for designing communities, buildings and infrastructure adapted to unexpected events.

Leveraging the maturity of existing SCSs, complemented with insights from pioneering approaches, the next step should focus on strengthening the alignment of evaluation instruments with regenerative perspective by introducing the elements of the regenerative framework proposed for existing buildings. These tailored instruments would support the broader regenerative transformation of the building stock and contribute to climate commitments.

4 Conclusions

With a special focus on supporting the transition to achieve regenerative outcomes, this study provides a framework tailored to existing buildings. This regenerative framework is shaped by the main ambitions identified, structured through three pillars—Place-based (Pb), System-based (Sb), and Positive-oriented (Po)— and nine attributes that articulate the pillars (three in each): Building pre-conditions, Site usage patterns, and Location sensitivity (Pb-1,2 & 3); Long-term vision, Closed-looped systems, and Lasting value (Sb-1,2 & 3); Empathy with occupants; Responsible and nature-based elements, and Creativity and Innovation (Po-1,2 & 3). The hierarchical structure aims to enable practical application and support coherent assessments and decision-making.

The proposed framework is a conceptual approach that provides a structured basis for advancing regenerative transformation in existing buildings. The framework requires future validation through practical applications. Its implementation would require integrating regenerative criteria into evaluation processes and progressively aligning current assessment instruments with regenerative ambitions. In this sense, the framework represents an initial step towards the integration of regenerative principles into evaluation and decision-making processes.

The building stock must go beyond sustainability to face upcoming challenges, and the regenerative paradigm offers a promising approach. Buildings managed, operated and renovated according to the regenerative ambitions identified and outlined in the regenerative framework proposed—that is, ‘regenerative buildings’—could enhance quality of life, achieving positive impacts on both the built and natural environment.

edipavsar81@gmail.com

Abstract. Rapid urbanization, urban transformation, and high seismic activity in Türkiye significantly increase the generation of construction and demolition waste (CDW), particularly after large-scale disasters like the 6 February, 2023 earthquakes. This study evaluates the circular management and recovery potential of CDW in accordance with the waste management hierarchy. Methodologically, empirical field data were collected during the source-separated demolition of a representative five-storey building (1,000 m^2) in Kahramanmaraş province. The demolition yielded approximately 134.4 tons of recoverable materials. Extrapolating these findings to the 36,932 buildings collapsed during the 2023 disaster indicates a national recovery potential of approximately 5 million tons of CDW. The study examines recycling concrete, brick, and ceramic waste into secondary aggregates, alongside recovering ferrous and precious metals (iron-steel, copper, aluminum) within a circular economy framework. Based on current market prices, a simplified economic analysis estimates the total value of these recoverable materials to range between 130 and 140 billion TL (approximately 2.5–2.7 billion euros). Ultimately, integrating post-disaster CDW into sustainable recovery processes is vital for conserving natural resources, reducing energy consumption, mitigating carbon emissions, and enhancing economic sustainability.

Keywords: Construction and Demolition Waste · Waste Management · Resource Recovery · Circular Economy · Disaster Waste · Sustainability

1 Introduction

Technological advancements and changing living standards have had a significant impact on urban development, as in many other fields. The construction of high-rise buildings, the renewal of asphalt roads, and the restoration of residential buildings have been accompanied by a substantial increase in waste generation. Over the past century, the construction sector in Türkiye has undergone a remarkable expansion. The gross domestic product (GDP) derived from the construction sector increased from 33.6 billion TL in the second quarter of 2025 to 36.7 billion TL in the third quarter of 2025. Between 1995 and 2025, the average GDP generated by the construction sector amounted to 18.8 billion

https://doi.org/10.1007/978-3-032-34930-9_74

TL, reaching its highest level of 36.7 billion TL in the third quarter of 2025 (Trading Economics, 2025). According to the Construction Production Index data published by TÜİK for October 2025 (with 2021 as the base year = 100), the building construction sub-sector index increased by 28.8% compared to the same month of the previous year, while the non-building construction sub-sector index rose by 21.8%, and the specialized construction activities index increased by 29.9%. These data clearly demonstrate the critical importance of the construction sector for the Turkish economy (TUİK, 2025).

In such a rapidly growing sector, the supply of raw materials is of critical importance. Concrete and metals constitute the fundamental building blocks of the construction industry. In addition to these materials, a significant amount of recyclable waste is generated during the demolition phase of buildings. The natural disaster that occurred in Türkiye on 6 February 2023, for which a Level 4 earthquake alert was issued, affected an area of approximately 120,000 km^2. Within this region, where nearly 15 million people reside, demolition activities took place across 11 provinces, 124 districts, and 6,929 villages and neighborhoods. As a result of the earthquakes, 36,932 buildings collapsed at the time of the event, while an additional 311,000 buildings—comprising a total of 872,000 independent units—became uninhabitable due to severe structural damage. The number of buildings that collapsed by province is presented in Table 1. (TMMOB, 2023).

Table 1. Number of Buildings Collapsed in Earthquake-Affected Provinces

No	Earthquake-affected provinces	Number of collapsed buildings
1	Adana	88
2	Adıyaman	5,826
3	Diyarbakır	21
4	Elâzığ	56
5	Gaziantep	3,783
6	Kahramanmaraş	7,307
7	Malatya	4,238
8	Hatay	13,883
9	Kilis	448
10	Osmaniye	649
11	Şanlıurfa	633
	Total	**36,932**

This table demonstrates that Türkiye is a seismically active country and that pre-disaster risk management is an essential component of damage mitigation that must not be overlooked. It also highlights the significant scale of the construction sector in Türkiye within the context of crisis management. In addition, the large volume of construction and demolition waste generated as a result of such disasters should not be ignored, and these wastes should be incorporated into circular management and recovery processes. The processes of constructing, renovating, and demolishing buildings give rise to construction

and demolition waste consisting of a complex mixture of various material types. These wastes are generally classified as inert waste (such as sand, brick, and concrete) and non-inert waste (including plastic, paper, glass, wood, vegetation, and other organic materials) (Ulubeyli et al., 2017). While a portion of this waste can be recycled, others cannot be recovered. Among these waste fractions, concrete and iron constitute the largest proportions. In Türkiye, the management of construction and demolition waste is regulated under the Regulation on General Principles of Waste Management, and the waste types listed in Annex IV of the regulation. (ÇŞB, 2008). Therefore, the primary objective of this study is to quantify the recovery potential of CDW generated by the 6 February 2023 earthquakes and to evaluate its economic and environmental value within the framework of a circular economy. By analyzing empirical data from a representative demolished building, this study aims to provide actionable insights and a macro-level baseline for post-disaster waste management strategies.

2 Materials and Methods

Within the scope of this study, a five-storey building with a total floor area of 1,000 m^2 that was demolished in Kahramanmaraş province following the 6 February 2023 earthquake was selected as a case study. To obtain robust waste generation data, the demolition process was continuously monitored by an environmental engineer. Instead of visual estimation, the quantification of waste was conducted through direct measurement. During the demolition, materials were classified and separated on-site. The separated CDW fractions were then loaded onto transport trucks, and their precise net weights were recorded using industrial weighbridges before being transferred to licensed recovery facilities.

3 Results

As a result of the field study, the materials obtained from construction and demolition waste (CDW) generated during the demolition of the sample building and classified according to their types are presented in Table 2. All of these wastes were transferred to licensed recovery companies for evaluation, and efforts were made to minimize waste through sustainable management practices. In addition, among the remaining waste fractions, those classified under waste code 17 01 07 (mixtures of concrete, brick, tiles, and ceramics) were also included in the recovery process by being utilized as aggregates.

Aggregates constitute a critical input in concrete production, accounting for approximately 75% of the total concrete volume. However, on a global scale, only about 18% of the aggregates produced are obtained through recycling from waste materials such as industrial waste, ash, and slag (URL, 1, 2023). In Türkiye, it is estimated that approximately 200 million tons of aggregate are required annually for the production of around 110 million m^3 of ready-mixed concrete, based on an average requirement of 1.8–2.0 tons of aggregate per cubic meter of concrete (THHB, 2013). The extraction and processing of these materials from natural sources exert significant environmental impacts.

Under current conditions, natural aggregates are predominantly used in concrete production. Since these materials cannot be reused after consumption, substantial economic costs arise at both the production and consumption stages, along with considerable environmental challenges. Practices aimed at the recycling of construction and demolition waste (CDW) were first implemented in the 1970s in certain regions of the United States and Europe due to the depletion of natural resources used in concrete production. During the 1980s, the establishment of separation and recycling facilities accelerated as a result of limited landfill capacity, environmental problems caused by construction and demolition waste, and increasing environmental awareness regarding raw material consumption. Today, the most commonly applied disposal method in the management of construction and demolition waste is recycling, followed respectively by incineration and landfilling. In European Union countries, practices related to the recycling of construction and demolition waste began in the 1990s, while in Türkiye the first recycling facility for these wastes became operational in 2006 (Ulubeyli et al., 2017).

Table 2. Amounts of Recyclable Materials Obtained from the Demolition of a Building with a Total Floor Area of 1,000 m^2

Waste type	Amount (kg)	Description
Plastic	3,000	Pipes, some interior coverings
PVC	26,000	Doors and windows
Iron and steel	90,000	Columns, beams, and slab reinforcements
Fixtures (brass)	300	Bathroom and kitchen sources
Fixtures (copper)	400	Bathroom and kitchen sources
Mixed cables	2,500	Electrical, plumbing, and antenna connections
Glass	2,200	Windows and other glass components
Wood	2,000	Doors, cabinets, parquet flooring, and windows
Aluminum	2,000	Door and window frames
Copper	6,000	Electrical installations
Total	**134,400**	

Construction and demolition waste that is not contaminated with hazardous substances have the potential to be fully recovered. The recovery of these wastes contributes to the conservation of natural resources while also reducing waste disposal costs (Eren and Şen, 2023). Across European Union member states, the average annual generation of construction and demolition waste per country is approximately 20.2 million tons, with an average recovery rate of about 49.4% (Vieira, 2015). Materials recycled from construction and demolition waste (CDW) are processed in accordance with relevant technical standards by companies licensed by the Ministry of Environment, Urbanization and Climate Change, and are subsequently used either alone or in combination with natural aggregates in concrete production, road and pavement construction, drainage applications, and infrastructure and superstructure projects (Eren and Şen, 2023). The

reuse of materials obtained through the recovery process is of great importance from both economic and environmental perspectives. The utilization of these materials as secondary raw materials not only contributes to the conservation and sustainable management of natural resources but also provides significant benefits in terms of human health and environmental protection. Within the waste management hierarchy, when the prevention or reduction of waste generation—the highest priority—cannot be achieved, reuse or recycling represents the most effective management option for construction and demolition waste (EC, 2020).

Recovery of Concrete Materials: Concrete waste separated from construction and demolition waste (CDW) is transported to recovery facilities. Upon arrival at the facility, the incoming waste is recorded in the automation system and then subjected to crushing by being fed into a primary crusher. Subsequently, the material is further reduced in size using a jaw crusher and conveyed to screening units via conveyor belts. The screened materials are passed through a magnetic separator to remove any remaining metal content. The resulting materials are then classified according to sieve sizes, and the aggregates prepared for shipment are stored in separate areas using conveyor systems. The recovered aggregates can be used not only in concrete production but also as fill material in new construction sites, road works, and various applications requiring ground filling (Poon et al., 2001). A schematic diagram of the process is presented in Fig. 1.

Recycling of Plastic Materials (Clean and Contaminated): Plastic waste is accepted at licensed recovery facilities. The received plastics are subjected to a shredding process using crushers and reduced to the desired particle sizes. The shredded plastics are then transferred to washing tanks to remove impurities adhering to their surfaces. During this stage, the waste is washed and purified from contaminants. The cleaned and dried plastics are subsequently conveyed to the granulation line, where they are melted through thermal processing and formed into strands. These strands are cooled in a water bath and then transferred to the cutting line, where they are cut into granules of the required size using appropriate blades, thereby converting them into secondary raw materials (Fig. 2). These raw materials can be utilized in various sectors depending on market demand, including textiles, agriculture, industrial and technical products, as well as a wide range of materials commonly used in daily life (Hopewell et al., 2009).

Recycling of Ferrous Materials: During the initial stage of demolition, iron materials originating from the reinforcement of columns, beams, and slabs are separated on-site. The separated ferrous materials are transported to metal recovery facilities together with the iron obtained through magnetic separation during the aggregate recovery process from concrete waste. At the facility, following size reduction processes, the materials are melted in high-temperature furnaces and cast into molds to obtain products in the desired form. Metals can be recycled indefinitely through this process (Reuter et al., 2013). The recycling process of ferrous materials is presented in Fig. 3.

Recycling of Glass Materials: Glass waste collected during the demolition process is transported to recovery facilities, where it is sorted according to color. The sorted glass waste is then crushed in milling machines to reduce particle size and completely remove impurities. Subsequently, the material is melted in furnaces at temperatures ranging

between 1,400 and 1,600 °C, shaped, and prepared for market distribution (Fig. 4). Glass waste derived from construction and demolition activities is primarily used in the production of glass wool insulation materials or as an additive in asphalt pavements during road construction. Since glass is a material that can be recycled indefinitely, it plays a significant role in promoting environmental sustainability. Glass recycling not only reduces raw material consumption but also leads to substantial reductions in carbon emissions and energy use (Corinaldesi et al., 2005).

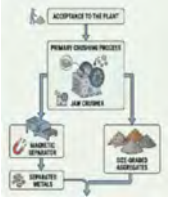

Fig. 1. Schematic representation of the concrete recovery process

Fig. 2. Schematic representation of plastic materials recycling process

Fig. 3. Schematic representation of ferrous materials recycling process

Fig. 4. Schematic representation of glass materials recycling process

Recycling of Precious Metals (Aluminum, Copper, etc.) Precious metals recovered from construction and demolition waste are first subjected to a classification process. During this stage, metals such as copper, aluminum, and brass are separated by type, cleaned, and reduced into smaller pieces. These metals are primarily obtained from bathroom and kitchen fixtures, doors and windows, and electrical installations. After sufficient size reduction, the precious metals are transferred to melting furnaces, where they are converted into a molten state through thermal processing. The molten material is then poured into casting molds to obtain products in the desired form. In some cases, complex mixed wastes may also undergo additional separation using electrolysis tanks. The recovery of precious metals not only contributes to the conservation of natural resources but also significantly reduces energy consumption. Due to their high economic value, the recovery of these metals represents a substantial economic benefit (Reuter et al., 2013). The precious metal recovery process is illustrated in Fig. 5.

Fig. 5. Schematic representation of precious metals recycling process

4 Discussion

The field data demonstrate that construction and demolition waste (CDW) possesses substantial recovery potential. Reusing inert materials, such as concrete, brick, and ceramics, as aggregates conserves natural resources and mitigates the environmental impacts of mining. Furthermore, recovering recyclables like iron, aluminum, copper, glass, and plastics provides significant environmental and economic benefits. This process reduces landfill requirements, saves energy, and lowers carbon emissions, strongly supporting circular economy principles.

Empirical findings show that approximately 134.4 tons of recoverable CDW can be separated from a representative 1,000 m^2 five-storey building. Extrapolating this to the 36,932 buildings collapsed during the 6 February 2023 earthquakes yields a national estimate of roughly 5 million tons of recoverable waste.

The economic potential of these materials is immense. A simplified market valuation estimates the value of iron/steel scrap at approximately 79 billion TL, plastics at 33.6 billion TL, copper at 15.5 billion TL, aluminum at 3.3 billion TL, and other wastes at 1–2 billion TL. Overall, the total economic value is projected to reach 130–140 billion TL (2.5–2.7 billion euros). These findings confirm that effective CDW recovery delivers substantial economic gains alongside environmental benefits.

Importantly, this economic valuation is strictly based on average domestic secondary raw material and scrap market prices valid in the final quarter of 2023, with conversions relying on the average exchange rate of that period. These estimated figures represent gross potential revenue; operational expenses, including demolition, separation labor, transportation, and metallurgical processing costs 4were excluded from this calculation.

5 Conclusion

In conclusion, the effective management of construction and demolition waste is of critical importance not only for environmental protection but also for economic sustainability and resource efficiency. In accordance with the waste management hierarchy, when the prevention of waste generation cannot be achieved, the widespread implementation of reuse and recycling practices becomes essential. In this context, supporting licensed recovery facilities, increasing on-site separation practices, and ensuring the effective enforcement of regulations are of paramount importance. The adoption of recovery-oriented approaches within the construction sector will contribute to the conservation of limited natural resources and promote more sustainable urban development.

Abstract. Cold plasma (CP) is emerging as a promising advanced oxidation technology for decentralized water disinfection, offering broad-spectrum antimicrobial potential, low energy demand and minimal chemical residuals. In the context of circular and resilient urban water systems, a key challenge is to move beyond millilitre-scale laboratory reactors towards scalable units that can be integrated into building and district water loops. This work presents the conception and proof-of-concept evaluation of a dielectric barrier discharge (DBD) cold-plasma reactor equipped with a microbubble diffuser, specifically designed to enhance gas-liquid interaction and enable modular upscaling for the built environment. The prototype allows treatment of 500 mL water volumes, representing a substantial increase compared with conventional benchtop configurations, and is validated using *Escherichia coli* as a representative fecal indicator organism. The reactor ensures stable discharge and reproducible antimicrobial performance, achieving multi-log reductions in colony-forming units within treatment times compatible with on-site or point-of-use sanitation. Design choices are discussed in terms of footprint, energy efficiency and potential integration in greywater reuse systems and high-risk building effluents. The reactor concept provides a flexible platform for future assessment of clinically relevant pathogens, antibiotic residues and microplastics-associated contaminants, contributing to safer water reuse streams and to reshaping the built environment through sustainability and circularity.

1 Introduction

The transition towards circular, healthy and resilient cities requires closing water loops while guaranteeing microbiological safety and controlling emerging contaminants such as pharmaceuticals and antibiotic resistance determinants [1]. Urban water reuse schemes

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 642–649, 2026.

at building and district scales are increasingly promoted to reduce potable water demand and augment local water resilience, yet conventional disinfection processes often rely on chemicals that generate disinfection by-products and require complex dosing and storage infrastructure. These constraints are particularly problematic in decentralized or small-scale systems, such as greywater reuse in buildings, hospital effluent polishing or emergency water supply, where compact, low-chemical and easily automatable solutions are needed [2–4].

Cold atmospheric plasma (CAP) has gained attention as an advanced oxidation and disinfection technology capable of generating reactive oxygen and nitrogen species, UV photons and transient electric fields directly in water or at gas-liquid interfaces [5, 6]. Numerous studies have demonstrated efficient inactivation of *Escherichia coli* and other pathogens in small-volume systems, including dielectric barrier discharge (DBD) reactors, plasma jets and plasma sparks, often achieving several-log reductions within minutes [7–9]. Plasma-activated water (PAW), where water is exposed to CAP and subsequently used as a disinfectant, has also been proposed as a versatile antimicrobial solution for sanitation and cleaning [10, 11]. However, most experimental configurations treat volumes in the microlitre-to-millilitre range or rely on batch activation of a few hundred millilitres, which limits direct translation to flow-through units compatible with building-scale water flows [6].

Improving plasma-liquid mass transfer is a critical step towards scalable water treatment reactors. Recent work has shown that integrating microbubble generation with CAP can significantly enhance gas-liquid contact area and increase the transport of reactive species into the bulk liquid, thereby accelerating microbial inactivation [12, 13]. At the same time, there is growing interest in plug-and-play plasma modules that could be integrated into decentralized water infrastructures, emphasizing compact form factors, modular design and compatibility with existing hydraulic layouts [14, 15].

The present study addresses these gaps by developing and testing a bubble-enhanced DBD reactor designed for integration in circular water systems within the built environment. *E. coli* is used as a model fecal indicator microorganism to characterize reactor performance and assess the feasibility of achieving rapid and reproducible inactivation at a 500 mL scale. The work focuses on reactor conception, operating conditions relevant for on-site applications, and comparison with a reference microvolume CP treatment, rather than on detailed mechanistic analysis or extended pathogen panels, which are reserved for future studies.

2 Materials and Methods

2.1 Reactor Design and Configuration

A cylindrical dielectric barrier discharge reactor was constructed to enable treatment of 500 mL water volumes in batch mode (continuous operation is feasible but was not evaluated in this study). The reactor consisted of a quartz tube acting as the dielectric barrier, with a coaxial electrode configuration comprising an inner stainless-steel rod electrode and a copper electrode wrapped around the outer surface of the tube. The inter-electrode distance was defined by the quartz wall thickness and reactor geometry, ensuring stable discharge under atmospheric conditions.

The reactor configuration was selected following preliminary testing of different dielectric materials (PVC, borosilicate glass, quartz) and electrode geometries (rod, screw-type inner electrodes; linear and helical outer electrodes), with quartz and coaxial rod-cylinder configuration providing the most stable discharge, lowest current variability, and minimal thermal effects during operation. Reactor temperature was monitored during operation using an infrared thermometer to confirm non-thermal conditions.

For indirect plasma treatment, a bubble diffuser (with a diameter of 10 cm) was installed at the bottom of the reactor and connected to a compressed air supply via a flow regulator. The diffuser generated fine bubbles (with a diameter of ≈100–400 μm) that traversed the liquid column, enhancing gas-liquid interfacial area and promoting the transfer of plasma-generated RONS into the bulk liquid. The gas flow rate was fixed at 2 L min^{-1} for all experiments, based on preliminary optimization showing stable discharge and consistent physicochemical conditions.

Cold plasma was generated in atmospheric air using a custom-built high-voltage alternating current power supply operated at 15 kV and 5 kHz. Under these conditions, the discharge current was approximately 2.3 mA, corresponding to an input power of ~34.5 W. Voltage and current waveforms were monitored using a high-voltage probe and current sensor connected to an oscilloscope to ensure stable plasma generation throughout the experiments.

Based on these operating conditions, the specific energy input for a 30 min treatment of 500 mL was approximately 124 kJ L^{-1}, providing a preliminary estimate of the energy demand of the system under proof-of-concept conditions.

2.2 Culture Conditions

Escherichia coli (strain ATCC25922) was selected as a representative fecal indicator organism and model pathogen widely used in plasma disinfection research. Overnight cultures were grown in LB nutrient media at 37 °C.

For each experimental run, 500 mL of sterile distilled water was spiked with an *E. coli* suspension prepared from overnight LB cultures; cells were concentrated by centrifugation (4,000 × g, 5 min), washed three times in sterile PBS and resuspended to the target density. Suspensions were adjusted by OD_{600} using a standard curve and confirmed by serial dilution and plating, achieving an initial challenge concentration of approximately 1 × 10^7 CFU·mL^{-1}.

The gas flow rate applied voltage and treatment duration were set according to the operating conditions selected for proof-of-concept evaluation and with lowest power input where plasma was stable (15 kV and 2.3 mA). After plasma exposure, aliquots were immediately collected, serially diluted and plated withoit neutralization on blood agar to determine surviving colony-forming units (CFU). Plates were incubated at 37 °C for 24 h before enumeration. Parallel aliquots were measured by OD*600* before plating preparation and showed no appreciable change, indicating minimal loss during sample processing.

2.3 Experimental Design and Sampling

Inactivation experiments in the 500 mL reactor were conducted in triplicate. Sampling times were selected to capture the early, intermediate and advanced stages of inactivation, with measurements at 0 (untreated control), 10, 20, 30, 45 and 60 min. At each time point, aliquots were withdrawn aseptically from the reactor, neutralized if necessary to quench residual reactive species, and processed for CFU enumeration. Cold plasma was applied during the first 30 min, followed by 30 min of post-treatment without discharge to assess the residual disinfection potential of plasma-generated species.

Bacterial inactivation was expressed as percentage of surviving bacteria relative to the initial concentration at time zero and as inactivation rate (percentage reduction). Triplicate measurements were used to compute mean values and standard deviations for each time point. Inactivation curves were plotted as survival fraction versus exposure time, and error bars reflected variability between replicates.

3 Results and Discussion

The DBD source coupled to the air diffuser produced a homogeneous discharge in the gas phase, and the resulting plasma-activated air was continuously bubbled into the 500 mL water volume (Future 1). The discharge remained stable over the full 30 min treatment in all three replicates, with no arcing or hot spots, consistent with indirect CAP configurations where RONS generated in the gas phase are transferred into the liquid via bubbling (Fig. 1) [12].

Fig. 1. Dielectric barrier discharge (DBD) source coupled to the air diffuser, showing a stable, homogeneous and continuous cold plasma discharge in the gas phase of the reactor.

The gas flow rate was fixed at 2 L/min, providing intense but well-controlled bubbling that delivered plasma-generated species without excessive splashing or droplet entrainment into the discharge region. Under these conditions, bulk liquid heating was limited and the process remained clearly non-thermal, in line with other plasma-activated water systems.

Mean initial concentration across the three replicates was 4.96×10^8 CFU 100 mL^{-1} ($\pm 6.30 \times 10^7$). After 30 min of exposure the mean concentration fell to 1.27×10^8 CFU 100 mL^{-1} ($\pm 7.49 \times 10^7$), corresponding to a 74.4% reduction and a $\log_{10}$ reduction of 0.59. At 45 min the mean CFU was 4.35×10^6 CFU 100 mL^{-1} ($\pm 1.10 \times 10^5$), representing a 99.12% reduction and a log reduction of 2.06. After 60 min (30 min post-treatment) the mean CFU reached 2.08×10^6 CFU 100 mL^{-1} ($\pm 2.08 \times 10^5$), corresponding to a 99.58% reduction and an log reduction of 2.38. Error bars in Fig. 2 represent ±SD.

This behaviour supports the hypothesis that efficient gas–liquid transfer of plasma-generated RONS enables effective treatment of larger volumes by distributing these species throughout the bulk liquid [7, 13].

From a built-environment perspective, the ability to achieve nearly complete inactivation in a 500 mL batch using an indirect, air-fed system suggests that bubble-assisted plasma modules could be scaled as side-stream units for small storage tanks, flush reservoirs or other building-level disinfection points, without the need for chemical dosing.

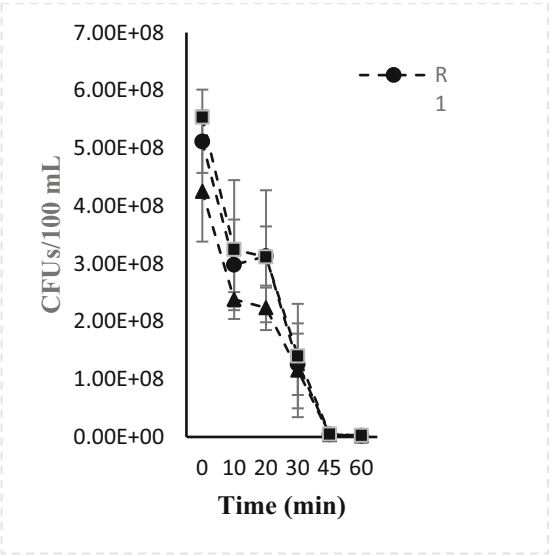

Fig. 2. Inactivation of *E. coli* in the laboratory-scale bubble-assisted DBD reactor: temporal evolution of CFU/100 mL over 60 min for three independent replicates (R1–R3), showing progressive reduction to below the detection limit.

By relying on plasma-activated air and long-lived RONS rather than stored chemical disinfectants, bubble-assisted DBD modules have potential as compact side-stream polishing units for building tanks or reservoirs; however, this study tested only distilled water in batch mode and therefore provides proof-of-concept rather than validated field performance. The present results demonstrate that plasma-derived species can persist and contribute to extended microbial inactivation in a simple water matrix, but the efficacy and kinetics observed here will likely change in complex waters due to oxidant demand, particulate shielding and variable ionic strength.

Accordingly, broader applications such as greywater tanks, rainwater cisterns, hospital effluent polishing should be considered as future directions rather than immediate outcomes. Key next steps include testing under realistic matrices (representative greywater and hospital effluent), evaluating the impact of organic load and turbidity on RONS lifetime and transfer, assessing virus and protozoan susceptibility, and performing continuous-flow and scaled side-stream experiments to confirm hydraulic compatibility and treatment throughput. Energy and life-cycle assessments should also be undertaken to compare the modules with established decentralized treatments and to quantify environmental trade-offs.

These targeted limitations and follow-up experiments will better position the reactor concept for translation into circular built-environment applications while preventing overinterpretation of the current laboratory-scale findings.

4 Conclusions

The laboratory-scale, bubble-assisted DBD reactor operating in indirect mode was successfully demonstrated as a compact disinfection unit suitable for integration in the built environment. Using *E. coli* as a model organism, the system achieved 73.31% inactivation after 30 min of plasma exposure and 99.58% after an additional 30 min without active discharge, confirming the strong and persistent antimicrobial effect of long-lived plasma-generated species in the treated water. These results suggest that efficient transfer of reactive oxygen and nitrogen species from plasma-activated air into water can provide robust microbial control at volumes relevant for building-scale storage and reuse. The laboratory findings therefore indicate that similar bubble-assisted plasma modules could be developed as decentralized, low-chemical disinfection blocks for circular water systems, supporting safe greywater and rainwater reuse while reducing reliance on centralized treatment and conventional disinfectants. However, this is a very preliminary study. Other bacteria, viruses, should be evaluated as well as antibiotics and other contaminants of emerging concern. Energy efficiency needs to be explored as well as scalability potential.

Abstract. Building rehabilitation is a strategy for delivering Social Housing (SH) in consolidated urban areas, yet systematic design knowledge remains limited. This study proposes context-specific new design patterns (NPs) for SH rehabilitation, exploring how pattern languages can be empirically extended to address its challenges. We mapped the occurrence of selected patterns from Christopher Alexander's Pattern Language – originally conceived as generative elements of human-centered environments – across twenty rehabilitated buildings in Brazil and Portugal and compared them with a control sample of five peripheral projects from a Brazilian SH program. Pattern co-occurrence networks were constructed and analyzed using centrality metrics to identify structurally salient patterns and relational differences between contexts. Rehabilitated cases exhibited more integrated pattern networks, while peripheral developments showed weaker relational structures, revealing recurrent absences interpreted as "anti-patterns". Associated affordance gaps enabled the codification of twenty taxonomically structured NPs. By linking rehabilitation constraints, circular reuse of existing assets, and long-term adaptability, the study contributes preliminary design knowledge for more regenerative and context-sensitive SH rehabilitation.

Keywords: Building Rehabilitation · Design Patterns · Social Housing

1 Building Rehabilitation and Pattern Languages

Building rehabilitation has emerged as a strategic approach to delivering Social Housing (SH) in central urban areas, where infrastructure, services, and vacant building stocks are concentrated [1]. Rather than promoting peripheral expansion, it leverages existing assets and reconnects SH to established networks of mobility, employment, and amenities [2, 3]. It also operates as a circular and regenerative practice by extending building service life, reducing material consumption, and reactivating underused urban assets within consolidated urban fabrics [4]. Thus, rehabilitation must reconcile existing structural constraints with contemporary requirements and affordability demands. Unlike new construction, it cannot define spatial organization from the outset; instead, it must determine which conditions can be preserved or adapted to support habitability.

This makes rehabilitation a productive domain for pattern-based reasoning, where patterns can be interpreted as adaptive configurations rather than generic solutions [5]. "A Pattern Language" by Christopher Alexander and his team [6] offers a generative vocabulary for coherent built form and a problem-adjacent lens to analyse how design solutions manifest, interrelate, and, at times, remain absent [5]. Comprising 253 patterns, each formulated as a context-sensitive response to recurring spatial problems [6], the framework links functional requirements to human perception and everyday use. Rather than prescribing isolated interventions, it emphasizes interdependence, with patterns operating in combination across urban, architectural, and constructive scales [5]. Alexander's later work reframes patterns as expressions of underlying forces shaping form in recurrent situations [7]. From this perspective, design is morphogenetic, emerging through context-sensitive processes rather than fixed models. These structure-preserving operations strengthen the existing whole through incremental changes that enhance its "life," assuming spatial systems are organized around interacting centers that interventions should reinforce rather than erase [7].

This adaptive logic is inseparable from the concept of "wholeness", understood as an objective structure formed by interrelated centers whose coherence determines the degree of life in a spatial system [7]. Rather than a compositional totality, it is an emergent property across scales, with patterns serving as instruments to sustain and intensify it over time. When patterns fail to maintain this integrity – due to contextual shifts, technical constraints, or changing modes of inhabitation – loss of wholeness manifests in recurrent dysfunctions of use and appropriation [7], indicating the need for new configurations capable of restoring or strengthening the system's structure [8].

An additional lens is offered by affordance theory, which refers to the action possibilities an environment offers to an organism, emerging from the relational properties between spatial form and embodied capability [9]. Although not explicitly named, descriptions of how spatial configurations invite or constrain use [7] align with this perspective. Patterns can thus be seen as arrangements that generate affordances – enabling interaction, adaptation, and appropriation without prescribing specific behaviors.

Understanding patterns through these complementary concepts has direct implications for the evolution of pattern languages. When grounded in observed forces and the affordances generated by spatial configurations, shifts in social practices, technologies, or constraints may require extending or refining the existing lexicon. Rather than a closed system, pattern languages are conceived as continuously evolving frameworks responsive to emerging conditions [6, 7, 10]. Accordingly, new patterns can be justified when evidence reveals persistent gaps not addressed by the original corpus [8, 11, 12].

Thus, patterns function as testable hypotheses about how configurations generate affordances across scales, while repeated failures to deliver expected outcomes can be read as "anti-patterns" – self-reinforcing arrangements that undermine spatial performance and social well-being, often observed in large-scale SH [13–16]. In Brazil, the Minha Casa Minha Vida Program (PMCMV) became the country's largest housing initiative; however, persistent issues include peripheral siting, limited adaptability, and weak urban integration [17, 18]. They stand in opposition to Alexander's principles which prioritize spatial adaptability, diversity, and social well-being [19].

Taken together, this literature supports deriving new patterns from convergent evidence rather than isolated criteria. In this context, this paper proposes a set of preliminary, context-specific new design patterns for SH rehabilitation.

2 Methods

This study combines empirical pattern mapping, network metrics, and affordance-based interpretation to derive anti-patterns and propose new patterns for SH rehabilitation. Figure 1 summarizes the methodological steps described in the following sections.

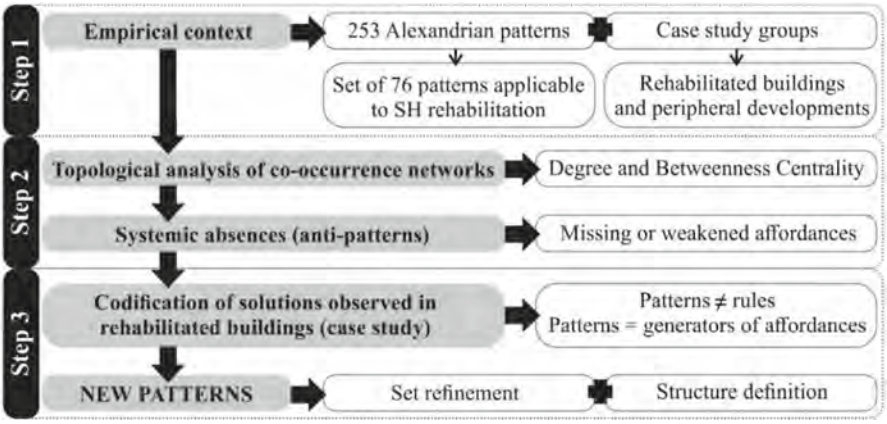

Fig. 1. New pattern derivation process.

2.1 Pattern Identification Across Case Groups

This research builds on a preliminary set of patterns identified in a previous study [16]. The 253 patterns [6] were first screened to exclude those unrelated to SH, followed by a second filter removing patterns not applicable to building rehabilitation. The resulting set was validated through a focus group [20], composed of participants with academic and professional expertise, yielding 76 patterns considered applicable to rehabilitation.

The presence of these patterns was analyzed in twenty rehabilitated buildings across Portugal and Brazil. The Portuguese cases are located in Porto, comprising buildings of three to seven floors. In Brazil, the sample includes buildings in Porto Alegre (two) and São Paulo (eight), ranging from four to twenty-three stories. Selection criteria included (i) location in dense urban areas with established infrastructure; (ii) multi-family typology with shared circulation (iii) adaptive rehabilitation of existing structures; and (iv) provision as subsidized housing. Despite scale differences, both contexts show similar housing dynamics – significant vacancy (12–13%) and deteriorated building stocks.

A control group of five peripheral multifamily developments was defined based on the Minha Casa, Minha Vida Program (PMCMV) database [21], filtering completed

Faixa 1 vertical projects with complete addresses in Porto Alegre and São Paulo. Five cases were randomly selected for exploratory comparison. To ensure comparability, five rehabilitation cases were randomly drawn from the initial twenty. In both datasets, pattern occurrence was assessed through document and drawing analysis, photographic records, and on-site observation. To make pattern identification explicit, each pattern was assessed through at least two operational questions derived from its original formulation. Figure 2 illustrates the presence of patterns and anti-patterns.

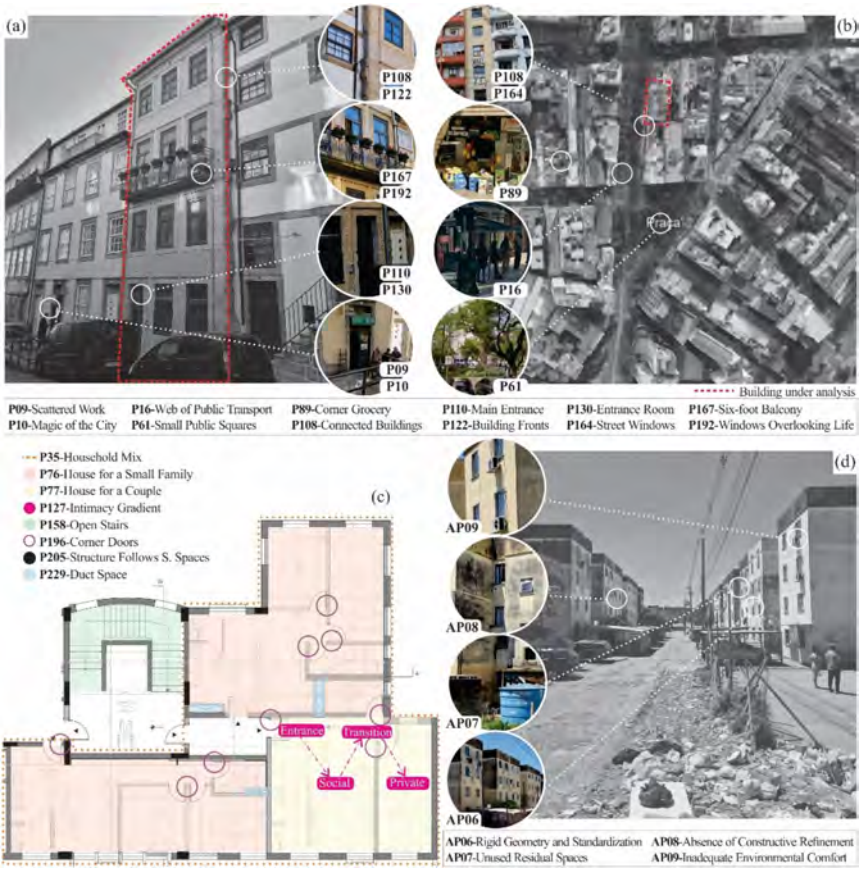

Fig. 2. Identification of design patterns in (a) a rehabilitated building; (b) its immediate surroundings; and (c) floor plan; identification of (d) anti-patterns in a peripheral development.

2.2 Research Step 2: Deriving Anti-patterns from Network Evidence

Co-occurrence (CO) matrices were constructed to quantify how often pairs of patterns appeared together across cases, including both the rehabilitated corpus and a control group of five peripheral buildings. These matrices were converted into CO networks,

with patterns as nodes and CO as edges. Two centrality measures were applied to identify structurally salient patterns [22]: Degree Centrality (DC), representing overall connectedness, and Betweenness Centrality (BC), indicating bridging roles between groups. To compare networks of different sizes, DC was normalized as DC/(n−1).

Anti-patterns were derived by comparing two networks: the peripheral SH sample and a subset of five rehabilitated buildings. DC, BC, and network density were examined to characterize each relational structure. The rehabilitated network, with higher density and stronger interdependencies, served as an empirical baseline. Anti-pattern evidence was defined by the consistent absence, isolation, or weak connectivity of structurally significant baseline patterns in the peripheral network.

2.3 Research Step 3: Deriving NPs from Anti-pattern-Based Affordance Gaps

For each anti-pattern, a corresponding affordance gap was defined as an expected action possibility in everyday habitation that is systematically unsupported. Design responses observed in rehabilitated buildings that countered these conditions were translated into affordances and treated as generative strategies for new patterns (NPs). At this stage, validation was internal and procedural rather than post-occupancy based. Each NP was checked against three criteria: (i) derivation from an identified anti-pattern or affordance gap; (ii) correspondence with a design response observed in the rehabilitation cases; and (iii) non-duplication of an existing pattern [6]. Each NP followed a taxonomic structure comprising: Problem, Discussion, Solution and Graphic scheme.

3 Results and Discussion

Step 1 produced a binary dataset recording pattern occurrence across (i) 20 rehabilitated buildings in Portugal and Brazil and (ii) five peripheral PMCMV developments. For comparability, five rehabilitation cases were randomly selected to match the control sample. Of the 76 patterns, 48 were identified in the rehabilitated subset and 21 in the peripheral developments. CO matrices were then constructed for the matched 5-case subsets and the full 20-building corpus to capture pattern interdependence. These were converted to .json network format and analyzed in VOSviewer to compute network metrics and support inspection (Table 1).

Table 1. Dataset and derived network summary.

Dataset	Cases (n)	Patterns as nodes	Links (n)	Density
Rehabilitation baseline (random subset)	5	48	1053	0.934
Peripheral PMCMV control	5	21	178	0.848

When compared, the peripheral network shows fewer patterns (21 vs. 48) and far fewer links (178 vs. 1053), indicating more limited combinations. Table 2 compares the seven most connected baseline patterns and their roles in the peripheral network.

Table 2. Baseline-salient patterns and their reduced DC/BC roles in the peripheral network.

Pattern	REHAB baseline			PMCMV control

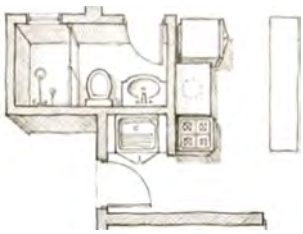
The rehabilitation baseline shows multiple patterns with maximum connectivity (DC = 47; normDeg = 1.0), while their counterparts in the peripheral network are frequently absent or show reduced normalized degree. For example, among the ten most connected patterns in the baseline, several are absent from the peripheral network (e.g., P10, P35, P95, P130), while others remain present but with lower integration (e.g., P9: normDeg $1.0 \rightarrow 0.70$; P129: $1.0 \rightarrow 0.50$). This comparison yielded ten anti-pattern (AP) categories, each defined as a recurrent constellation of missing or fragilized baseline-salient patterns rather than as isolated omissions. The full anti-pattern set is not reported here. Instead, we present one worked example randomly selected from the ten APs to illustrate the derivation logic based on network evidence (Table 3).

Table 3. Worked example of anti-pattern derivation from network evidence.

Anti-pattern	Definition (cluster logic)	Absent design patterns (examples)	Network evidence	Practical manifestation
AP10-lack of flexibility	Absence of interconnected adaptability and spatial resilience patterns supporting change over time.	P35-Household Mix P75-The Family P77-House for a Couple P78-House for One Person P127-Intimacy Gradient P196-Corner Doors P205-Structure Follows… P229-Duct Space	High DC/BC in rehabilitated network; null or marginal connectivity in peripheral network.	Rigid layouts unable to respond to household change and variety.

AP10-Lack of Flexibility was derived from the systematic absence (or minimal integration) in the peripheral PMCMV network of architectural-scale patterns that are structurally salient in the rehabilitation baseline. These patterns form a highly connected constellation in the baseline; their absence in the peripheral network suggests the loss of interdependent functions associated with adaptability and spatial resilience. The same procedure was applied to derive the remaining APs [16]: AP01-Urban Disconnection and Isolation, AP02-Monofunctionality; AP03-Disconnection from the Street; AP04-Lack of Communal Areas; AP05-Lack of Resident Protagonism; AP06-Rigid Geometry and Standardization; AP07-Unused Residual Spaces; AP08-Absence of Constructive Refinement; and AP09-Inadequate Environmental Comfort.



These APs provide the empirical basis for Step 3. Recurrent affordance gaps were mapped from anti-pattern evidence and translated into NPs for rehabilitation-oriented SH design. Initially, 29 candidate solutions were identified from the case study. After overlap removal and comparison with existing patterns [6], the set was refined to 20 NPs. We do not reproduce the full set of NPs. Instead, we outline the three decision layers structuring the NP catalogue (Cities, Architecture and Construction) and present one representative NP: NP19-Technical Core for Progressive Adaptation. NP19 was selected as a worked example because it demonstrates how the proposed method translates an anti-pattern condition into a design-oriented response. It links AP10-Lack of Flexibility and AP08-Absence of Constructive Refinement to a technical-habitable solution that can be applied during rehabilitation design: concentrating service infrastructure to preserve the adaptability of the remaining floor plan (Table 4).

Table 4. Structure of NP19-Technical Core for Progressive Adaptation.

NP19-Technical core for progressive adaptation	
Problem	The dispersion of technical installations constrains future reconfigurations and increases the cost of modifications, often rendering subsequent adaptations financially burdensome or unfeasible.
	The dispersion of technical installations is one of the main constraints on long-term housing adaptability. In existing buildings, fragmented systems across multiple walls and slabs hinder spatial reconfigurations, increasing the complexity of interventions and raising adaptation costs [23]. It usually contributes to functional obsolescence, as any programmatic change requires invasive construction interventions [24, 25].

(*continued*)

Table 4. (*continued*)

NP19-Technical core for progressive adaptation			
Discussion	Concentrating on technical infrastructure zones allows for spaces for reorganization, reducing conflicts between structure, installations, and occupation [26]. Technical cores function as supporting infrastructures. They enable incremental adaptations without requiring extensive demolition [24]. In rehabilitation, this strategy can be relevant. Permanent technical core reconciles the building's constructional limitations, accommodating changes in household composition, domestic practices, or technical requirements in the building's life cycle [23]. Also, it facilitates maintenance and technological upgrades, reducing operational costs and improvised interventions risks [27]. By freeing the rest of the layout for flexible use and future reconfiguration, the technical core supports residential adaptability as a structural quality of the design, extending the dwelling's functional lifespan and reducing the need for invasive interventions over time [23, 27].		
Solution	Concentrate electrical, hydraulic, sanitary, and other complementary systems within a permanent technical core, freeing the remainder of the layout for future reconfigurations. This core functions as a technical anchor, enabling the housing unit to evolve over time without invasive interventions.	Graphic scheme	

4 Conclusions

This study demonstrates how pattern languages can be empirically extended to address SH rehabilitation. By mapping Alexander's pattern CO in rehabilitated buildings and comparing them with peripheral developments, it reveals differences in both pattern presence and structural relationships. Rehabilitated cases showed denser networks, while the peripheral sample displayed weaker relational structures, supporting the identification of recurrent absences and fragmentations interpreted as anti-patterns (APs).

Building on this evidence, the study translated APs conditions into affordance gaps and identified design responses observed in rehabilitation cases that counteracted these deficiencies. Through a process of refinement, these responses were codified into a set of 20 taxonomically structured NPs. The practical relevance of the proposed NPs lies in their capacity to translate recurrent problems of SH – such as fragmented technical systems and limited adaptability – into spatial configurations that can inform early design decisions. In this sense, the contribution to more generative and context-sensitive rehabilitation strategies is linked not only to material reuse, but also to extending building service life through adaptable, maintainable, and socially integrated configurations.

Acknowledgments. This study was partly financed by the Coordination for the Improvement of Higher Education Personnel – Brazil (CAPES) – Finance Code 001 and by the National Council for Scientific and Technological Development (CNPq).

Abstract. The high demand for natural resources and climate change require integrated management approaches capable of balancing the pillars of sustainability. This study aims to apply a methodological approach to the NEXUS Water Energy and Food (WEF) concept, implementing sustainable solutions regarding resource demand on the campus of the State University of Rio de Janeiro, Maracanã, Rio de Janeiro-RJ-Brazil. The methodology included characterizing the facilities and resource use associated with the NEXUS WEF at the University Restaurant, enhancing the analysis of quantitative and qualitative parameters related to consumption volume (water), installed and consumed power (energy), and food products purchased and consumed (food). Alternative sustainability technologies were implemented, with the installation of: a rainwater harvesting system with a storage capacity of 90 m^3 of water and a photovoltaic system (solar carports) in three (3) parking spaces on campus, capable of powering electric vehicles and generating an average of 2,359.91 kWh/month, contributing to a reduction in fossil fuel consumption and CO2 emissions. The systems can meet part of the non-potable water and energy demand of the campus, with environmental, social, and economic benefits, in addition to developing research and studies applied to sustainable management at the university, promoting a space for innovation and reference integrating the 3 elements of the Nexus with the principles of the circular economy and energy transition, establishing a replicable methodology for sustainable public administration.

Keywords: NEXUS Water-Energy-Food · Sustainability · State University of Rio de Janeiro · Resource Management · University Restaurant

1 Introduction

Data from the United Nations (2024) [9] project that the world population may reach approximately 9.9 billion inhabitants by 2054. According to Bleischwitz et al. (2018) [3], this increase accelerates demand for natural resources and consequently tends to generate risks and threats to human beings and ecosystems, in different proportions related to water, energy, and food issues.

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 660–666, 2026.
https://doi.org/10.1007/978-3-032-34930-9_77

According to Mabhaudhi et al. (2019) [7], water, energy, and food are essential resources that sustain life and the livelihoods of society. In this context, Liu et al. (2018) [6] argue that reducing water scarcity, fossil fuel energy use, and food insecurity are interconnected global challenges, given their interdependence and interrelationship.

The Water, Energy and Food Nexus (WEF Nexus) approach seeks integrated solutions and actions to address the scarcity of these three elements (Kurian, 2015) [5]. These actions can be applied at smaller scales, yet with high potential for visibility and replication of the concept.

The global debate on high resource demand and climate change thus underscores the need to develop an integrated methodological approach addressing water, energy, and food through the WEF Nexus framework in academic settings, given that the use of these resources in institutional environments can yield broad reach in research and technological development as a contribution to the field.

This study presents research conducted at a university campus equipped with three sustainable management systems whose interactions create significant potential for applying the NEXUS approach: a Rainwater Harvesting System (RHS), solar car-ports, and a water footprint analysis of the University Restaurant. The objective is to apply a methodological framework for NEXUS analysis at institutional micro-scale, correlating quantitative and qualitative indicators of water, energy, and food across the three systems implemented on campus, under the principles of the circular economy and energy transition.

Beyond the methodological innovation of analyzing the NEXUS at micro-scale, the study is embedded in strategic axes by evaluating the possible interrelationships between these alternative systems in the university environment, reinforcing the potential of the campus as a space for innovation and a sustainable reference for society.

2 Methodology

The study area for this research is the State University of Rio de Janeiro (UERJ), located in the Maracanã neighborhood, in the city of Rio de Janeiro, RJ – Brazil. The University Restaurant (UR) of UERJ is situated in an outdoor area of the campus.

The methodology consists of: (i) analyzing the rainwater harvesting system; (ii) monitoring the carport photovoltaic system; (iii) investigating the water footprint of meals served in the university restaurant; and (iv) conducting an integrated Nexus analysis.

2.1 Rainwater Harvesting System - RHS

The installed RHS (Fig. 1) consists of 6 underground tanks of 15 m^3 each, with a total rainwater storage and utilization capacity of 90 m^3 or 90,000 l. The availability of rainwater was calculated based on historical local monthly precipitation data, the projected catchment area of the roof, a surface runoff coefficient for roofs, and a filtration efficiency factor that disregards first flush deviation and filtration waste. This volume can meet part of the institution's non-potable water demand.

Monthly water consumption at the University Restaurant was estimated for this scenario to monitor how the system can contribute to this reduction. For water quality,

monthly physicochemical analyses are conducted in compliance with applicable local regulations, including: NBR 15.527 (ABNT, 2019a) [2], NBR 16.783 (ABNT, 2019b) [1] for the use of alternative non-potable water sources, and Ordinance GM/MS N°. 888/2021 (MS, 2021) [8] regarding portability standards, as the most restrictive quality reference.

Fig. 1. Rainwater Harvesting System is installed on campus.

2.2 Solar Carport

The system consists of photovoltaic modules and is composed of 42 photovoltaic panels, with a peak power capacity of 24.75 KWp, capable of powering electric vehicles. With the installation of the solar carport (Fig. 2a and b), monthly energy generation monitoring is carried out to measure the system's potential and capacity to offset conventional energy consumption in the UR.

This monitoring is performed through the S-Miles Enduser application connected to the system, which allows real-time tracking of generation in kW and identification of the system's potential, as well as comparison with the corresponding CO_2 emission reductions. Initially, the system was estimated to generate an average of 2,359.91 kWh/month. However, as the study progresses, it can be observed that the actual value may exceed this forecast.

2.3 Water Footprint of Served Food

The Water Footprint study of food served at the University Restaurant adopts the methodology of the Water Footprint Network, as established by Hoekstra et al. (2011) [4]. This methodology accounts for water appropriation along the entire agricultural and operational supply chain, categorizing consumption into three distinct water components: green, blue, and grey.

The calculation was conducted based on data on the menu offered and the ingredients used in the preparation of the meals served, to obtain the results. The volumes found are

Fig. 2 a. Solar carport installed on campus. b. Electric vehicle charging station.

incorporated into the NEXUS indicator analyses used to develop the interrelationship among the 3 elements.

2.4 Integrated Nexus Analysis

The integrated analysis stage consists of developing the indicators to be identified and evaluated. The effective implementation of this concept depends on the creation and applicability of robust indicators (Table 1), capable of enhancing synergies and efficiencies in the correlations: Water × Energy, Energy × Food, and Food × Water.

Table 1. Example indicators table

Indicators	Unit	Description
Specific water consumption	L/person/day	Average amount of water consumed per person in the building.
Volume of rainwater collected	m^3/month or % of demand	Measures how much of the total demand is met by harvesting systems.
Quality of reused water	Parameters	Compliance indicator against quality parmeters.
Specific energy cosumption	kWh/m^2/month	Energy consumed in the building.
Solar energy generation	kWh/month	Total amount generated by the system.
Avoided CO_2 emissions	tCO_2eq/year	Estimate of avoided carbon emissions.
Water consumption in production	L/Kg	Water volume in UR food production.

Source: Prepared by the author (2026), based on the International Renewable Energy Agency (IRENA). Renewable energy in the water, energy & food nexus.

3 Partial Results and Discussion

The results obtained so far indicate positive trends. Physicochemical parameters (pH, color, turbidity, conductivity, alkalinity, hardness, and chloride) of the rainwater collected by the system were analyzed, and the results were characterized according to the standards established by applicable legislation. These results confirm the suitability of this water for non-potable uses in the study area.

The RHS (90 m^3) can meet part of the campus non-potable water demand in months with adequate rainfall, establishing the first measurable Nexus synergy: each cubic meter of potable water replaced represents energy saved in the utility's treatment and distribution cycle.

The solar carport has been installed, and testing began through app-based monitoring. Figure 3 shows the system's energy production for the period between September 2025 and February 2026. It can be noted that the system produced above the values estimated at the beginning of the project, demonstrating potential that makes it more efficient and enables higher returns for the project. Its peak generation reached 2,551 kWh in December 2025.

To date, the system has recorded a real production of 13.95 MWh, equivalent to a reduction of 14.89 tons of CO_2 emissions, contributing to the minimization of environmental impacts from atmospheric pollutant releases.

Fig. 3. Monthly energy generation of the solar carport

Regarding the Water Footprint, based on data provided on the food served at the University Restaurant, it was possible to break down its three (3) components by food type. The characterization by food type was subdivided into: protein foods, dairy products, vegetables, legumes, and grains.

Thus, foods such as meat and dairy products have significantly higher WF than plant-based foods. In terms of sustainability, the inclusion of more plant-based foods and fewer animal-origin products can reduce the environmental impact associated with the restaurant's food service. Efficiency in water use can be achieved by replacing high water footprint ingredients with lower-impact alternatives, such as legumes and vegetables, as a strategy for the sustainable management of water resources.

Many challenges are associated with study. Among them, we highlight the collection and integration of sector-specific information, which slows down the implementation process. In this regard, integrated environmental management is necessary to consolidate these data more effectively.

This study is of great relevance as it offers a methodological proposal capable of addressing the identified challenges, applying the NEXUS as an institutional coordination tool with high replication potential in other public institutions. By proposing indicators applicable to this context, the research contributes to the strengthening and monitoring of sustainable actions developed by the university, based on reliable data.

4 Conclusions and Recommendations

The partial results obtained up to the conclusion of this work reinforce the potential of applying the WEF Nexus approach in the academic context as a tool to efficiently promote sustainable campus management. Based on the preliminary analyses con-ducted across the three axes comprising the Nexus, the technical feasibility and potential positive impacts of integrating these systems in the university environment are evident.

As these are preliminary analyses, it should be noted that conclusive changes may still occur based on results.

In the Water axis, the water quality analysis of the rainwater harvesting system demonstrated satisfactory results, within the recommended standards for non-potable uses, in accordance with NBR 15527:2019. These data validate the qualitative water safety and efficiency, indicating that the system can operate adequately. Continued monitoring will improve understanding of the system's capacity in response to seasonal variations and provide data for potential expansion and application to others buildings on campus.

Regarding Energy, the preliminary assessment of the photovoltaic solar generation system through the installed solar carports indicates a positive energy generation outlook, in line with the installed system's potential. The average monthly generation estimate represents an important contribution to the local energy matrix and to the mitigation of CO_2 emissions, while also being integrated with the electric mobility system. Should the research yield satisfactory and concrete results, the system opens pathways for new expansion possibilities and the pursuit of an energy model capable of minimizing total dependence on utility providers.

Regarding Food, the Water Footprint results from the university restaurant revealed important data on the dietary habits of users and the characteristics of meals served. These data enable the development of strategies for reducing institutional water footprint and promoting initiatives involving sustainable food education for the academic community, contributing to more conscious food choices.

In light of the findings, the relevance of the WEF Nexus approach as a fundamental tool for rethinking natural resource management in the institution is emphasized Adopting integrative practices around the WEF Nexus enables improvements in institutional processes and consolidates the university as a space for innovation and commitment to sustainability.

Universities and research centers can play a fundamentally important role in documenting, analyzing, and disseminating case studies, to foster replication of best practices and adapt them to different contexts.

[3] Department of Architecture, Built Environment and Construction Engineering, Politecnico di Milano, Milan 20133, Italy

Abstract. In Italy, 57% of school buildings are almost 50 years old and are characterized by poor energy performance, high climate impact, and inadequate Indoor Environmental Quality (IEQ). The urgent need to renovate these buildings in order to achieve carbon neutrality and improve indoor air quality has become a priority on the political agenda. Although the urgency of intervention is widely acknowledged, several barriers—related to both financial and cultural constraints—still hinder the large-scale renovation of school buildings. In this context, the RERoadS project aims to address this challenge by proposing a methodological framework based on three interconnected objectives: the implementation of a School Building Renovation Passport in line with current EU directives; the development of dedicated Educational Paths aimed at raising environmental awareness within the school community and tailored to students at different educational levels; and the establishment of a School Advisory Board, a multidisciplinary group of external experts, such as, academics, school managers, local authorities, and policy makers, to provide qualified scientific support for renovation decision-making processes. This paper presents the RERoadS methodology and tools aimed at reshaping the Italian school building sector towards more effective renovation processes and increased sustainability awareness.

Keywords: Sustainability Education · Circularity Awareness · Digitalization · Building Renovation Passport · Educational paths

1 Introduction

The Italian educational building stock comprises a total 30.604 schools, including 15.907 primary schools, 7.737 secondary 1st grade schools, and 6.960 secondary 2nd grade [1]. Most of these buildings were designed and constructed according to regulatory,

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 667–675, 2026.
https://doi.org/10.1007/978-3-032-34930-9_78

technological, and environmental standards that no longer reflect current requirements. Nearly 57% of the national school building stock is nearly 50 years old [2] and is characterized by poor energy performance and high environmental impact.

Although the urgency of intervention is widely acknowledged, several barriers still hinder the large-scale renovation of school buildings. While some barriers are linked to financial and economic constraints, others are rooted in limited cultural awareness of the importance of such interventions [3]. In this context, fostering awareness and environmental responsibility has become a strategic priority to support the renovation of the existing school building stock towards healthy, energy-efficient, and zero-emission schools. Sustainability education represents a fundamental step that should be introduced from the earliest learning stages [4]. Various initiatives have been developed to educate students on sustainability-related issues through innovative and effective methodologies, such as serious games and game-based learning [5].

The imperative to enhance awareness and accelerate renovation efforts is further reinforced by national and European targets on carbon neutrality, energy efficiency, and indoor air quality [6]. Addressing these challenges requires effective, scalable, and replicable tools and strategies capable of supporting large-scale renovation processes across diverse territorial and climatic contexts.

The European regulatory framework supports these efforts through the Energy Performance of Buildings Directive (EU) 2024/1275 (EPBD IV), which strengthens long-term renovation strategies and introduces new instruments to accelerate deep renovation processes across Member States. Among these, the Building Renovation Passport (BRP), introduced in Article 12, provides a structured and tailored roadmap prepared by qualified professionals to guide staged building renovation processes [7]. Unlike the static Energy Performance Certificate (EPC), the BRP provides a strategic roadmap for progressively achieving higher performance standards, from nZEB to ZEB levels. It must be accessible to both users and digital systems, enabling integration with national and European public data platforms and improving information interoperability [8].

From this perspective, an integrated and coordinated effort among multiple stakeholders in the educational, construction, administrative, technical, and research sectors is essential to develop a tailored instrument specifically designed to address the technical, functional and environmental needs of school buildings. In response to the outlined challenges, the national research project "Renovation and Education Roadmaps for Healthy and Resilient School Buildings towards Carbon Neutrality" (RERoadS), funded by the Italian Ministry of University and Research, aims to support large-scale renovation pathways for school buildings through the development and validation of the first School Building Renovation Passport (SBRP) for the Italian context, focused on sustainability, energy performance and Indoor Environmental Quality (IEQ). The project also promotes dedicated Education Paths (EP) to increase environmental awareness within school communities and encourage sustainable behaviours among younger generations. In addition, it establishes a School Advisory Board (SAB), bringing together researchers, professionals and stakeholders to provide scientific and technical support for school renovation decision-making processes. Besides this introduction, the following

sections foreseen the IMRAD structure: Sect. 2 describes the RERoadS methodological framework; Sect. 3 outlines the RERoadS outcomes; Sect. 4 focuses on RERoadS results; finally, Sect. 5 presents conclusions and further works.

2 RERoadS Methodological Framework

The RERoadS project seeks to address the identified challenges described in Sect. 1, following a methodological framework (Fig. 1) structured into 4 main phases.

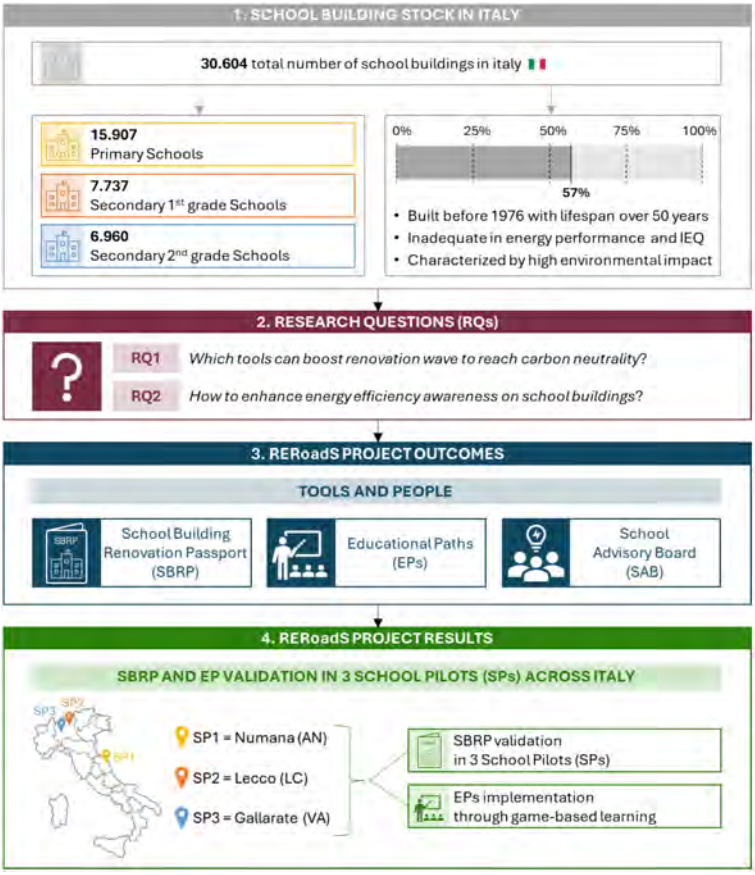

Fig. 1. Graphical overview of the methodological framework adopted by RERoadS project. Source: authors' elaboration.

In phase 1, a deep analysis of the school building stock in Italy has been conducted to identify main issues and challenges to be addressed and led to the identification of two main Research Questions (RQs) of phase 2: RQ1) How to enhance energy efficiency awareness on school buildings? RQ2) Which tools can boost renovation wave to reach carbon neutrality?

The phase 3 focuses on the development of the RERoadS project outcomes, derived from the RQs, corresponding to three distinct but interconnected instruments.

(1) The creation of the first SBRP, aimed at facilitating the deep renovation processes required by current EU directives by proposing a tool specifically tailored for school buildings.
(2) The development of dedicated EPs for school communities based on innovative teaching methods, addressing the need to promote sustainability awareness among younger generations.
(3) The creation of the SAB, to support the development of EPs and SBRP, ensuring their coherence, applicability, and effectiveness.

Finally, in phase 4 the project results are validated into three School Pilots (SPs) across Italy.

3 RERoadS Outcomes: Tools and People

The RERoadS outcomes respond to the main project RQs by the creation of two tools (SBRP and EPs) in reply to RQ1 and a group of experts (SAB) to RQ2. In the following subsections the overall process for their development and definition are presented.

3.1 RERoadS School Building Renovation Passport

The RERoadS School Building Renovation Passport represents the first BRP experience tailored for schools in the Italian context, aligned with current EU regulation and targets. The RERoadS SBRP is intended as an efficient and user-friendly tool guiding staged and performance-oriented school renovation processes. Its overall structure is based on the majority of the existing and in use BRPs, including two main elements: the Digital Building Logbook (DBL) and the Renovation Roadmap (RR).

The DBL is a digital tool designed based on an analysis of existing DBL frameworks, including ALDREN, iBRoad, X-Tendo, EUB SuperHub, as well as more recent initiatives such as OneClickReno and GreenReno. These are adapted considering the Italian context and the building typology, as no dedicated DBL frameworks for educational buildings were identified in the literature. The RERoadS DBL is conceived to be closely interconnected with existing Italian educational and building databases, including Unica – Scuola in Chiaro, Portale Unico dei Dati della Scuola, and Anagrafe Regionale Edilizia Scolastica 3.0, including information on energy performance, Indoor Environmental Quality (IEQ), and sustainability. This integration enables a simplified compilation process for the assessor through the automatic pre-filling of indicator values that are easily accessible in the databases. The DBL aims not to function as a static repository but supporting informed decision-making and ensuring data continuity throughout the building lifecycle.

Starting from the DBL data collection, a tailored Renovation Roadmap (RR) is generated according to the school building's current condition and characteristics, identified by selected key performance indicators such as school building archetype, construction technologies, and system configuration. The RR outlines a long-term, step-by-step

renovation pathway proposing a sequence of tailored, cost-effective, and sustainable Elementary Renovation Actions (ERAs), including envelope insulation measures, integration of renewable energy solutions, and replacement of obsolete technical systems, taking into account the preferences or requirements expressed by the school building owner as well as the available incentives in Italy [9]. The roadmap supports a progressive planning approach, moving from low-cost measures to deep retrofit strategies according to the building's characteristics and its assessment in terms of energy performance, IEQ, and sustainability. The RR validation, applied to the three SPs, consists of a detailed analysis comparing the interventions suggested by the roadmap with the results obtained through building performance simulations.

3.2 RERoadS Educational Paths

The development of targeted Educational Paths (EPs) aims to raise environmental awareness within the school community. This activity primarily involves students and teachers, while also indirectly influencing families and the broader school community. The EPs are tailored to students at different educational levels, including primary school, lower secondary school, and upper secondary school. Rather than delivering a purely technical training program, RERoadS adopts innovative educational methodologies to design diverse learning experiences for students of different age groups. These approaches ensure an appropriate level of complexity and engagement, while emphasizing experiential and participatory learning.

For primary school students, introductory modules address basic sustainability concepts in the construction sector, including bioclimatic design, building life cycle, energy efficiency, and carbon footprint, combined with hands-on laboratory activities. Conversely, students at higher educational levels are engaged through quiz-based and game-based learning strategies aimed at enhancing critical thinking and decision-making skills related to energy-saving behaviors and emission reduction.

3.3 RERoadS School Advisory Board

The establishment of the School Advisory Board (SAB) is closely connected to the first two outcomes. The RERoadS SAB is a multidisciplinary group of external experts providing scientifically informed guidance for school renovation decision-making, involving representatives from academia, school management, local authorities, and policy makers. SAB members are actively involved throughout the project development process. The collaboration among these diverse stakeholders contributes to providing expert input and strategic advice that supports the design and refinement of both the SBRP and the EPs.

4 RERoadS Results

The RERoadS results correspond to the validation of the outcomes, tested in three SPs, and in this section the current level of their implementation is presented.

4.1 RERoadS SBRP Application to School Buildings for Validation

The validation of the REROadS SBRP is planned to be carried out in three SPs located in different geographic contexts and presenting different geometric, technological, and energy characteristics, enabling the generation and testing of differentiated SBRP roadmaps. Specifically, SP1 is a primary school, located in Numana (Marche region – climate zone D); SP2 is a secondary 1st grade schools located in Lecco (Lombardia region – climate zone E); and SP3 is a secondary 2nd grade schools located in Gallarate (Lombardia region – climate zone E). Currently, the SBRP is under construction in a modular structure as described in Sect. 3.1 and it will be used as decision-support tool for defining renovation interventions based on information regarding the current state of the building.

4.2 RERoadS EP Implementation Through Game-Based Learning

The second result of the REROadS project is the implementation of targeted Educational Paths (EPs). To date, three out of the five educational modules planned for primary school have been implemented in the School Pilot (Fig. 2). The first module, "Discovering Our Green Footprints", introduced students to the environmental impact of human activities and buildings throughout their life cycle. Through practical experiments, including a classroom demonstration of the greenhouse effect, students critically reflected on individual and collective behaviours associated with high ecological footprints. The second module, "Homes Around the World: Building with Climate", focused on the principles of climate-responsive design across different environmental and construction contexts. Working in groups, students developed models of traditional building archetypes representative of different climatic regions worldwide. In the third module, "Building Planet-Friendly Buildings", students explored energy-efficiency strategies for buildings. A real-time experiment demonstrated the effectiveness of thermal insulation, while collaborative activities allowed students to design retrofitted buildings adapted to different climatic conditions, learning how renovation strategies should respond to local climate characteristics.

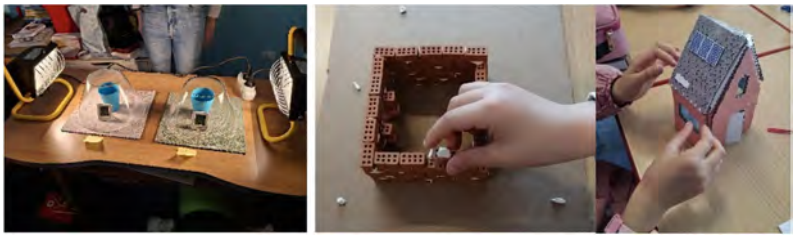

Fig. 2. Images from the three modules implemented in primary school: greenhouse effect experiment, masonry building construction in temperate climate, and planning of energy retrofit interventions for a Nordic climate house.

Regarding secondary 1st grade school, an initial educational activity focused on sustainability and circularity, introducing these topics through interactive team-based

games aimed at calculating students' ecological footprints, quizzes on the principles of the circular economy, and the creation of "Haiku" rhyming compositions related to sustainability themes. A second module aimed to increase students' awareness of their school building, using technical drawings to investigate the building's historical evolution and to introduce the main architectural elements of the façade, while practical demonstrations were also carried out to familiarize students with building survey activities and measurement procedures (Fig. 3).

Fig. 3. Images from the two implemented modules in the lower secondary school where students experienced how to perform an on-site survey of a building both with manual instruments and digital ones.

Besides these experiential learning activities, as a final EP module, RERoadS will develop a dedicated board game addressed to teenage students, aimed at encouraging reflection on the relationship between individual choices, energy consumption, and environmental impact. The RERoadS board game kit will consist of a physical tabletop game designed to allow students to explore how different renovation measures, and the extent of their implementation, can contribute to improving the performance of school buildings and the quality of the surrounding environment.

4.3 RERoadS SAB Technical Meetings

The SAB technical meetings play a key role in supporting the effective implementation of the project outcomes and promoting awareness across broader stakeholder groups. The SAB is composed of representatives from public bodies and local authorities, school building managers and maintenance operators, designers and professionals experienced in educational spaces, direct school users (students, families, teachers, and staff), and stakeholders with expertise in the construction, environmental, educational, and social sectors. SAB's inaugural meeting took place at the end of the first year of the project with the aim of sharing the initial expected results and gathering suggestions for the development of the project's outcomes, in line with the guidelines and needs of all stakeholders in the supply chain.

5 Conclusions

This paper presented the methodological framework, the first results achieved and the next steps planned for RERoadS. The overall project goal is to support school building renovation through an integrated approach combining technical tools, educational initiatives, and stakeholder engagement.

Several activities have already been completed, including collaboration with the three SPs and the involvement of stakeholders within the SAB, whose contributions helped identify operational aspects affecting information exchange and decision-making processes during renovation initiatives. Regarding the EPs, some modules have already been implemented in primary and lower secondary schools, while further activities are planned according to an agreed calendar with teachers of the SPs.

Future developments will focus on the application of the RERoadS SBRP within the three School Pilots to validate the proposed methodology and assess the effectiveness of the renovation roadmaps in terms of energy performance, sustainability, and indoor environmental quality. The pilot applications will contribute to refining the tool and exploring its scalability across the Italian and European school building stock, supporting more effective and sustainable renovation processes.

Abstract. The Fifteen-Minute City (FMC) model, along with other proximity-centred frameworks, challenges the dominant mobility paradigm that has shaped urban development and contributed significantly to environmental degradation through air and noise pollution and elevated greenhouse gas emissions. This paper aims to: (i) understand the role of public transport (PT) within the FMC; (ii) operationalise the diversity component of the framework developed by Guzman et al. (2024) at a local scale, with a particular focus on PT; and (iii) assess how PT accessibility and perception influence the applicability of the FMC model in Matosinhos. The adopted methodology combines an objective assessment, through spatial analysis, with a subjective evaluation conducted via a questionnaire survey to assess the applicability of the FMC model in the study area. Results show a clear relationship between transport accessibility and functional diversity. Areas with stronger PT provision exhibit higher diversity scores, not necessarily due to greater concentration of local amenities, but due to the extended accessibility enabled by the transport network.

Keywords: Fifteen-minute City · Proximity-based Planning · Urban Resilience

1 Introduction

Cities today face increasing pressure to reconcile urban growth with environmental sustainability, accessibility and quality of life. Over recent decades, many urban areas have expanded through low-density development and dispersed land-use patterns, reinforcing dependence on private vehicles [1]. This has led to higher levels of air and noise pollution and significant greenhouse gas emissions, all of which negatively affect both environmental sustainability and public health [2, 3]. The COVID-19 pandemic further exposed the limitations of mobility-dependent urban systems [4, 5]. Lockdowns re-centred daily

life around the neighbourhood scale, making disparities in local accessibility more visible and reinforcing the importance of proximity in supporting everyday activities [6]. In this context, proximity-centred accessibility models have gained increasing attention, particularly the Fifteen-Minute City (FMC), which proposes compact, mixed-use neighbourhoods where essential services are accessible within a short walking or cycling distance [2, 4, 6, 7]. The FMC can reduce car dependency, cut down on GHG emissions, and promote active, healthier lifestyles by shifting the focus from long-distance mobility to proximity-based access [8].

While the FMC prioritises walking and cycling within neighbourhoods, it implicitly depends on efficient and accessible PT systems to ensure connectivity between local areas and the broader urban region [6, 9]. As such, proximity and connectivity should not be understood as opposing paradigms but as complementary dimensions of accessibility [2, 10]. Recent conceptual developments of the FMC have increasingly acknowledged this need for integration. Expanding on Moreno's original framework, [9] introduce additional dimensions - such as connectivity, highlighting the importance of linking neighbourhoods through cohesive transport networks. Connectivity ensures that proximity-based environments remain functionally integrated rather than spatially isolated [9], enabling residents to travel easily beyond their neighbourhood when necessary, reducing the need for car ownership while supporting the FMC's proximity goals [6, 11]. Thus, integrating PT within proximity-based planning contributes to broader sustainability goals, making it an enabler within the FMC context [11]. By providing viable alternatives to private car use, it supports modal shifts towards more energy-efficient and equitable forms of mobility [6]. At the same time, PT mitigates one of the key criticisms of the FMC, namely the assumption of self-sufficient neighbourhoods [12, 13], by ensuring that residents are not constrained to limited spatial boundaries and can access a wider range of opportunities without increasing car dependency [4, 9]. Although this study focuses on mobility and accessibility within the framework of the Fifteen-Minute City, it also contributes to the circularity agenda in urban development. By promoting proximity, reducing car dependency, and improving the use of public transport and existing urban infrastructure, the proposed approach supports more efficient use of built assets and helps to limit land consumption, the need for new infrastructure, and resource-intensive urban sprawl. In light of the above, this paper aims to: (i) understand the role of PT within the FMC; (ii) operationalise the diversity component of the framework developed by [9] at a local scale, with a particular focus on PT; and (iii) assess how PT accessibility and perception influence the applicability of the FMC model in Matosinhos.

2 Case Study

The municipality of Matosinhos is located within the Porto Metropolitan Area (AMP) and has a population density of 2.876 inhabitants per km^2, considerably higher than both the metropolitan (864,6 hab./km^2) and national (116,6 hab./km^2) averages [14]. Matosinhos is part of a polycentric metropolitan structure in which the city of Porto functions as the primary urban node, surrounded by several sub-centres such as Senhora da Hora and São Mamede de Infesta [15]. Mobility patterns in Matosinhos reflect

its strong metropolitan integration. Approximately 53% of employed residents work outside the municipality, highlighting the importance of inter-municipal flows in daily mobility. While private vehicles remain the dominant mode of transport (54% of daily trips), active modes such as walking and cycling represent approximately 14% of journeys [14]. These dynamics illustrate both the municipality's accessibility within the metropolitan network and its dependence on motorised mobility. Matosinhos' density, compact urban form and service concentration make it a relevant context for assessing proximity-based accessibility models, with public transport playing a key role in connecting neighbourhoods with different levels of service provision. This paper focuses on UOPG 5, a functional planning unit in Matosinhos based on similar territorial characteristics and urban dynamics [16], selected for its high population density, estimated at approximately 5,539 inhabitants per km^2, and its strategic role as a metropolitan mobility hub, making it suitable for assessing the applicability of the FMC model.

3 Methodology

This study adopts and adapts the analytical framework proposed by [9] for evaluating the applicability of the FMC model at the neighbourhood scale. The FMC Index comprises two main components: diversity and walkability. Diversity refers to the range and balance of essential services available within a fifteen-minute walk from each residential block, while walkability reflects the quality of the pedestrian environment, capturing how safe, comfortable, and feasible it is for residents to walk to those services. Particular emphasis is placed on the operationalisation of the Diversity Index, as it encapsulates not only the physical distribution of services but also the social and behavioural dimensions that condition their relevance to urban life. Thus, two main analyses will take place. Firstly, an objective study that identifies the existing distribution of infrastructure in UOPG 5 (Accessibility). Secondly, an inquiry to the local communities to understand their individual preferences regarding the relative importance of different amenities within walking distance (Individual Preferences). Lastly, the Diversity Index is subsequently computed, taking the previous two analyses into account. By combining these two sources of information, the analysis allows for a more nuanced understanding of accessibility, considering not only the geographical proximity of services but also their perceived relevance to the local population. Given the central role of mobility in shaping accessibility beyond the neighbourhood scale, particular attention is given to the PT category across all analytical dimensions.

Accessibility is operationalised as the number of establishments of a given type that fall within a fifteen-minute walking isochrone drawn from each residential block. In this context, it means measuring the proximity of amenities to each residential building. This analysis is conducted using the Origin-Destination (OD) Cost Matrix Tool from ArcGIS, which enabled the mapping and evaluation of spatial relationships between residential buildings and points of interest (POIs). POIs are classified into six categories of essential services – education, groceries, healthcare, public transport, recreation and services, each composed of many subcategories representing specific types of amenities. Within the PT category, POIs correspond to bus stops, metro stations and railway stations. The accessibility analysis comprises two main steps: i) calculating accessibility per subcategory, where, for each origin and service type, the number of destinations reachable

within 15 min on foot is counted using a cumulative opportunities approach based on the network distance; ii) normalise the accessibility values to allow for comparison between origins and services. To complement the spatial analysis, a questionnaire survey was conducted to capture residents' perceptions of local accessibility and service provision. The survey targeted residents of UOPG 5 and collected information on socio-demographic characteristics, mobility patterns, and the perceived importance of different categories of amenities. Its main purpose was to estimate the relative importance, or weight, of each type of establishment, and, thereby, to understand how residents value and prioritise the selected essential services. In addition, the respondents were asked to indicate which services they considered lacking in their vicinity. This information was essential for identifying residents' priorities and perceptions regarding local accessibility. To compute the resulting weights, which will later be used for the Diversity Index, the weighted linear combination method was used, which integrates the evaluation criteria and their corresponding weights through a weighted average. The Diversity Index captures the equilibrium across different categories of services and incorporates the relative importance that residents assign to each. The diversity score for each block is calculated through a weighted geometric mean of the normalised accessibility values, using the individual preference weights as coefficients.

4 Results

4.1 Accessibility Index

The Accessibility Index reveals a relatively dense but uneven distribution of PT infrastructure within UOPG 5. As illustrated in Fig. 1, which maps the spatial distribution of PT points of interest (POIs), bus stops are widely dispersed across the study area, providing a broad level of baseline coverage. In contrast, metro stations are more spatially concentrated, primarily located along main corridors and central areas, resulting in higher accessibility levels in these zones. This spatial configuration creates differentiated patterns of accessibility. Central areas, where both metro stations and a higher density of bus stops are present, benefit from greater connectivity and redundancy in transport options. Conversely, peripheral and predominantly residential zones rely more heavily on bus services, which, despite their wider distribution, may offer lower service frequency and reduced connectivity. Accessibility values were then normalised using a min–max method.

4.2 Individual Preferences Questionnaire

Using the Weighted Linear Combination method, weights were assigned to each service category. The results indicate that Healthcare (0,22) and Public Transport (0,20) are the most valued categories.

Most respondents report commuting times up to 30 min, which shows that most respondents experience short to moderate commuting times. This does not necessarily align with the 15-min city framework, as the main mode of transportation used is unknown. Nevertheless, considering that nearly half of the respondents commute to

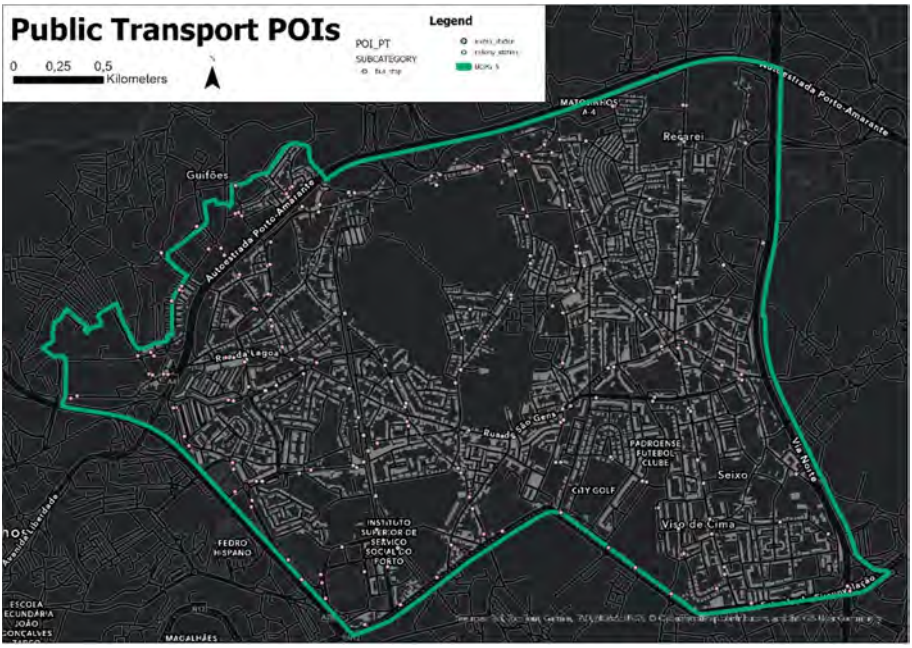

Fig. 1. Public Transport Points of Interest

another municipality, it is reasonable to assume that these journeys are undertaken primarily by PT or private vehicle. Additionally, 18% of respondents travel within the same municipality but to a different parish, and 11% work in the same parish they reside in. Overall, this distribution reinforces the predominance of local and intra-metropolitan mobility patterns, with limited evidence of long-distance commuting among participants.

The mobility patterns help explain why PT emerges as one of the most valued service categories among residents, which may reflect both the current reliance on public transportation for daily mobility or the desire to do so in the future. Interestingly, PT is one of the categories respondents find most lacking. Most respondents chose PT as one of the most deficient categories. Respondents described it as unreliable, complaining about long waiting times and limited destinations. The lack of metro coverage across the municipality was also a popular critic.

4.3 Diversity Index

The Diversity Index, when analysed specifically for the PT category, highlights the role of transport infrastructure in shaping accessibility patterns within UOPG 5. By integrating spatial accessibility with residents' perceived importance, this analysis provides insight into how effectively PT supports proximity-based accessibility. As illustrated in Fig. 2, which presents the spatial distribution of the Diversity Index values for the PT category, higher scores are concentrated in central areas of the study area.

These zones correspond to locations with greater proximity to both metro stations and dense bus networks, resulting in stronger integration within the metropolitan transport

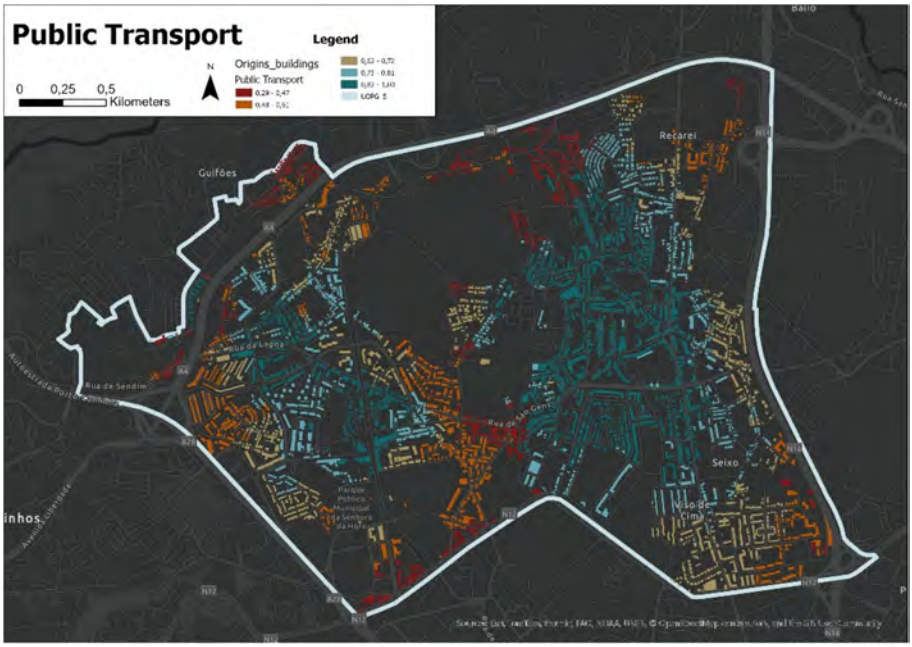

Fig. 2. Diversity Index for the Public Transport category.

system. In these areas, PT enhances accessibility by enabling residents to reach a wider range of services beyond the immediate neighbourhood. In contrast, lower diversity scores are predominantly found in peripheral and residential zones, where accessibility to PT is more limited. These areas tend to rely primarily on bus services, often characterised by lower frequency and reduced connectivity compared to metro corridors. As a result, residents in these locations experience weaker access to the broader urban system, which constrains their ability to compensate for limited local service provision. This spatial pattern reveals a clear relationship between transport accessibility and functional diversity. Areas with stronger PT provision exhibit higher diversity scores, not necessarily because of a greater concentration of local amenities, but due to the extended accessibility enabled by the transport network. Conversely, areas with weaker transport connectivity display lower diversity levels, reinforcing their relative isolation within the metropolitan context.

5 Discussion and Concluding Notes

The results highlight the critical role of PT in shaping accessibility within proximity-based urban models. While the study area presents relatively favourable conditions for spatial accessibility, these are not sufficient to ensure equitable access to services across all neighbourhoods. Mobility emerges as a critical enabling factor. The effectiveness of the FMC in metropolitan contexts depends not only on proximity-centred accessibility but also on broader transport connectivity. Without effective alternatives to private car

use, the principles underpinning the FMC risks remaining aspirational rather than operational, which explains why the category of public transport is comprised both in the accessibility and diversity indexes. Areas with higher Diversity Index scores not only encompass greater concentration of local services but also benefit those with stronger integration within the metropolitan transport network. These findings challenge simplified interpretations of the FMC as a purely localised and self-sufficient urban model. Although proximity-based planning seeks to reduce dependence on long-distance mobility, the questionnaire's results show that daily life within UOPG 5 remains strongly connected to inter-municipal commuting dynamics. PT emerged simultaneously as one of the most valued and most deficient service categories, reflecting the extent to which residents rely on metropolitan mobility networks while also perceiving significant shortcomings in their quality and coverage. In this sense, proximity and connectivity should not be understood as opposing paradigms, but as complementary dimensions of accessibility. Furthermore, the study highlights persistent territorial inequalities within the study area. Peripheral and predominantly residential zones continue to experience weaker accessibility due to lower transport frequency, limited modal diversity and reduced connectivity to metropolitan corridors. This suggests that implementing the FMC may reproduce existing spatial inequalities if proximity-based planning is not accompanied by stronger investment in sustainable mobility systems and inter-municipal coordination. Methodologically, the Diversity Index provides a useful overview of functional accessibility by integrating objective spatial analysis with residents' perceived priorities. Nevertheless, treating all POIs equally may oversimplify the complexity of urban experience, as services differ in scale, frequency of use and social relevance. Future research should therefore further explore the relationship between objective proximity and perceived accessibility, while developing more nuanced weighting systems capable of capturing differentiated urban needs and mobility practices.

Finally, although the study is centred on mobility and accessibility, its findings also contribute to circularity in the construction sector by showing how proximity-based planning and improved public transport connectivity can enhance the use of existing urban infrastructure, reduce car-oriented spatial demands and support more resource-efficient urban development.

[2] Postgraduate Program in Architecture and Urbanism, Federal University of Espírito Santo, Espírito Santo, Brazil

Abstract. Climate change and light pollution are interconnected environmental challenges with combined effects on energy consumption, human health, and the biodiversity of urban ecosystems. However, a better understanding of the combination between the topics is still needed. The objective of this study was to map and compare scientific production on the relationship between light pollution and climate change, covering the period from 2015 to 2025, in order to provide a comprehensive overview of the evolution of this knowledge. The methodology consisted of bibliometric research, using PubMed, Scopus, SciELO, and CAPES Journal Portal databases. Although there was an upward trend during the time frame under review, an analysis of the articles revealed fluctuations in scientific output over the period analyzed, with a concentration of publications in recent years, particularly after 2020. The literature reviewed confirms light pollution as a factor reinforcing climate change, manifested by increased energy use and impacts on urban ecology. In conclusion, although the topic is globally rising, the concentration in a few sources and the marked regional gap signal the urgency of integrating this theme into public policies.

Keywords: Artificial Light at Night · Global Warming · Urban Ecology · Bibliometrics · Research Gap

1 Introduction

In the current field of study of urban spaces, light pollution is emerging as a significant factor exacerbating the impacts of climate change. With the invention of electricity during the Industrial Revolution in the 19th century, the large-scale use of artificial lighting in public and private areas began [1]. Consequently, the excess of artificial light, especially in large metropolises, increases electricity consumption, intensifies local warming [2], and contributes to greenhouse gas emissions [3]. Furthermore, rapidly urbanizing

https://doi.org/10.1007/978-3-032-34930-9_80

regions, the expansion of artificial lighting has become increasingly associated with unsustainable patterns of energy consumption and environmental degradation [4]. In the long term, these effects have direct and indirect repercussions on human health and local biodiversity [5, 6]. In this context, Falchi et al. [7] defines light pollution as the alteration of natural nocturnal light levels caused by anthropogenic sources, namely, the excessive emission of artificial light from building facades, billboards, and street lighting that scatters into the atmosphere.

Beyond high energy consumption, light pollution causes significant environmental imbalances. The intensive use of electrical energy for lighting accounts for a considerable amount of carbon emissions, intensifying the effects of climate change. Furthermore, scientific evidence demonstrates that light pollution contributes to environmental degradation in various ways [8]. One of the most perceptible problems caused by excessive artificial lighting in cities is the obscuration of the night sky, which compromises astronomical observation and the human connection with the starry sky [9]. It is estimated that approximately 80% of the world's population lives under skies altered by this glow, leaving few areas where the sky maintains its natural characteristics. It should be noted that 99% of the population in Europe and the United States lives under altered skies, making it almost impossible to see the stars with the naked eye [10]. This loss of stellar visibility represents not only an environmental impact but also a symbolic rupture in the relationship between humans and nature.

In principle, light pollution can harm fauna and flora by altering essential ecological cycles. In fauna, excess artificial light interferes with the behavior of various species, affecting processes such as migration, feeding, and reproduction. In some cases, it prevents mating and the perpetuation of species, as observed in turtles, fireflies, bats, and fish. Regarding flora, excessive artificial light compromises the process of photosynthesis, hindering the conversion of carbon dioxide into oxygen [2]. Additionally, it influences leaf fall and extends the growth period of plants, generating significant effects on local vegetation [11].

The excess of artificial light, besides affecting other life forms, also represents a significant threat to human health, disrupting essential biological rhythms and contributing to a range of medical conditions. Studies indicate that excessive exposure to artificial light can cause eye irritation and chronic fatigue [8]. Additionally, it directly interferes with the circadian cycle, impairing sleep quality and favoring the development of metabolic problems such as obesity and type 2 diabetes mellitus [12, 13]. This circadian dysfunction also leads to the interruption of melatonin production, affecting the synthesis of growth hormone [14, 15], and aggravating psychological disorders such as depression [16]. In the oncological context, there is evidence of an approximately 11% to 14% increase in the risk of breast cancer in women exposed to higher levels of outdoor artificial light at night, even after adjusting for environmental variables such as air pollutants and vegetation index [17, 18].

Despite these evident risks, light pollution remains a largely unrecognized challenge. A lack of public awareness regarding its effects sustains behaviors that worsen the problem [19], such as common sources including residential lamps, unshielded public streetlights, vehicle headlights, and the excessive lighting of urban centers, which reflects off clouds and amplifies the night sky glow [11]. This lack of knowledge negatively

affects personal motivation to adopt correct behaviors [19] and the perception of the issue, compromising its recognition as a legitimate form of ecological deterioration and hindering the development of public policies [8].

Moreover, global entities responsible for formulating government policies have not included light pollution among their priority goals for controlling environmental degradation. It was only in 2020 that the European Union recognized it as an environmental problem [20]. In Brazil, there is a scarcity of debate regarding the excess of artificial light, reflecting negatively in the absence of legislation and standards for the national lighting system. However, the Brazilian Association of Technical Standards (ABNT) has published a new guideline, occupying nearly an entire chapter of a technical standard, which delves further into light pollution, although it remains insufficient [21]. These recent advances highlight the need to integrate light pollution into discussions on climate change and urban ecosystems, urging collective actions to mitigate its impacts.

In this context, this work conducts a bibliographic review of academic production on light pollution from 2015 to 2025. The objective is to synthesize current knowledge on the subject regarding its relationship with climate change, considering its impacts on energy consumption, the environment, and human health.

2 Methodology

This study is characterized as an integrative literature review combined with a bibliometric analysis of scientific production, adopting a qualitative-quantitative approach. The methodological flow was structured into the following stages:

Database Selection and Search Strategy: The bibliographic survey was carried out across national and international databases such as SciELO, PubMed, Scopus, and the CAPES Journals Portal. A "general" search was performed using the "any field" (all fields) parameter. The search was conducted using seven combinations of keywords in Portuguese and English, as detailed in Table 1.

Table 1. Search Terms used in the databases.

Number	Terms
1	"Poluição Luminosa"
2	"Light Pollution"
3	"Artificial Light at Night"
4	"Light Pollution" and "Climate Change"
5	"Light Pollution" and "Climatic Changes"
6	"Artificial Light at Night" and "Climate Change"
7	"Artificial Light at Night" and "Climatic Changes"

Timeframe and Data Organization: The study focused on scientific production from the last decade (2015 to 2025). For analysis and organization purposes, the material was segmented into two five-year periods: 2015–2020 and 2021–2025.

Exclusion Criteria: Editorials, event abstracts, and opinion pieces without evidence were excluded, as well as works without a direct and in-depth correlation between light pollution and environmental or climatic impacts.

Snowballing Technique: For the theoretical framework, the snowballing technique was applied following the guidelines of Wohlin [22]. This consisted of backward snowballing, examining reference lists of key articles to identify primary sources and seminal studies.

Data Systematic Processing: Files were organized into specific folders and a structured spreadsheet, segmented according to the search terms and the defined periods. Duplicate identification and removal were performed using Mendeley software. For each publication, information such as year of publication, country of origin, and primary theme was recorded. During the analysis, it was observed that the results obtained from the isolated search terms presented in lines 1, 2, and 3 of Table 1 were disconnected from the central objective of the research. Therefore, only studies containing combined search terms, as presented in lines 4, 5, 6, and 7 of Table 1, were retained to ensure alignment with the relationship between light pollution and climate change. To identify the geographical origin when it was not explicitly stated, priority was given to the institutional affiliation of the first author, followed by the location of the case study and the journal's editorial affiliation.

Final Sample Refinement: A detailed review was conducted by reading the abstracts of the identified studies to exclude "false positives" such as studies mentioning light pollution without addressing its relationship with climate change. This stage also included a final check for duplicates, ensuring the quality and precision of the analytical set.

3 Results

The study selection process revealed a progressive refinement of the sample. Initially, 8,055 publications were identified across the consulted databases, excluding results from Google Scholar. After the first stage of duplicate removal, the number of records was reduced to 4,803.

Upon applying the keyword combination criteria and the established timeframe, the initial volume of studies was significantly reduced to 216 publications. After a meticulous screening, a preliminary corpus of 99 documents considered potentially relevant to the research was defined. This relatively small number reflects both the specificity of the scope and the relative novelty of the theme in the current academic landscape.

During the bibliographic survey, a near-absence of publications in Portuguese addressing the direct intersection between the two central themes of this research was observed. This disparity may be attributed, in part, to the specificity of the descriptors used; while the searches in English integrated combined terms (as per lines 4 to 7 of Table 1), which effectively filtered the correlation between artificial light and climate, the results in the Portuguese language (primarily obtained through the single descriptor "Poluição Luminosa") tended to focus on fragmented aspects of the phenomenon, lacking the climatic connection required by the inclusion criteria. This highlights a gap in integrated scientific production within Portuguese-speaking countries, reinforcing the need for research that unifies these axes.

After the systematic refinement process described in the methodology, the final analytical set consisted of 90 studies. The quantitative and qualitative analyses of these publications are presented below, beginning with the temporal and geographical distribution of the production.

The analysis of the temporal distribution of the publications revealed variations throughout the observed period. The year with the highest number of published studies was 2021, with 17 publications. This was followed by 2024, with 11 publications, and 2017, with 10 studies. Figure 1 shows the total amount of publications by year.

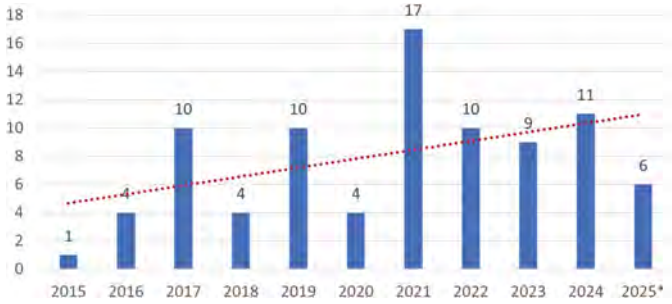

Fig. 1. Number of publications by year with a trend line for the period analyzed.

It can be observed that the growth in the number of publications was not constant and that there is no clear line of trends. Although the number of publications varied throughout the analyzed period, greater concentration of studies can be observed in recent years, showing an upward trend. Also, the year 2025 presented 6 publications, a figure lower than those observed in previous years. This result may be attributed to the fact that data collection was conducted during 2025, which may have limited the identification of studies that had not yet been published or indexed in the consulted databases at the time of the research.

The study of the geographical origin of the publications also revealed a significant concentration of research in Northern Hemisphere countries. Figure 2 presents the percentage of publications by continents. It can be noted that almost half of the production comes from Europe and almost 3/4 comes from its combination with North America. Less than 15% of the studies come from the Global South.

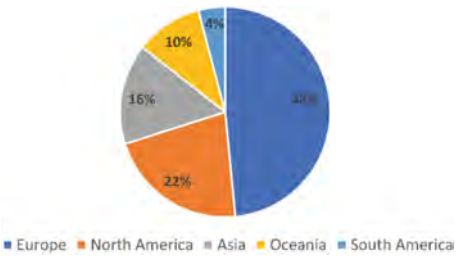

Fig. 2. Percentage of publications by continent.

These data indicate a predominance of research developed in Europe and North America, while scientific production in other regions of the world remains more limited. Among the countries with the highest number of publications, the United States stood out with 16 studies, followed by the United Kingdom with 11, and Germany with 9 publications. Figure 3 consists of a map with the numerical distribution of the publications by countries.

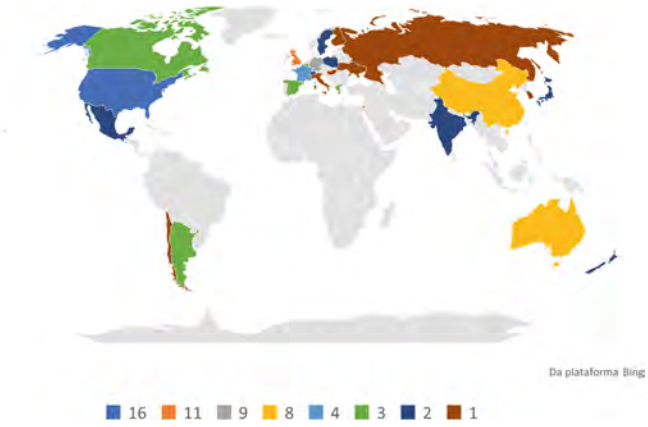

Fig. 3. Number of publications by country.

In South America, only Argentina, with 3 publications, and Chile, with 1, had identified studies in the area. In Oceania, Australia concentrated 80% of the publications. In Asia, China had around half of the publications of the continent.

4 Conclusion

The predominance of studies published in Europe and North America may be related to factors such as greater investment in scientific research, higher availability of technological infrastructure, and a more robust inclusion of environmental themes in the scientific and political agendas of these regions. Furthermore, European and North American countries possess a consolidated tradition in fields such as astronomy, remote sensing, and urban ecology, disciplines that frequently address light pollution as an object of investigation.

Advancements in satellite monitoring technologies and the growing scientific interest in the environmental impacts of urbanization have also contributed to the expansion of research on this topic [4]. On the other side, the low volume of publications in South America, particularly in Brazil, reveals a significant gap in regional scientific production. Although light pollution is present in major Latin American urban centers, the subject still receives limited attention within the region's academic circles [23].

This gap may be associated with the limited presence of the theme in environmental research agendas and the absence of specific public policies aimed at monitoring

and controlling this type of pollution. In this context, expanding regional scientific production on the subject becomes desirable to support the formulation of public policies, guide sustainable urban planning strategies, and contribute to actions mitigating the environmental impacts related to the excess of artificial lighting.

Beyond its environmental impacts, light pollution should also be understood as an indicator of inefficient urban resource management. Excessive artificial lighting reflects patterns of energy waste that contradict current principles of sustainable and circular cities. In this sense, addressing light pollution is not limited to protecting biodiversity or improving human health, but also involves rethinking urban lighting systems from the perspective of energy efficiency, environmental balance, and long-term urban resilience. Expanding research on this topic, especially in countries of the Global South, is essential for supporting more sustainable urban development models and environmentally responsible public policies.

kamillyme@gmail.com

[2] Programa de Pós-Graduação em Arquitetura e Urbanismo, Universidade Federal do Espírito Santo, Vitória, Brazil

Abstract. Light pollution is a global problem caused by the inadequate use of artificial light in the nighttime. The excess of artificial light causes changes not only in human life, but also in fauna and flora. The impacts are not only visual, and its inappropriate use is causing negative effects in several cities in Brazil and around the world, especially in regions undergoing territorial expansion. Thus, this research aims to analyze the evolution and trends of light pollution in the city of Santa Teresa, Brazil, through remote sensing from 2012 to 2024. The choice of this city is justified by the fact that it is a regional landmark due to its large areas of preserved Atlantic Forest, where high biodiversity stands in stark contrast to the city's rapid urban and population expansion driven by tourism over the past decade. The methodology is based on the analyses of annual light pollution maps generated from Visible Infrared Imaging Radiometer Suite (VIIRS) satellite imagery. With this method of analysis, it was possible to observe that there was an expansion of the urban territory with radiance emission, which can have a negative impact on local biodiversity, especially in regions further away from the urban center of the city. This study highlights the importance of proper planning for the expansion of cities and can assist in the implementation of mitigation policies for this type of problem. This will strengthen the dialogue between science and society in a city undergoing rapid expansion.

Keywords: Artificial Light at Night · Urban Expansion · Light Pollution Map · Radiance · VIIRS

1 Introduction

Light pollution is described as the inappropriate use of Artificial Light at Night (ALAN), whose oversizing causes drastic changes in the life of every living being [1, 2]. The daily, lunar, and seasonal cycles of natural light have been fundamental forms of environmental variation on the Earth's surface since the emergence of life [1], and the common use of natural light has been affected by the introduction of artificial light over the last few centuries as territorial expansion has occurred around the world, with the misuse of

© The Author(s) 2026
L. Bragança et al. (Eds.): ReSBE 2026, LNCE 905, pp. 692–699, 2026.
https://doi.org/10.1007/978-3-032-34930-9_81

public and domestic lighting. This has disrupted the human circadian cycle, fauna, and flora, and even the observation of celestial bodies, although there are new technologies that establish better use of ALAN [2, 3].

In recent decades, there has been rapid development of urban and industrial areas, largely at the expense of natural areas and open spaces [4]. The territorial expansion driven by rapid urbanization has intensified the excessive and inappropriate use of artificial light, a consequence that is reaching even regions far from large urban centers in Brazil. As a result, artificial light expands beyond city limits, reaching environmental preservation areas, posing risks to native vegetation and causing imbalances in environmental and climatic conditions throughout the biological process [5]. The inappropriate use of artificial lighting disrupts the nightlife of the entire local ecosystem and can impact a large number of species in environmental preservation areas, such as those in the municipality of Santa Teresa, Brazil, famous for its hummingbirds.

The exponential evolution of this region is directly linked to growing economic investment in the tourism sector, seen as one of the main sources of income in the region [6]. This factor has intensified the demand for urban landscape adaptation in terms of aesthetics and safety, directly influencing the expansion of the urban perimeter to supply local infrastructure. This has led to a significant increase in nighttime lighting, even in regions that are not yet urbanized.

Given this scenario, there is a growing need to raise awareness among the population and managers of these communities to harmonize the adoption of sustainable practices in the use of lighting as a result of expansion in risk areas, especially in regions of recent growth. As discussed by Freitas *et al.* [7] and Kyba *et al.* [8], studies on the spatial patterns of artificial nighttime lighting have been conducted predominantly in China, Europe, and North America, with little consideration given to tropical regions. The lack of more comprehensive terrestrial observations makes it difficult to construct global maps that establish sources of information and control the inappropriate expansion of ALAN, although smaller scales can and should be analyzed in greater detail [7].

As a way to encourage research on the topic in the region, this article aims to analyze the evolution of light pollution from 2012 to 2024 based on territorial expansion in the municipality of Santa Teresa, Brazil, through remote-sensing images of nighttime lights. Brazil, home to one of the world's greatest biodiversities, is a valuable field of study on the consequences of light pollution in conservation areas, and Santa Teresa, which encompasses a vast territory of the Atlantic Forest, is an important case study.

2 Methodology

The methodology is based on a territorial analysis of Santa Teresa, referring to the advance of light pollution through annual nighttime light maps produced from satellite images between 2012 and 2024. For the arrangement of the procedures adopted, this chapter was structured in three stages: I) presentation of the research area; II) data collection on territorial expansion; III) investigation of the light pollution database.

2.1 Presentation of the Research Area

Santa Teresa, a mountainous municipality in the state of Espírito Santo (Fig. 1), covers an area of 683.032 km^2 [9]. In the last population census in 2022, there were 22,808 inhabitants residing in the territory. The city is known for its mild climate, extensive Atlantic Forest preservation area, and cultural and gastronomic traditions, which drive the economy through tourism.

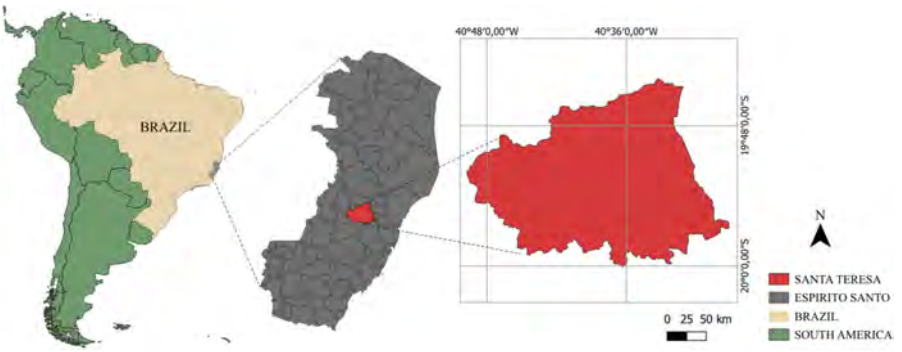

Fig. 1. Location map of the city of Santa Teresa, Espírito Santo.

2.2 Data Collection on Territorial Expansion

A review of historical census data compiled by Google Earth and IBGE - Instituto Brasileiro de Geografia e Estatística - showed that the territorial expansion of Santa Teresa is not directly linked to population growth. From 1980 to 2022, there was a decline in the region's population [9], and since it is a region driven by agrotourism, it is clear that the city's expansion is related to the growth of tourist activities. The municipality needed greater investment in landscape enhancement, leading to improved urban infrastructure in order to provide better mobility and experience for visitors [10]. Thus, occupation in preservation areas became a common practice to improve the region's source of income.

According to the comparative analysis of a historical series of aerial images generated from the research site, there was a change in land use from 2012 to 2024 (Fig. 2). It can be observed that there was an expansion of areas occupied by humans, mainly in areas close to native forest regions, which are environmental preservation sites.

Regarding temporal evolution through aerial image analysis, it was possible to delimit a region that was most influenced by territorial expansion, for subsequent analysis of the evolution of its light pollution. The selected region contains a considerable percentage of preserved areas, known as the Caravaggio Circuit.

2.3 Investigation of Light Pollution Sources

Due to increased spatial resolution, low light sensitivity, in-orbit calibration, and greater data dynamics, the VIIRS (Visible Infrared Imaging Radiometer Suite) product offers

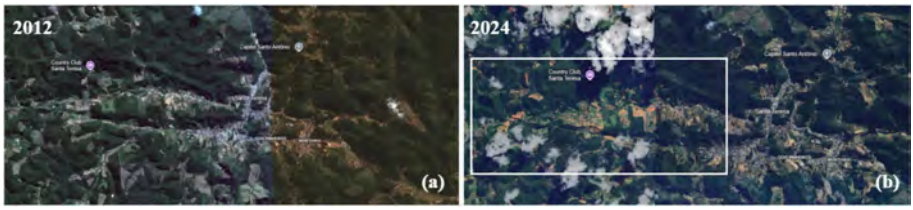

Fig. 2. Historical images of the city of Santa Teresa, Espírito Santo. Evolution from 2012 (a) to 2024 (b). Google Earth, 2025.

significant improvements for the study of socioeconomic phenomena [3]. Therefore, the analysis was carried out by collecting information from the Light Pollution Map portal (www.lightpollutionmap.info), using VIIRS overlay, on nighttime light data available for the period from 2012 to 2024. In this way, an area of the municipality was delimited for an analysis of the general data for the region, in addition to a more approximate cutout referring to the Caravaggio Circuit, in order to obtain a more accurate assessment of this area.

Georeferenced images were generated for each year analyzed. The format used was GeoTIFF with 32-bit floating point pixels, which is a geospatial data storage format related to radiance [11]. After the images were extracted, they were imported and processed using QGIS (Quantum Geographic Information System) version 3.44.4, a free program that allows the visualization, editing, and analysis of geospatial data.

Using the "raster pixels to polygons" tool, each pixel in the imported raster image was converted into an individual polygon within a vector layer. Since each layer represents a specific year, each resulting polygon represents a radiance value that is classified using graduated symbology. Finally, a color gradient was created and used in the map legend in order to preserve the highest sensitivity of corresponding radiance on the map, separated into ten levels of radiance, so that each interval is double that of the previous class (0–0.5–1.0–2.0–4.0–8.0–16.0–32.0–64.0–128.0 $nWcm^{-2}\ sr^{-1}$). This grading scale was created and proposed by this study to facilitate visual analysis of radiance levels in the investigated territory.

3 Results

The research was based on the analysis of maps and spreadsheets generated by QGis software for the period from 2012 to 2024, in addition to the IBGE [9]. Although the population data referred to 2010 and 2022, also a 12-year interval, it was understood that the estimate for population growth was minimal and did not interfere with the conclusion of the research.

The analysis of the region challenges the hypothesis of light pollution growth directly linked to population growth. Thus, in this first stage, an increase in population was identified between 2012 and 2024, but there was a 5% drop in *per capita* radiance (Fig. 3a). In 2024, the average radiance value per 1.000 inhabitants decreased to 44.77 $nWcm^{-2}\ sr^{-1}$, close to the mean of 45.2 $nWcm^{-2}\ sr^{-1}$ recorded in Brazil in 2024 [11]. The municipality recorded a mean radiance level of 0.29 $nWcm^{-2}\ sr^{-1}$ in the analyzes period, due

to its vast unoccupied area, while the national mean was 0.24 nWcm^{-2} sr^{-1}. Therefore, the research focused on territorial expansion as an aggravating factor of light pollution, as a result of the advance into environmental preservation areas.

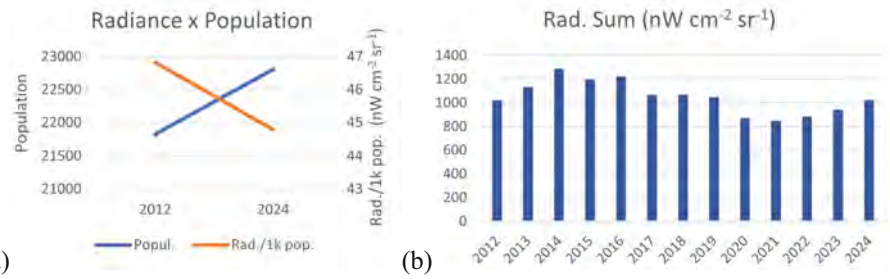

Fig. 3. Population growth and a decrease in *per capita* radiance over a 12-year period (a). Changes in the municipality's total radiance during the period analyzed (b).

In the second stage of the research, the growing territorial expansion of the municipality linked to the advancement of infrastructure that serves the tourism economy was taken into account. The diagnosis based on radiance data and QGIS image processing showed a relative reduction in radiance levels from 2017 to 2021 (Fig. 3b), mainly associated with the adoption of measures to renovate the street lighting system in the city center and its district with LED luminaires [12], which have greater control over their luminous flux. Although the municipality is taking care to produce more sustainable policies, there has been a growing increase in light pollution in recent years. The advance of radiance has become inevitable as the region has expanded.

In the third stage of the investigation, it was possible to verify that a specific region known as Circuito Caravaggio suffered the greatest impact from this recent expansion of the municipality, highlighted in Fig. 4. This is a location renowned for its scenic beauty, characterized by the valleys surrounding Santa Teresa, which in recent years has undergone major urban infrastructure expansion in terms of road systems, hotels and inns, restaurants, among others [13].

According to Kocifaj [14], light pollution produces visible light domes in the night sky near cities, illuminating large areas of the sky and reaching environments that would otherwise be dark, such as protected natural spaces. This phenomenon is noticeable in the region, directly impacting areas further away from the urban center of the municipality, such as the Caravaggio Circuit, a growing region, and reaching environmental preservation areas.

In addition, as it is considered a rural area, the radiance levels become a concern, since an increase in light pollution can be noticed in the region, even without the presence of street lighting. This is worrying because the growth in light pollution is due to the lighting that already exists in the establishments located there. It is common to see lights installed outside buildings to illuminate the area at night. In addition, there are requests for the installation of public lighting in the region due to the growth of road infrastructure, which may lead to more radiance emissions into space. In summary, this

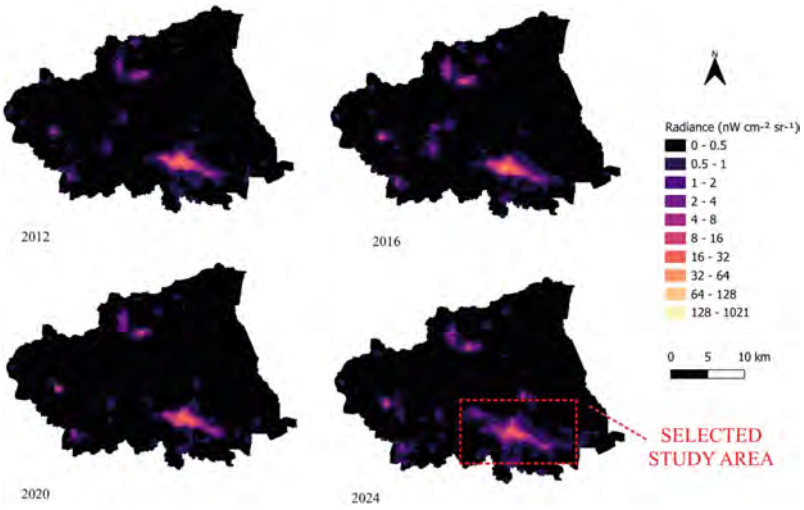

Fig. 4. Changes in radiance levels in the municipality between 2012 and 2024.

fact, combined with an increase in accommodation and leisure establishments in the region, may further aggravate the situation. Thus, when comparing the first year of the analysis (Fig. 5a) with the last (Fig. 5b), it is evident that the occurrence of pixels with radiance is spreading more in the region, reaching a larger portion of the territory and impacting environmental preservation areas adjacent to areas of human occupation.

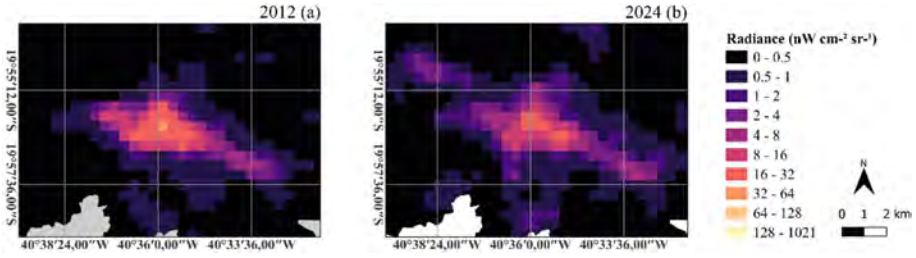

Fig. 5. Analysis of the urban center and the Caravaggio Circuit in 2012 (a) and 2024 (b).

The analysis showed that replacing light fixtures with more efficient models reduced the spread of ALAN in the city, proving to be an effective tool in controlling light pollution by reducing radiance levels. However, it is necessary to constantly inspect and maintain the light fixtures so that the problem does not spread and worsen, as happened in other districts. As the region is surrounded by biological reserves, light pollution can have a negative impact on entire ecosystems. Therefore, the analysis and monitoring of light pollution in this municipality is relevant as an example of environmental protection. Thus, with proper planning, the region has sufficient potential for the planning of responsible and efficient public lighting.

In comparison to this research, we can examine the study conducted on the city of Hong Kong [3]. Despite being a compact city, its high level of urban density classifies it as a region that requires constant investment in major infrastructure works. However, its radiance level remained partially stable during the analysis period, as it is a city that is already consolidated in terms of urban space and public lighting. In the case of Santa Teresa, it is still in the process of expansion and, although its radiance levels are moderate, unlike the Asian metropolis, the average radiance data has shown constant evolution over the last 4 years, and without proper planning, it may become a negative example in this regard. Therefore, it is recommended that preventive methods be implemented to mitigate light pollution in protected areas, integrated into the management plans for these areas, with a focus on local impact and national legislation or guidelines to control light pollution on a large scale [15, 16].

4 Conclusions

The analysis of the advance of light pollution in the municipality of Santa Teresa in line with its territorial expansion shows that greater knowledge about its causes and impacts is needed so that municipal management can plan urban expansion with greater care, reducing the possible impacts caused by artificial lighting. Not only urban planners, but also the population and local entrepreneurs need to be aware of this problem so that they can assist in policing municipal actions and help preserve the ecosystems present in the region, remembering that it is this ecosystem that sustains the economic base of tourism in the city. The mean and per capita radiance values recorded in the municipality are close to the values recorded in Brazil in 2024 [11], which may make this study an example with characteristics similar to those of the country.

Although the levels are not considered an alarming concern, there has been a gradual increase in light pollution in recent years, posing a potential risk that preserved areas will suffer negative influences from night lighting for the sake of tourism. Therefore, as long as urban expansion is properly planned and the population is made aware of the problem, environmental preservation can be guaranteed in the long term, even with the region's territorial expansion.

[2] City of Kragujevac—Chief Planner, Kragujevac, Serbia

Abstract. The Quality of Life Initiative (QoLI) is a novel programme launched by the UN Habitat in 2023. It is framed to support cities to assess and improve the quality of life at local level, for their inhabitants. Just about 20 cities worldwide have completed the QoLI process. One of these "pilots" is Kragujevac, the fourth city of Serbia. The essence of this process is to guide local policymakers, urban planners, and community leaders through practical steps to form, adjust and adopt the Quality of Life index, based on measuring global- and local-layer indicators. Global-layer indicators are created by the UN Habitat for all participating cities and organised in nine domains. In addition to them, each city had to create at least 12 local-layer indicators through local participation. Furthermore, both types of indicators had to be measured by using different data: statistical data, GIS calculations, mobile ping data and e-survey. The aim of this research is to show the whole QoLI process in the city through the different means of urban participation: information and communication tools, stakeholder meetings, co-creation mechanisms, and comprehensive e-survey with citizens. Such an approach enables forming the final Quality of Life index for the city, which is critical to compare Kragujevac with the other pilot cities in the QoLI, as well as to customise local policy documents and city budget to issues with the most noticeable gaps in the current and desired quality of life.

Keywords: Quality of life · Urban environment · Indicators · Urban development · Global-local

1 Introduction – Quality of Urban Life

In recent decades, urban areas have been increasingly affected by environmental degradation, traffic congestion, spatial overcrowding, and widening socio-economic inequalities, all of which directly influence everyday living conditions [1]. As urbanisation accelerates, the question of how people live, work, and thrive in cities becomes more urgent. These ongoing changes have revealed the need to assess the urban context using a systemic–holistic approach, taking into account both objective and subjective factors [2]. Consequently, within the framework of sustainable urban planning and development, quality of life has emerged as a central evaluative category for measuring socio-economic

advancement [3]. Its establishment is perceived as one of the main goals of planning policies worldwide [4, 5]. Therefore, global organisations have also attempted to address quality of life in their programmes, albeit without a global consensus on methodology and criteria for selecting the key domains of quality of life [6, 7]. The definition of quality of life varies depending on the disciplinary field in which it is examined. In fact, more than 100 definitions have been presented in the literature so far [8].

One of the promoters of the concept of the quality of life is the European Union (EU), whose assessments of quality of life in the EU and its Member States are based on statistical measurements conducted by Eurostat, the EU statistical office [9]. The EU main objective is to "promote the well-being of its citizens", which is why data on subjective life satisfaction in the EU are collected and analysed annually. The Organisation for Economic Co-operation and Development (OSCD) uses more than 80 indicators and demonstrates improvements in life satisfaction alongside persistent inequalities in its "How's Life?" programme [5].

Another example is the Quality of Life Index (QoLI), launched by the United Nations Human Settlements Programme (UN-Habitat) in 2023. This is an analytical framework designed to help cities understand and improve everyday urban living conditions. The QoLI assists cities in measuring and improving both the objective conditions and the subjective experiences that define urban well-being. The index examines how well a city serves its residents and provides a measure of progress from a people-centred perspective. Embedded within the UN-Habitat Strategic Plan (2020–2025), which prioritises improved quality of life in an urbanising world [10], QoLI operationalises a people-centred approach to urban evaluation at the city level. Structured around nine thematic domains, QoLI integrates global- and local-level indicators to assess quality-of-life outcomes, identify priority areas, and translate empirical evidence into planning strategies and policy interventions [11]. Each domain is evaluated through a dual-indicator structure, combining global indicators that enable cross-city comparisons with local indicators that capture city-specific needs and priorities. Although both systems are designed for implementation at the urban level, *in situ* application remains a challenge.

The aim of this research is to illustrate this process by presenting the implementation of the QoLI in Kragujevac, Serbia. The city was one of approximately 20 global "city pilots" within the UN-Habitat programme conducted in 2025. The process is presented through all stages of the QoLI implementation, including various forms of urban participation: information and communication tools, stakeholder meetings, co-creation mechanisms, and a comprehensive online survey conducted with citizens. Such an approach enables the formulation of a final Quality of Life Index for the city. This index is important not only for enabling comparison between Kragujevac and other pilot cities, but also for generating qualitative inputs to inform and adjust local policy documents and the city budget in response to the most significant findings identified through the QoLI process at the local level.

2 Methodology

This research integrates the elements of theoretical preview and a case study. The theoretical fundamentals about the quality of urban life are already explained in the introductory section. The second part is about the application of the QoLI process in Kragujevac,

which is basically a single-case study. A focus on single case has some noticeable differences to studying several cases. In the former one, there is no option to compare different cases in order to obtain respectable results. Hence, single-case study requires well-structured elements extracted from theory to be evaluated by analysing the case [12]. The QoLI exactly supports this approach with its structured rules for concrete *in situ* application. The final inputs from the QoLI process are gathered from this global-local analysis. These inputs are twofold; (1) some of them were unexpected and they are therefore important at local level, to (re)direct the future urban development and policy, while (2) the other ones are critical to compare Kragujevac at an 'international stage', with other city-pilots. Both elements are highlighted at the end of the research.

3 Local Context – Kragujevac, Serbia

Kragujevac is the fourth largest city in Serbia. By the last national population census from 2022, the administrative territory of the city has 171,000 inhabitants, of which about 85% live in its urban part [13]. The city is in the middle of Serbia, in centrally located Šumadija Region (Fig. 1).

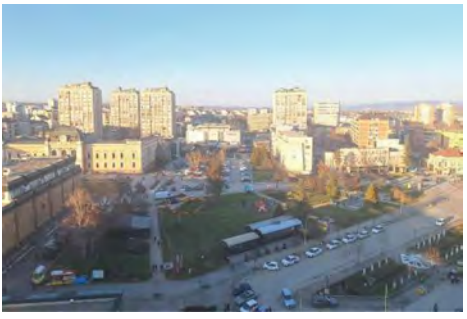

Fig. 1. (left) The skyline of central Kragujevac (Author: B. Antonić, 2025).

Fig. 2. (right) Cannon factory in Kragujevac from 1873, the oldest preserved industrial building on the Balkans, currently under state protection as an industrial heritage (Author: B. Antonić, 2025).

Kragujevac is seen as a "cradle" of modern Serbia at national level. However, the area of Kragujevac has been inhabited since prehistory, despite the city 'golden age' is related to modern times. The settlement was relatively small and unknown until the early 19th century, when the area around Kragujevac was the focal place of two Serbian uprisings against foreign Ottoman rule. This occasion was critical to position Kragujevac as the first capital of modern Serbia. The city was the capital of the Principality of Serbia in the period 1818–1841. During this period many "national firsts" happened in Kragujevac – the first professional theatre, the first museum, the first grammar school, etc. [14].

After the transfer of national capital to Belgrade, Kragujevac became the first industrial centre of Serbia, as well as on the Balkans. The canon factory was established in

1853, while the oldest preserved industrial building was from 1873 (Fig. 2). The industrial complex was significantly expanded in the early 20th century. However, the zenith of the city industry was during the second-socialist Yugoslavia (1945–1992). During this period, "Crvena Zastava" was formed as the main automobile-producing socialist factory of the country. The rapid industrialisation led to the demographic boom of Kragujevac [15]. This fast urban development was stopped with the post-socialist transition in the 1990s, when industrial sector collapsed. The last 15 years have been marked by the reindustrialisation of Kragujevac; nevertheless, this is still far away from the previous glory.

4 Quality of Life Initiative in Kragujevac

The QoLI procedure in Kragujevac was based on the main guidelines by the programme. The essence of the QoLI refers to the adequate application of the UN Sustainability Development Goals (SDGs) in local urban policy so as it facilitates (the rise) of the quality of local life. This can be obtained only by using innovative, globally important vs. locally implementable evaluation system. The main application guidelines of the QoLI are [11]:

- The ultimate goal is to calculate the cumulative QoLI value – a numerical index of the local quality of life.
- Such a goal can be achieved by applying five QoLI principles, by which the process had to be (1) human centric, (2) co-creative, (3) globally relevant while locally applicable, (4) inclusive and (5) evidence-based.
- The QoLI process relies on measuring indicators. There are two types of these indicators global- and local-layer ones. 29 global indicators are applied in all implementing cities. Local indicators – min. 12 of them – had to be developed locally, through urban participation.
- All global-layer indicators are organised in nine domains: (1) basic services & mobility, (2) culture & recreation, (3) economy, (4) education, (5) environment, (6) governance, (7) health & well-being, (8) housing, and (9) social cohesion. The formation of local-layer indicators can follow the same structure.
- Each indicator uses one of four types of data: statistical data, geodata, mobile ping, and data from social-media survey.
- Most of measured values for indicators must be "normalised", to be comparable to the values of other indicators, as well as to values for the same global indicators for other QoLI cities.
- The final QoLI index is an average of measured values for all indicators. As such, it can be easily compared with other cities included in the QoLI.

5 Urban Participation in Quality of Life Initiative

Citizen participation has become an imperative in any process related to urban development today, but it is still an operational challenge [16]. Its main aim is to enable local community to jointly participate, create, and shape desired socio-economic urban policy [17]. However, dynamics and modes of urban participation can vary greatly and

should be adapted to local needs and objectives. New observations show that combining offline and online participatory techniques are more and more common [18]. Generally, it is recommendable to: (1) alter between phases which are more directive and more free-minded; (2) adapt the process to local conditions; and (c) to set up local process which can be comparable to the other ones [19]. These recommendations were basically applied in the QoLI process in Kragujevac. The QoLI prescribed several types of urban participation to be implemented step by step, plus some were added to ensure more community-based decision making.

The first step was an inception meeting for stakeholders, which was held online on April 8, 2025 (Fig. 3). 15 local and regional stakeholders were presented. The main purpose of this first participatory event in the QoLI implementation is to provide stakeholders with a clear overview about the QoLI framework and activities and how they can successfully participate in it. Thus, the inception meeting had a clear format based on the PPTX presentation in mother tongue (in Serbian), which was followed by the stakeholders' comments about if they understood the QoLI basics.

Fig. 3. (left) An inception meeting held online on April 8, 2025 (Author: B. Antonić, 2025).

Fig. 4. (right) The first stakeholder workshop held in person in Kragujevac on April 23–24, 2025 (Author: J. Stefanović, 2025).

The second step – the first stakeholder workshop on April 23–24, 2025 – was diametrically different that the first one, as it was organised in person and in a more open atmosphere (Fig. 4). The workshop had a format of a focus group and about 30 stakeholders took part in it. Its topic was the process of a jointly decision about the urban indicators the evaluation of which would adequately represent local quality of life. Although this workshop was divided into four sessions, they only had general topic and related explanations, while all other elements were free for discussion. This participatory environment proved to be good, so discussions were long and fruitful.

The third step in local urban participation was introduced by local team implementing the QoLI in Kragujevac. The first stakeholder workshop resulted in more prospective indicators than expected. Therefore, this step was added, to complete the selection of local indicators, with a special intention to determine those ones that would be measurable and applicable. The form of an e-survey with an e-questionnaire (Google Forms) was considered efficient in this case. The majority of the stakeholders present at the first workshop responded and fulfilled the e-survey. The e-survey was obviously more

directive than the workshop, but stakeholders already had good insight in the QoLI and understood the purpose of this additional step.

The fourth step was probably the most directive one. It was another survey, but this one was conducted among citizens as it was prescribed in the QoLI guidelines. The survey covered the subjective indicators about the local quality of life, i.e., it was arranged to measure them. Moreover, it had a relatively rigid format of closed questions, although the last possible option in all questions was to skip answer. The reason for this approach was due to its aim to have a good sample of respondents, i.e. to be mass applied. In total, 1,336 Kragujevac inhabitants (>1% of adult city population) completed this survey during August 2025. To achieve this sample, the survey was conducted both offline, on city streets (Figs. 5 and 6) and online, through SurveyMonkey application promoted by the city press and social media. Obtained local responses were critical to measure subjective- and quality-based indicators in the QoLI process.

Fig. 5. (left) A survey with citizens on streets in Kragujevac, held in August 2025 (Author: I. Radulović, 2025).

Fig. 6. (centre) A survey with citizens on streets in Kragujevac, held in August 2025 (Author: I. Radulović, 2025).

Fig. 7. (right) The second stakeholder workshop held in person in Kragujevac on November 5, 2025 (Author: J. Stefanović, 2025).

The fifth and last step in urban participation during the QoLI process was on November 5, 2025, on its end. It was organised after measuring all the indicators of the quality of life in Kragujevac. This was the second stakeholder meeting, again held in person in Kragujevac (Fig. 7). Its main objective was to check the whole process and, especially, measured values for all analysed indicators by stakeholders. Aside of this, the its purpose was also to make stakeholders aware of the results and importance of the entire QoLI process and eventually apply them in the future policy development in Kragujevac. Approximately 25 stakeholders were presented at this workshop.

Apart of these more concrete participatory activities, the City of Kragujevac also implemented more 'passive' modes of urban participation in the form of information for citizens through general media, by posting press releases and news about the conducted activities and the QoLI through the official media channels and other communication tools. All in-person QoLI activities were also covered by general media teams, too.

6 Conclusions – From Extreme Outcomes to Shaping the Future Urban Development

Measuring the local quality of life as a paramount input for good urban planning and development. It thus requires a well-organised and comprehensive approach. In line with this, citizen participation in this process also had to be systematically organised, using the different means of participation to accommodate contact to and reactions from the wider scope of local population. The Quality of Life Initiate as global programme exactly utilised this approach, which was implemented.

The QoLI implementation in Kragujevac in 2025 illustrates these diverse approaches. First, it applied the offline/in-person and online modes of participation, further employing outdoor in-person participation on city streets. An advantage in this case is also that these two modes were also altered to enable a more dynamic process.

Second, the QoLI application in Kragujevac also adopted the alteration between more directive and more free-minded steps in participation. This approach allows the fine tuning of the ultimate goals of the QoLI process; (1) to form the list of local indicators as a more free-minded process with stakeholders, who are professionally more involved in this topic, with (2) measuring these indicators by working with wider pool of participants (local population) as more a directive step.

To enable this alteration, the whole process was first adapted to local conditions, in the first half of its duration (March–June 2025). This was also a part of online training done by the central QoLI office through webinars, as well as given in all QoLI guidebooks. The Kragujevac team furthermore customised the participatory process to local conditions by adding a new step (Google Form Survey) when it realised that this addition was necessary.

The last conclusion about the possibility to compare urban participation in the Kragujevac case with the other ones is also interesting, as it is in the essence of the QoLI Programme. The QoLI was globally established to facilitate the comparison and joint work of included cities across the globe by measuring the quality of local life. 29 QoLI indicators are set up by the programme as global-layer ones, i.e., to be analysed and measured in each city so to be comparable worldwide. After completing the QoLI in Kragujevac, obtained values for all indicators, as well as the cumulative index of the quality of local life, were posted at the QoLI main website with the same ones for other cities which passed through this process. In this way, the comparison of included cities is even accessible to everybody all over the World as each city can easily understand its position in wider network.

Abstract. This paper explores pathways toward a regenerative built environment through the case study of the Innovative Bioclimatic School of European Education in Crete. It presents a whole-lifecycle approach that links research and practice by integrating nature-based design, circular material development, and validated passive systems, forming a "didactic instrument" for environmental education.

An integrative design process reinterpreted the vernacular Mediterranean courtyard typology. Sustainable operation was optimized through simulation (CFD, IES-VE, ENVI-met, Climate Studio) to validate passive strategies including Trombe walls, winter gardens, controlled thermal mass, natural vertical and cross-ventilation, daylight optimization, and microclimate modulation through vegetation and water features. Concurrently, a circular construction methodology involved research (Aristotle University) to develop stabilized Compressed Earthen Blocks (CEB) using excavated site soil and hemp fibers, supplemented by other natural materials such as Cretan limestone and timber.

Final design-stage simulations indicate strong performance, including a 51.1% LEED energy-cost reduction compared with the ASHRAE 90.1–2010 Appendix G baseline, including renewables, and compliance with ASHRAE 55 thermal comfort criteria. The nature-based design delivered 79.7% spatial Daylight Autonomy and 94.9% Quality Views. The circular material research was supported by laboratory testing: the CEBs achieved 6.77 MPa compressive strength and contributed to passive indoor humidity regulation (50–55% RH). A closed-loop water system with constructed wetlands supports regenerative operations.

This best-practice case study provides a replicable model for Sustainable Buildings. It demonstrates how synergies across scales—from nature-based design and passive environmental performance to circular material science—embed actionable sustainability and enable a regenerative trajectory for future public buildings.

1 Introduction

The "Innovative Bioclimatic School of European Education in Crete" (Fig. 1) was awarded 1st prize in an International Architectural Competition (2012) under UIA and SBO auspices. Located on a 15,748 m^2 plot within the Heraklion University Campus, the 7,600 m^2 complex accommodates 780 students for Kindergarten, Primary and Secondary Education.

Fig. 1. Southeast and southwest perspective view of the school complex.

The design leverages local climatic data, integrating traditional Mediterranean courtyard typologies (Fig. 2) with advanced passive strategies to promote student well-being and environmental sustainability. Connection with nature acts as a catalyst for learning and experiential sustainability education. The project completed the final detailed design at the end of 2025; therefore, the reported results are design-stage predictions. In 2026, the project tendering process is being carried out.

Fig. 2. Courtyards of Kindergarten, Elementary School (top), and Secondary School (below).

2 Integrated Methodology and Design Interaction

The regenerative design is a synthesis of components and parameters, all connected like communicating vessels in equilibrium. Environmental design reinforces education and awareness, natural materials promote a healthy environment and passive performance strategies teach an awareness on nature's wisdom.

Contextual Analysis: Site-specific climate data, orientation, topology, educational use, soil composition (clay), local materials (limestone), ancient courtyard archetypes, informed the initial design parameters.

Material Performance: Laboratory testing at Aristotle University on stabilized Compressed Earthen Blocks (CEB) made with site-excavated clayey soil and hemp fibres achieved a compressive strength of 6.77 MPa. These results informed the material assumptions used in the simulations. The 30 cm "hyper-thick" walls ensure high indoor air quality and humidity regulation. These locally manufactured, low-embodied energy blocks remain exposed or clay-plastered, creating a "breathing" building envelope for the Kindergarten (Fig. 3).

Fig. 3. Earthen Block Wall in the Kindergarten's Multi-purpose Hall and Earthen Blocks from laboratory tests with hemp fibers.

Integrated Simulation: IES-VE was used for energy and thermal comfort analysis; ClimateStudio/Radiance and Ladybug Tools for daylight, solar and comfort post-processing; ENVI-met for outdoor microclimate; OpenFOAM for wind movement; and Archiwizard, COMFEN, THERM and DesignBuilder for façade, thermal and environmental design support (Fig. 4).

Validation: Simulation outputs led to the refinement of the passive systems (winter gardens, Trombe walls, vegetation placement) being implemented in the construction phase.

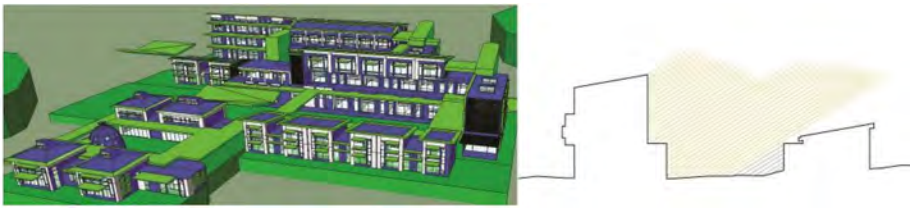

Fig. 4. Southeast perspective view of the school complex: IES-VE energy study model and courtyard lighting diagram, showing the placement of low-rise buildings to the south.

3 Passive Performance Strategies

3.1 Solar and Thermal Management

The Mediterranean courtyard typology is central to the design, utilizing narrow building depths to ensure 100% south-facing orientations for maximum winter solar gain (Fig. 5).

Fig. 5. Section of the school complex showing summer-winter solar radiation and natural cooling via the stack effect.

Thermal Mass: High-capacity materials, including exposed CEBs and fired bricks, minimize indoor fluctuations.

Passive Heating and Cooling: Beyond direct gain, winter gardens and insulated Trombe walls/air collectors on southern facades ensure immediate heating (Figs. 6 and 7). Trombe walls play a role in cooling in the summer months as well.

Fig. 6. Winter gardens and operation diagram (right) showing winter and summer.

Fig. 7. Trombe walls in the Science Laboratories: exterior view in summer with open skylights; interior view with closed insulated shutters; and operation diagram for winter and summer.

3.2 Cooling and Natural Ventilation

Natural cooling is achieved through vertical and cross-ventilation via 'stack effect' with roof skylights acting as cooling chimneys and north-facing low-level windows, night cooling of thermal mass, and strategic shading (Fig. 8). Advanced simulation software (Ladybug Tools, Radiance, ClimateStudio, Archiwizard, OpenFoam, IES-VE, and DesignBuilder) was used to analyze solar/shading, air movement, and thermal behavior (Fig. 9A).

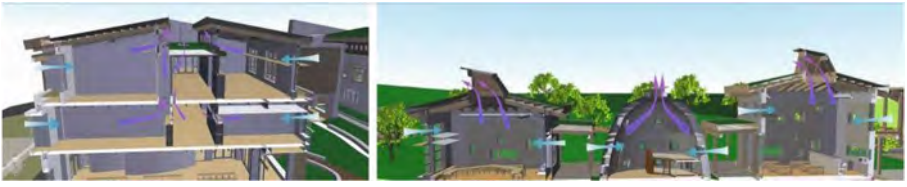

Fig. 8. Natural ventilation for classrooms in the Secondary School and Kindergarten.

3.3 Thermal Comfort and Energy

Dynamic simulations using **IES-VE 2023** validated the school's performance against ASHRAE 55–2010 (Fig. 10B).

Energy Reduction: The design achieved a 51.1% reduction in energy consumption compared to a baseline model (Fig. 10B, C).

Thermal Compliance: Simulations indicated compliance with ASHRAE 55 criteria. Passive and mixed-mode strategies reduce cooling reliance in teaching spaces, while active cooling remains included for offices and multipurpose spaces (Fig. 10).

3.4 Circular Materials

Internal walls utilize high thermal mass to stabilize indoor temperatures. Specifically, the Kindergarten features non-bearing walls made of CEBs developed from excavated site soil.

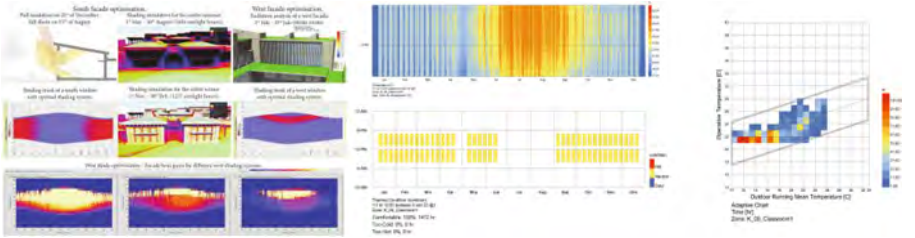

Fig. 9. A. Optimization simulations for southern, eastern, and western facades and openings, using Ladybug Tools, Archiwizard, and COMFEN. B. Adaptive thermal comfort results for a primary classroom throughout the year, using IES-VE and Ladybug Tools software.

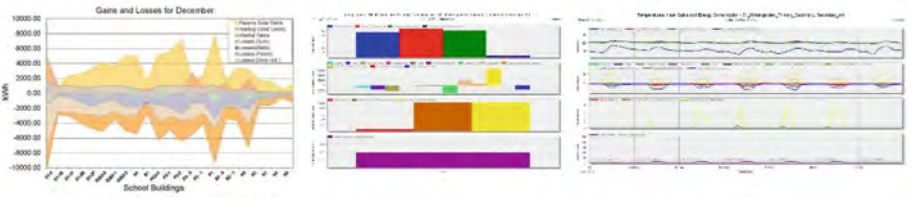

Fig. 10. A. Dynamic thermal simulation. Gains and losses for December. B. Results with consumption of 1 kWh/m^2. C. Results showing that during sunny days, heating is not necessary.

Hygroscopic Regulation: CEBs maintain indoor relative humidity between 50–55%, mitigating the extreme fluctuations (20–70%) found in conventional buildings.

Embodied Energy: By using local clay, hemp fibers, and Cretan limestone, the project minimizes transportation emissions and ensures 100% recyclability at end-of-life.

4 Environmental Quality and Biophilic Design

4.1 Lighting and Visual Comfort

ClimateStudio/Radiance simulations predicted 79.70% sDA and 4.20% ASE, meeting the LEED v4.1 daylight criteria; movable shading is included where local ASE risk remains (Figs. 11 and 12). Quality-view analysis indicated 94.9% compliance with LEED v4.1 criteria (Fig. 12C). Strategic layout and opening design integrate biophilia (Qiannan Guo, 2024) to enhance user well-being (Fig. 11C).

4.2 Microclimate Modulation

ENVI-met simulations predicted improved outdoor comfort compared with a typical Greek school with conventional construction materials and a low-vegetation baseline, across winter, summer, and intermediate seasonal scenarios (Fig. 13). This is achieved through Vegetation: Green roofs and endemic planting, and Water Elements: Shallow ponds and streams for evaporative cooling (Fig. 14).

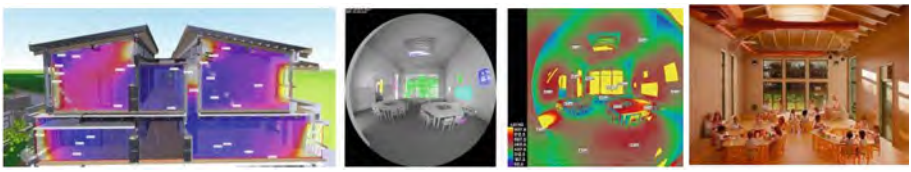

Fig. 11. A. Natural lighting simulation results for Secondary School spaces, B. Glare study for a Kindergarten space, September 21st, using Archiwizard and Ladybug Tools/Radiance software and C. The Kindergarten classroom.

Fig. 14. Ponds, streams and planting in the surrounding area.

Wind Protection: ENVI-met indicated winter reduced local wind exposure, while OpenFOAM was used separately to assess wind movement around the building massing, optimizing the seasonal use of outdoor "didactic instruments" (Fig. 15).

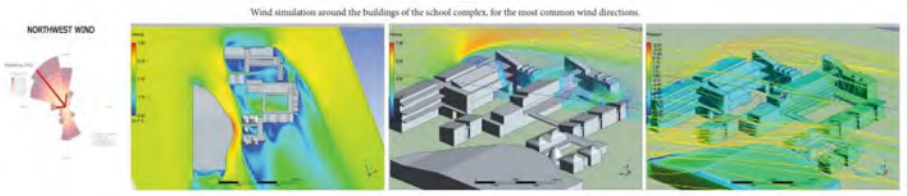

Fig. 15. Wind movement simulation images (OpenFoam) of the main air directions.

5 Discussion: Transferability and Lessons Learned

Climate Dependency: While optimized for Crete's high solar radiation and summer breezes, these principles may be adapted to other public buildings where climate, materials and regulations allow. Replication in Northern Europe would require adjusting glazing ratios and insulation thicknesses while maintaining the core principles of circular material use. The integration of a BEMS to automate active and passive synergies (e.g., night cooling skylights) remains a critical lesson for achieving 50% energy savings compared to conventional baselines. **Material Availability:** The circularity of the CEBs depends on soil composition; silty or sandy soils would require different stabilization agents than the Cretan clay used here. **Regulatory Barriers:** A major challenge was the certification of non-standard materials like earth blocks within public procurement frameworks, a lesson for future public projects.

6 Conclusion

The Innovative Bioclimatic School in Crete demonstrates that regenerative performance is achievable through the synergy of vernacular wisdom and advanced simulation. It exemplifies a regenerative trajectory where architecture serves as a "didactic instrument" for sustainability. By synchronizing circular material science (CEBs) with bioclimatic interventions (Trombe walls, winter gardens, courtyards), the project achieves exceptional energy efficiency and psychological comfort, offering a standardized methodology for future healthy educational environments.

This case study offers a reference for future educational buildings, showing how nature-based and circular strategies can support substantial energy-cost savings and improved comfort.

natalia.saavedratoro@sydney.edu.au

Abstract. Climate change is intensifying extreme weather events and elevating temperature and humidity, increasing moisture risks in buildings, including condensation, mould growth, and material degradation that threaten durability and occupant health. Despite mould affecting an estimated 10–50% of dwellings globally, moisture management remains insufficiently addressed in housing design and construction. This study reframes building envelope design for moisture resilience through a critical review of best practices and hygrothermal performance assessment methods. Considering environmental and design factors, it progresses from evaluating conventional moisture-control practices to emerging technologies, including vented cavities, airtight construction, and detailing strategies, assessing their influence on moisture ingress and long-term performance. Findings show traditional design and construction practices that follow conventional assessment methods and regulatory standards are insufficient to ensure moisture resilient envelopes. An integrative approach combining improved detailing, adaptive materials, and proactive monitoring would support extending building life cycles. Responsive façade systems are highlighted as promising for long-term performance under changing conditions. Advanced solutions including smart coatings, moisture-adaptive sealants, self-healing materials, moisture-responsive ventilation systems, and IoT-enabled sensors offer strong potential to improve buildings durability and to withstand climatic stressors such as floodings. In response, this study proposes an integrative, climate-responsive five-layer framework linking (1) climate and exposure characterisation, (2) assessment method selection, (3) envelope strategy and materials, (4) junction detailing and constructability, and (5) monitoring, operation, and intervention. By reducing moisture-related failures and premature refurbishment or replacement, the framework supports longer service life and contributes to circular, lower-impact building outcomes through life extension and improved resource efficiency

1 Introduction

Climate extremes are intensifying the hydrological cycle, raising absolute humidity, wind-driven rain, and heavy precipitation [1]. These changes increase walls' exterior wetting and moisture ingress while constraining envelope drying, thereby elevating the probability of interstitial condensation, persistent dampness, and mould growth, with increased risks to material durability and occupant health [2].

The scale of moisture issues is already substantial. The World Health Organization reports that indoor dampness is estimated to affect 10–50% of indoor environments across Europe, North America, Australia, India, and Japan [3]. Dampness and mould are consistently associated with adverse health outcomes, including exacerbation of asthma, allergies, and respiratory infections [4]. Beyond health, excess moisture accelerates materials degradation, compromises structural integrity, reduces thermal resistance, increases energy use and elevates chemical emissions from building materials and furnishings [5], thereby, further degrading indoor environmental quality. Despite this evidence, moisture management remains insufficiently integrated in design workflows and regulatory frameworks, which still favor prescriptive provisions over proactive, integrated strategies. In Australia, both surface and interstitial condensation have affected buildings for decades. Studies link these issues in part to the strengthened energy-efficiency provisions in the National Construction Code, while acknowledging that other factors also contribute [6]. As insulation levels increase and envelopes tighten, indoor moisture loads and mould risk also rise unless airtightness is explicitly paired with adequate ventilation and moisture control measures [7]. Given these challenges, there is a pressing need to reframe building-envelope design to withstand moisture risks. This study reviews conventional and emerging approaches to moisture control in building envelopes and opens a discussion to guide durable, health-oriented design.

2 Research Methodology

This study undertook a structured literature review on conventional moisture-control strategies, hygrothermal assessment methods, and emerging moisture-resilient technologies. Searches were conducted in Scopus using targeted keywords (for example, moisture control, building envelopes, rainscreen/vented cavity, condensation, mould growth, hygrothermal/HAM, WUFI/DELPHIN, and terms associated with relevant standards and protocols). Records were screened in stages (duplicate removal, title and abstract screening, then full-text review), retaining only peer-reviewed journal articles directly relevant to envelope moisture performance and assessment. No exclusions were applied solely on geography or climate; instead, climate context was noted where reported to support interpretation. The search yielded approximately 80 relevant studies, from which a subset of approximately 25 is presented and discussed in this paper across the three thematic areas. The review is complemented by the authors' earlier studies [8–10], which provides empirical evidence and supports the discussion on moisture-resilient envelope design.

3 Findings

3.1 Conventional Moisture-Control Strategies

Conventional moisture strategies in building envelopes rely on several construction components. Some of these include the application of weather-resistive barriers and vapour-control layers, designed to deflect liquid water and to limit water-vapour diffusion through assemblies [7], however effectiveness depends on continuous detailing, correct installation, and construction quality control at flashings, membranes, and sealant systems [7, 11]. Placement of vapour barriers or retarders is climate- and drying-path dependent (typically interior in cold climates and exterior in warm-humid climates) and must be coordinated with drainage and ventilation, ensuring at least one reliable drying pathway to avoid trapping moisture within the assembly [12]. Prior empirical testing by the authors showed that unventilated cavity air gaps in cold-temperate climates (including climate zones 22 and 62 in Victoria, Australia) exhibited mould growth risk when assessed using ASHRAE 160 and DA07 protocols. Introducing cavity ventilation substantially mitigated this risk, reducing predicted mould growth by more than 99% relative to non-vented conditions [8, 9], as shown in Fig. 1. Drained and ventilated rainscreen assemblies, incorporating a continuous ventilated cavity between cladding and the weather-resistive barrier, reduce interstitial condensation by limiting wind-driven rain, creating a capillary break, and enabling drainage and convective drying [13] with performance contingent on ventilation rate, cavity dimensions, climate, and robust detailing [14]. However, this performance can be challenged under elevated moisture exposures, such as flooding or intense rain events. In the authors' empirical work [9], an additional external moisture load was applied to a tiled roof assembly to represent intense rainfall (in addition to the standard 1% rain load per DA07), and the results showed that increased rain loads elevated moisture risk in the tiled roof type, which had previously presented low mould-growth risk under standard conditions.

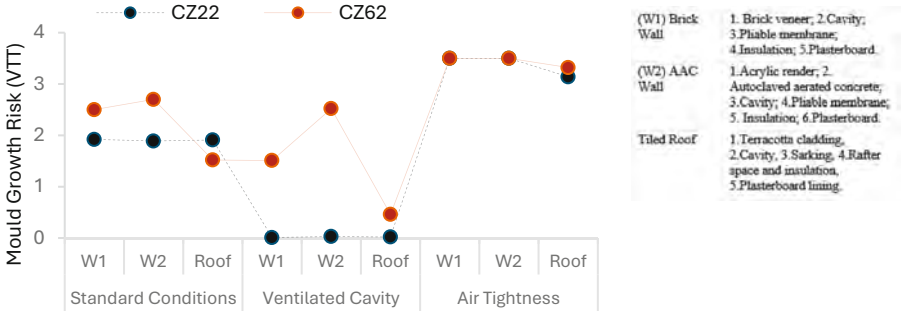

Fig. 1. Mould growth index (VTT) reproduced from the authors' previous work [8, 9] for three assemblies across two climate zones (CZ22 and CZ62), representative of Victoria, Australia under three Scenarios: (i) Standard conditions, based on ASHRAE 160 and AIRAH DA07 criteria with unventilated cavity; (ii) Ventilated cavity, constant cavity ventilation at 25 ACH (ACH = Air changes per hour); (iii) Airtight envelope, building ACH = 0.25. VTT results are reported at the insulation–membrane interface (towards the exterior) for each assembly.

Risk factors that can compromise conventional moisture-control strategies include insulation selection and airtightness. The authors' empirical testing and simulations [10] indicate that, in temperate climates, timber-framed walls with synthetic PIR[1] exhibit medium mould-growth risk, whereas mineral and natural insulation show near-zero risk, highlighting the influence of insulation type. Higher insulation levels also require careful coordination with vapour control, since shifted dew-point locations and reduced incidental drying can increase mould risk [15]. In terms of airtightness, if not balanced with adequate ventilation, it can elevate indoor humidity. Consistent with this, Fig. 1 shows that increasing airtightness to 0.25 ACH led to a further rise in mould-growth risk across all assemblies, reaching a mould index of 3.5 under the ASHRAE 160 protocol.[2]

3.2 Hygrothermal Assessment Methods

The hygrothermal assessment methods discussed here focus on those most commonly applied in practice, ranging from steady-state approaches to computational tools, selected according to their capacity to represent increasingly complex moisture-transport phenomena. Simplified, steady-state approaches, such as the Glaser method referenced in ISO 13788, evaluate steady-state heat conduction and vapour diffusion, however, do not account for transient effects [7]. In contrast, numerical simulation tools and transient HAM models (e.g., WUFI Pro, DELPHIN, and related platforms) simulate coupled heat, air, and moisture transfer under time-dependent boundary conditions; WUFI Pro is widely recognised and has been validated against the EN 15026 framework [16]. To resolve localised risks, two-dimensional simulations (e.g., WUFI 2D) can identify weak points where heat and moisture fields are non-uniform, particularly at construction details such as junctions and interfaces, providing insight that are not available in one-dimensional analyses [17]. To address gaps in simulation boundary conditions, particularly incomplete indoor-climate data and material properties (for example, water-vapour diffusion parameters), empirical field monitoring and testing of temperature, relative humidity, and moisture content within assemblies provide real-world datasets for calibrating and validating simulations, thereby improving the reliability of model parameters and assumptions [10]. In parallel, accounting for variability in transient assessments is essential: moving beyond conventionally adopted assessment methods to incorporate predictive climate scenarios and project-specific indoor conditions captures the wider range of real-world exposures that assemblies are likely to encounter, and improves the robustness of moisture-risk appraisal [9].

3.3 Emerging Moisture Resilient Technologies

As buildings face increasingly frequent and severe climatic conditions, supplementary strategies are needed to safeguard long-term durability, reinforcing the case for advanced technologies that augment, rather than replace, conventional moisture-control

[1] PIR = Polyisocyanurate insulation panels

[2] Hygrothermal Performance Criteria: VTT Mould Growth Index (MI). Low Risk M1 < 1; Medium Risk $1 <$ MI < 3; High Risk M1 > 3.

approaches. In this context, emerging technologies can be integrated alongside conventional moisture control methods to enhance water shedding, maintain seal integrity, accelerate drying, and provide early-warning diagnostics as follows:

Smart coatings and surface treatments, can include nano-modified hydrophobic treatments for exterior concrete that enhance moisture resistance and durability [18], and inorganic mineral coatings (carbon-absorbing) for concrete and masonry that offer high bonding strength with reduced capillary uptake [19].

Moisture-adaptive sealants and barriers can range from water-resistive barriers with humidity-responsive permeance that respond to wetting and drying in wall systems [20], to hydrogels for adaptive façade skins that provide high moisture buffering, with strong absorption and release cycles [21], and hygromorphic materials that are responsive to humidity for smart moisture regulation [22].

Self-healing materials address durability at the source of damage. Lime and lime-based plasters for wall and ceiling applications, provides moisture buffering and natural self-healing of microcracks [23]. Self-healing cementitious systems (microcapsules, bacteria, mineral agents) for renders, mortars, and structural wall layers can seal cracks, recover impermeability, and reduce water ingress through humidity-activated healing [24, 25]; superhydrophobic self-healing wood coatings for timber façades reduce water uptake and maintain hydrophobicity after damage, supporting dimensional stability [26].

Moisture-responsive ventilation provides control at the system level. Humidity-sensitive air inlets and demand-controlled ventilation can reduce energy use, manage moisture loads, and prevent condensation and mould risk [27]; CFD-informed hybrid systems assist in complex contexts such as heritage or underground spaces, providing targeted RH control and optimised equipment placement [28]; moisture-recovery ventilation and heat or moisture exchangers help balance ventilation while recovering energy and improving indoor humidity control [29]. Finally, IoT-enabled sensors support proactive prevention: moisture and humidity sensors enable real-time monitoring and predictive maintenance [24, 30], while leak-detection systems in residential settings facilitate rapid intervention to avoid repair costs and reduce water-related damage [31].

An integrative approach that combines robust detailing, adaptive materials, and proactive monitoring strengthens envelope moisture resilience, prevents damage, extends service life, and supports healthier indoor air quality. Within this approach, responsive façades add adaptability by modulating ventilation or surface behaviour as conditions change, improving performance under climatic uncertainty.

4 Discussion and Conclusion: Towards Moisture-Resilient Envelope Design

Findings from the literature review and the authors' previous empirical work converge on one core point: moisture resilience requires an integrative approach to building-envelope design that is responsive and adaptable to extreme climatic events. The principal contribution of this paper is to open a structured discussion through a practical framework, reframing moisture management from isolated technical measures into a coherent, project-wide decision process that supports durability and health-oriented design across the building life cycle. To support this discussion, Fig. 2, proposes a five-step assessment framework:

(1) climate and exposure characterisation, which establishes the risk profile the envelope must withstand by analysing site conditions such as wind-driven rain and flood risk; (2) assessment method selection, which defines the hygrothermal analysis method in line with the moisture-risk profile, and sets boundary conditions and test scenarios; (3) envelope strategy and materials, which iterates system configurations, such as cavity depths, weather-barrier selection, insulation, surface protection, and adaptive materials; (4) junction detailing and constructability, which evaluates construction details to limit water ingress, applies 2D virtual simulations where appropriate, and defines commissioning tests to verify correct implementation; and (5) monitoring, operation, and intervention, which plans operational monitoring with targeted sensors at critical interfaces, sets alert thresholds and response/intervention protocols, and addresses any issues identified during commissioning.

Fig. 2. Integrative and climate responsive assessment framework for moisture-resilient envelope design.

Taken together, these steps propose a route to moisture-resilient envelopes that protect durability and indoor environmental quality under present conditions and extreme climatic events. The framework is intended to guide design decisions and support consistent, verifiable performance from concept through operation.

Circular Strategies for the Built Environment in Timber: Renovation Scenarios for Traditional Timber Framing Methods

Meriem Rezzag Lebza(✉) and Thomas Haavi

NTNU Norwegian University of Science and Technology, Trondheim, Norway
meriem.r.lebza@ntnu.no

Abstract. This study evaluates insulation retrofits and heat pump installation in an early 1900s dwelling. An air-to-air heat pump provides the greatest single reduction in supplied energy (42.5%), while insulation measures show diminishing returns, especially beyond 10 cm. Combined wall-roof insulation outperforms wall-floor configurations, while additional thickness yields minimal gains once a heat pump is installed. CO_2 analysis over 60 years shows that operational savings decrease as insulation thickness increases, and embodied emissions can outweigh benefits, particularly with repeated heat pump replacements. In a decarbonizing energy system, moderate insulation with efficient heating technologies offers the most effective lifecycle carbon strategy.

Keywords: Timber frame systems · Energy efficiency · Life cycle assessment · Timber construction

1 Introduction

Construction activities account for 36% of global energy consumption and 39% of CO_2 emissions, making the built environment a critical target for decarbonization [16]. Among structural materials, timber offers a compelling alternative to concrete, with studies reporting a 42% reduction in production-stage emissions [18]. However, the environmental benefits of timber are significantly undermined by end-of-life incineration practices, underscoring the importance of strategies that extend building service life rather than accelerating material turnover [19]. This study examines renovation optimization as a strategic pathway to extend the service life of Norway's pre-standard timber housing stock. Buildings constructed before the introduction of building regulations, representing approximately 20% of all houses built in Norway [20], remain outside the scope of current national retrofit guidelines, which are calibrated to modern light timber framing techniques developed after the 1940s [9]. Traditional Norwegian timber construction, exemplified by the Reiseverk typology, differs fundamentally from its modern counterpart in both structural configuration and thermal behavior. Whereas contemporary light timber frames rely on spaced studs that introduce systematic thermal bridges, traditional frames incorporate a continuous wood layer across the facade [9].

Applying sarendardized modern retrofit specifications with a current recommendation approximating 300 mm of insulation for walls and 150 mm for floors and roofs to these buildings is therefore materially inefficient [17]. Such approaches risk over-insulating structures whose existing thermal mass already confers significant energetic advantages, while failing to account for typology-specific behavior. Typology-sensitive renovation strategies, tailored to the structural and thermal characteristics of pre-regulation timber buildings, offer a more measured and resource-efficient alternative. By optimizing rather than standardizing retrofit interventions, it is possible to extend the service life of this housing stock significantly, preserving embodied carbon.

2 Methodology

By leveraging national geospatial datasets, specifically FKB-Bygning and SEFRAK-Bygning, a comprehensive mapping of the building stock within the designated study area was conducted. These datasets provide critical architectural and historical metadata, including building typology, footprint area, and chronological construction periods.

The analysis integrated both contemporary and historical building inventories, including structures designated under SEFRAK Class 2 protection (those with cultural value but potentially subject to energy retrofitting or regulation). To characterize the residential urban fabric, the dataset was filtered exclusively for the residential building category. This methodology enabled the identification of a representative case study reflecting the most prevalent building characteristics within our regional context.

Due to limited data on contemporary structures, the study analyzes historical buildings by categorizing them by construction volume across time periods (Fig. 1) This temporal distribution helps identify typical structural systems and construction techniques for each era and supports the development of deep-renovation strategies to meet modern standards such as TEK17, Low Energy buildings, Passive House, and Zero Energy Building targets. Preliminary findings show that contemporary buildings are mainly single-family detached houses, while historical stock is dominated by residences and agricultural barns. Most historical buildings date from 1900–1924 and were primarily timber frames with rectangular planks (Fig. 2). (NO: plankerreisverk). These buildings accounted for nearly 80% of new construction by the 1920s, a consequential effect of the introduction of sawmills by the late 1850s [7].

Spatial data of footprint area and perimeter length were mapped to evaluate their bivariate distribution. The calculated median (L: 49,9 m, A: 131,8 m^2) serves as the geometric basis for the case study, ensuring the energy simulation reflects the prevailing building typology within the dataset (Table 1).

- The total percentage of windows (openings) to wall ratio is 16% (single glazing).
- The floor is assumed to be on the ground.
- The walls are assumed to have a continuous layer of wood studs (Reiseverk).
- The roof is assumed to be a ceiling with an unventilated loft (36°).

According to (Holopainen.et al. 2015) in one case study, the primary energy performance in Finnish conventional houses average 330 kWh/m^2 with similar system (electric radiator) and a thermal transmittance of the house envelope of 0,78 W/m^2K.

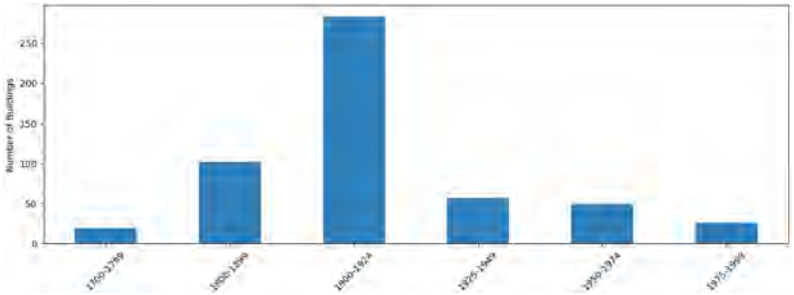

Fig. 1. Historical buildings classified by their construction volume and time period.

Table 1 Composition and thermal transmittance value of components in older timber buildings

Building category	Dimension of exterior wall	U-value (W/m^2K)			
		Wall	Roof	Floor	Windows
Wood frame houses built 1890–1928	76 mm (3″) planks + air layer and exterior cladding [8–14]	0.85	0,8	0,96	4,1–4,5

2.1 Study Case and Assumptions

The study case in this paper is assumed to be a single-family residential house built in a period timeframe between 1890–1928. All other assumptions/simulation settings are provided in Table 2 (Table 3).

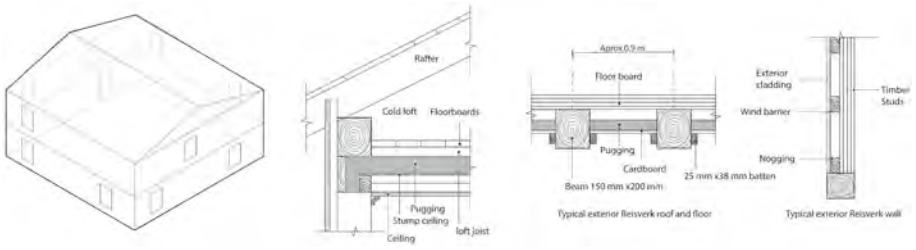

Fig. 2. 3D model of our study case "detached house" (far left) and illustrations of building components for single houses built between 1890–1928 (Byggforsk).

The energy system consists of an air-to-air heat pump [15] sized for residential use with a 15-year service life. Embodied emissions are assessed using a cradle-to-grave system boundary consistent with EN 15978, excluding end-of-life benefits. The primary metric is total lifecycle CO_2 in kg CO_2/m^2 over a 60-year study period, within which the heat pump undergoes three replacement cycles. The embodied carbon of both replacements and added mineral wool insulation is included in all scenarios, ensuring deeper insulation levels are weighed against their upfront emissions. Operational energy

Table 2 Simulation settings parameters

Building volume	625 m^3	Building height: 5 m, footprint:125 m^2
Building envelope	470 m^2	Perimeter: 44 m, number of floors: 2
Heated floor Area	250 m^2	Total of both floors
Windows and doors [6]	16% ratio	11 windows (1 m x 1.5 m) + 1 door (1 m x 2 m)
		Reference case U-value =4.5 (W/m^2K)
		New U-value for upgraded = 0.8 (W/m^2K)
Furniture intensity	N/A	Average furnishing for a house
Ventilation CAV	1.20 m^3/h m^2	Set up to natural ventilation (TEK17)
Thermal bridges	0,07 W/m^2K	The studs are assumed as a continuous layer (TEK17)
Thermal conductivity [2]	0,035 W/(mK)	Typical range for mineral wool
Air leakage [5] q50	3,9 l/s m2	Reference case built in Denmark (similar construction and climate) in 1880 with a footprint of 250 m2
Air leakage [5] n50	10.55 1/h	

Table 3 Thermal transmittance values for different insulation thicknesses

Selected Building category	Adapted U -value for building components [W/m2K]		
	External walls	Floor	Roof
Original U-value (1890–1928)	0,85	0,96	0,8
Addition of 50 mm of insulation	0,391	0,40	0,377
Addition of 100 mm of insulation	0,251	0,25	0,243
Addition of 150 mm of insulation	0,185	0,19	0,18
Addition of 200 mm of insulation	0,145	0,15	0,143

demands are simulated annually in SIMIEN [4], with emissions computed by applying a linearly decarbonizing grid emission factor following NS3720, from $f_{2025} = 0.018$ kg CO_2/kWh in 2025 [3] to $f_{2050} = 0.0$ kg CO_2/kWh by 2050, expressed as:

$$f(t) = f_{start} - \left(\frac{f_{start} - f_{2050}}{2050 - t_{start}}\right) \times (t - t_{start})$$

3 Scenarios

In all cases, the house already has existing heat panels installed. The insulation varies as follows:

Reference basepoint (Electric heating system):

Uninsulated original house + existing Heat Panels

With a heat pump:

Uninsulated original house + existing Heat Panels + Heat pump (set up as a primary source for heating)

Insulated Envelope walls/Roofs/Floors:

Original house + existing Heat Panels +50 mm/100 mm/150 mm/200 mm.

Windows upgrade: Windows according to TEK17 of minimal U value =0,8 W/m^{2}K.

3.1 Results

3.1.1 Energy Mitigation through a Single Application of Thermal Insulation

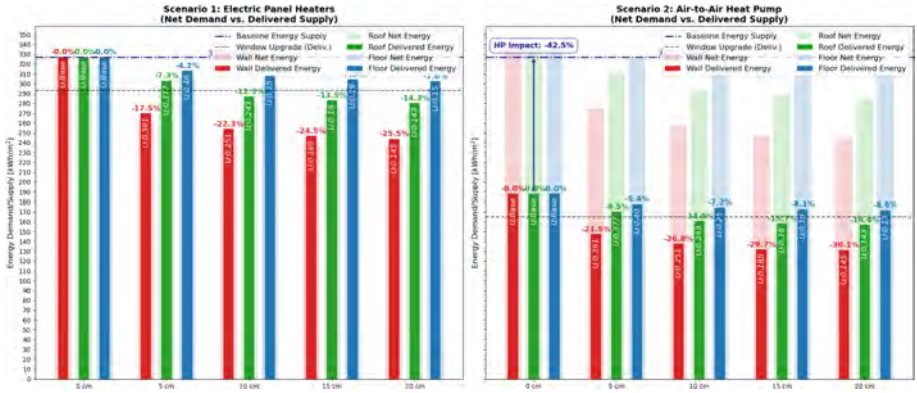

Fig. 3. Direct correlation between addition of different thickness of insulation in different building components with reduction of energy supply (Left: Without heat pump, right: With heat pump).

For an early 1900s conventional house, the most impactful single intervention is installing an air-to-air heat pump, which reduces supplied energy by 42.5%. Among envelope upgrades, wall insulation is the most effective, reducing supplied energy by 21.5% at 5 cm, 26.8% at 10 cm, and plateauing at 30% for 15 cm and 20 cm; these thicknesses correspond to net demand reductions of 17.5%, 22.3%, 24.5% and 25.5%, respectively. Roof insulation follows in effectiveness, offering supplied energy mitigation of 9.5% to 16.4% and net demand reductions of 7.4% to 14.3% across the 5 cm to 20 cm range. Floor insulation provides the least benefit for both energy supply and net demand mitigation (Fig. 3).

3.1.2 Energy Mitigation through a Combined Application of Thermal Insulation

Wall-roof insulation pairings outperform wall-floor configurations in reducing heating demand, as upward loss dominates and soil buffering limits floor insulation gains. With the heat pump, returns diminish beyond 10 cm wall +10 cm roof insulation, with further thickness yielding only marginal energy savings (Fig. 4).

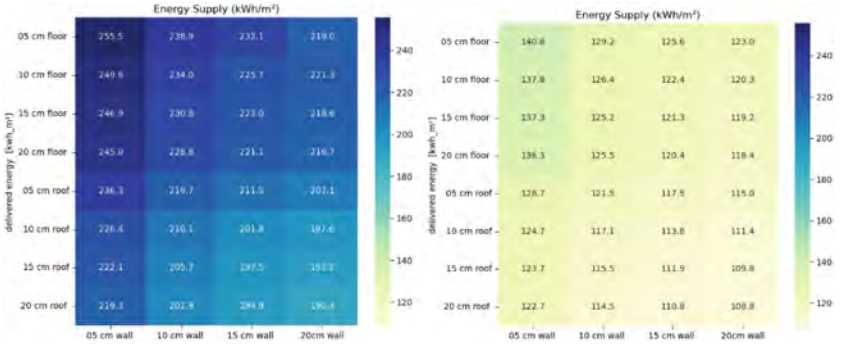

Fig. 4. Yearly energy supply (Left: Without heat pump, right: With heat pump).

3.1.3 CO_2 Emission Savings and Net-Zero Target by 2050

The heatmaps in Fig. 5 illustrate cumulative CO_2 emission reductions over the 60-year building lifetime for each insulation scenario, covering walls, floors, roof, and heat pump contributions. The results reveal diminishing returns with increasing insulation thickness: augmenting wall and roof insulation from 10 to 20 cm yields only a marginal improvement, from −49.16 to −51.11 kg CO_2 eq/m^2 with a heat pump, and from −27.40 to −32.03 kg CO_2 eq/m^2 without.

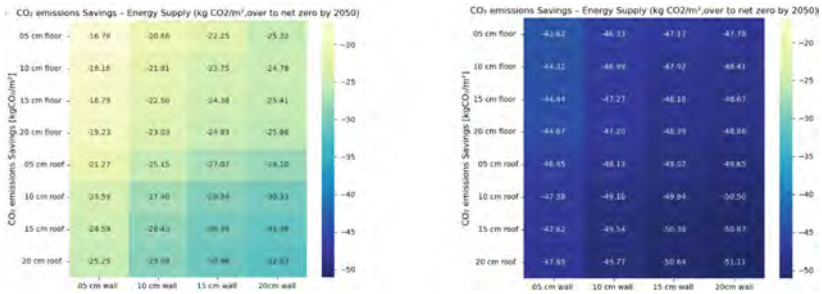

Fig. 5. CO_2 emission savings due to reduction in delivered energy to the building during operation (Left: Without heat pump, right: With heat pump).

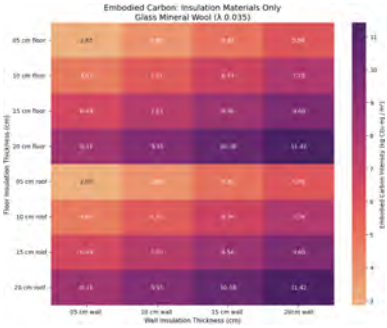

Fig. 6 Embodied carbon associated with thermal insulation materials exhibiting a thermal conductivity of 0.035 W/m·K [1].

3.1.4 Embodied CO_2 Emissions from Insulation and Heat Pump (Fig. 6)

3.1.5 Net Carbon Emission Savings

The insulation is assumed to require no replacement over the 60-year study period while the heat pump reference service life is assumed to be 15 years (Fig. 7).

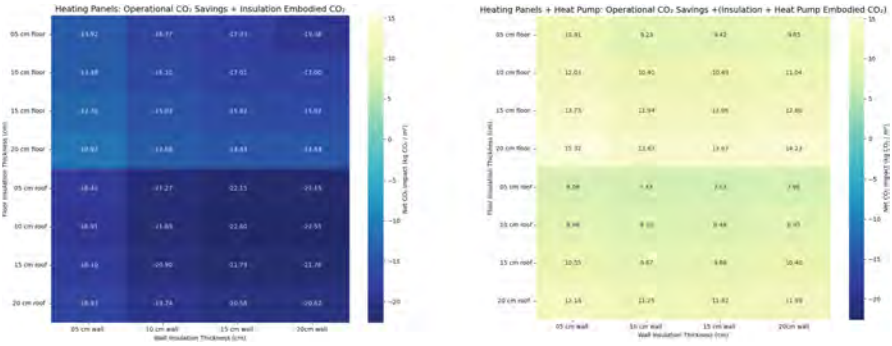

Fig. 7. Left: Operational CO_2-emission savings (without heat pump) plus embodied CO_2 from insulation. Right: Operational CO_2-emission savings (with heat pump) plus embodied CO2 from insulation and heat pump.

In this analysis, the results indicate that variations in insulation thickness combinations yield only marginal differences in net CO_2 savings across both scenarios. In the second scenario, which includes the integration of a heat pump, the net CO_2 emissions become positive across all configurations.

4 Discussion

The linear grid decarbonization trajectory defined by NS3720 represents a policy target rather than a guaranteed outcome. Occupant behavior introduces additional variability not captured in the simulation, as the well documented energy performance gap is particularly pronounced in older building stock. The assumed 15-year heat pump service life is likewise a conservative estimate; lifespan extension beyond 20 years under optimal maintenance would reduce replacement frequency and could shift the heat pump's net lifecycle CO_2 balance from a net increase to a net reduction. Finally, as the case study represents a single building derived from median dataset characteristics, results may not generalize to buildings with significantly different geometries or envelope to floor area ratios.

5 Conclusion

While a heat pump achieves the largest reduction in delivered energy (42.5%), its lifecycle CO_2 performance is compromised by embodied carbon from repeated replacements, yielding a net emissions increase across all insulation configurations over the 60-year period. Optimal insulation thicknesses range from 50 to 100 mm for the roof and 100 to 150 mm for walls. The most robust lifecycle CO_2 mitigation strategy therefore prioritizes moderate, typology-specific envelope upgrades. Heat pump integration remains contingent on substantial grid decarbonization and equipment service life exceeding current reference values before delivering a net carbon benefit.

Abstract. This study investigates the relationship between urban environmental variables and air quality in the Mediterranean climate of Tel Aviv through in-situ monitoring of microclimatic conditions across three representative urban settings: two adjoining high-rise office towers, a pedestrian bridge located above a major urban highway and railway corridor, and a nearby low- to mid-rise residential neighborhood. Measurements of temperature, wind velocity and $PM_{2.5}$ concentrations were conducted during July under hot summer conditions. Data collected on site were compared with satellite observations and records from nearby meteorological and air-quality monitoring stations within a 5 km radius

Results reveal strong correlations between elevated pollutant concentrations, high air temperatures and reduced wind velocities. Urban morphology and building configuration significantly influence local microclimatic behavior, affecting pollutant dispersion and ventilation patterns. High-rise clusters can both enhance wind speeds locally through funneling effects and simultaneously create urban canyon conditions that trap pollutants

The findings highlight the critical role of urban form and building morphology in shaping air quality and thermal conditions. These insights emphasize the importance of integrating urban ventilation strategies and climate-responsive design principles into planning processes to mitigate urban heat island effects and reduce pollution exposure in dense cities

1 Introduction

Rapid urbanization and increasing population density have intensified environmental pressures within cities. Urban density alters local climate conditions, contributing to the formation of urban heat islands (UHI) and deteriorating air quality. These phenomena are closely associated with transportation activity, energy consumption and the urban morphology, affecting environmental variables and air quality [1].

Air pollution has become a major public health concern worldwide. Exposure to particulate matter, predominantly $PM_{2.5}$, is associated with respiratory and cardiovascular diseases and contributes to millions of premature deaths annually [2, 3]. The distribution and concentration of pollutants within cities are strongly influenced by microclimatic conditions such as wind velocity, temperature and urban geometry.

Tall buildings increasingly shape contemporary urban landscapes, especially in dense metropolitan areas. While high-rise development can limit urban sprawl, it also modifies airflow patterns, solar access and thermal conditions within the urban fabric [4]. Depending on their configuration, tall buildings can either improve ventilation through channeling effects or create canyons where pollutants accumulate. Tel Aviv provides a particularly relevant case study due to its rapid urban growth, dense urban morphology and hot Mediterranean climate. Previous research has documented significant urban heat island effects and microclimatic variations across the city [5].

However, there remains limited empirical research examining the interaction between urban form, environmental variables and air pollution at the micro-scale. This study aims to examine how different urban morphologies influence environmental conditions and pollutant concentrations. In-situ monitoring across three contrasting distinguished urban settings, investigate the relationships between temperature, wind velocity and $PM_{2.5}$ levels, providing insights to urban planning and public health.

2 Urban Study Area and Methods

2.1 Monitoring Sites

The study was conducted in Tel Aviv, Israel, located on the eastern Mediterranean coast. The city's climate is hot Mediterranean characterized by high summer temperatures, strong solar radiation and prevailing western sea breezes. The study was conducted during three days in July 2021 between 08:00 and 20:00, including two working days and one weekend day. July was selected because it represents one of the hottest periods of the year, allowing examination of environmental conditions under peak summer heat.

The three monitoring locations represent distinct urban morphologies and provide a useful comparison of microclimatic conditions within a dense urban environment, located within a radius of approximately 250 m:

1. **Yehudit Bridge** – a pedestrian crossing of Ayalon highway and railway.
2. **Alon Towers** – a 42-storey high-rise office complex of two towers.
3. **Bitzaron residential area** – a low- to mid-rise residential neighborhood.

All three monitoring sites are located in the eastern part of Tel Aviv, downwind of the dominant western wind, the Mediterranean breeze. Due to their position relative to the Ayalon highway and railway, it was assumed that pollution transported by the prevailing western winds could lead to higher pollutant concentrations there. It was also hypothesized that the high-rise tower cluster might generate a Venturi effect, influencing local airflow and pollutant dispersion.

Figure 1a presents the location of the three in-situ monitoring sites (green markers) together with six permanent meteorological and air-quality monitoring stations across the city (red markers). These stations are operated by the Ministry of Environmental Protection and the Ministry of Agriculture and Rural Development. Data from the permanent stations, located near the monitored sites, were used to validate the field measurements.

The HaShalom and HaHagana railway stations monitor air temperature, relative humidity and air quality. The Kremenetzky residential station records temperature and wind velocity, while the City Center station measures wind speed. The Lehi and Levinsky stations, both located in residential areas, monitor air quality. Figure 1 illustrates the location and characteristics of the three in-situ monitoring stations measuring air pollution concentrations and environmental variables such as air temperature, relative humidity, wind velocity and direction.

2.2 Data Collection

Air pollution was monitored using nitrogen oxide (NOx) and particulate matter ($PM_{2.5}$) sensors. Nitrogen oxides (NO and NO_2) were measured using a Monitor Labs ML 9841A NO–NO_2–NOx analyser (EU). Fine particulate matter concentrations ($PM_{2.5}$, $\mu g/m^3$) were recorded using a Continuous Ambient Particulate TEOM™ Monitor 1400ab (EU) and a Dylos PM1700 particle counter (USA). Data were collected continuously and stored in data loggers. Climatic variables were simultaneously monitored using HOBO USB Microstations (H-21). All instruments were calibrated, tested and compared under identical conditions prior to deployment. Two monitoring stations were installed at each study location to ensure cross-validation and calibration of the measurements. Table 1

shows the monitoring setup sites and monitoring equipment used for the collection of data.

Table 1. Location and characteristics of the three monitoring sites in Tel Aviv

Site	Alon Towers	Yehudit Bridge	Residency
Monitoring instruments	Two office towers connected by a pedestrian corridor, characterized by high pedestrian activity through the presence of restaurants and cafés.	A pedestrian and cyclist bridge crossing the Ayalon urban highway and railway corridor.	A residential balcony located along a narrow street in a neighborhood characterized by low-rise two-storey residential buildings.
				

3 Results

3.1 Air Temperature

Temperature measurements revealed significant differences between the three urban environments, for the three consecutive days investigated, see Fig. 2. The residential area consistently recorded the highest temperatures, reaching 33–36 °C, particularly during midday hours (13:00–16:00). In contrast, Yehudit Bridge and the Alon Towers exhibited lower temperatures, ranging between 28–32 °C. These lower values are likely related to the shading effects and improved airflow conditions created by the elevated structures and surrounding urban configuration.

Reduced traffic and rail inactivity on Saturday influenced the microclimate near Yehudit Bridge, resulting in temperature patterns like those observed at the HaShalom monitoring station**.** The Alon Towers initially recorded the lowest temperatures before gradually aligning with those at Yehudit Bridge later in the day. This trend suggests delayed heat absorption, likely associated with shading and enhanced airflow between the towers. Overall, the findings indicate that low-rise residential areas are more susceptible to heat accumulation, whereas a combination of low-rise and high-rise infrastructure can mitigate peak daytime temperatures, and shape local thermal conditions.

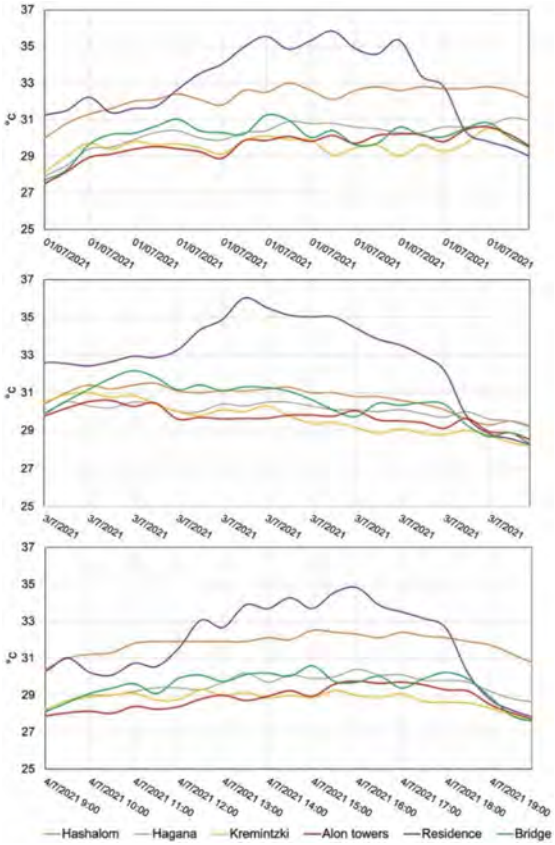

Fig. 2. Air temperature (°C) measured at the investigated sites between 08:00–20:00 during the monitoring campaign: (a) Thursday, 1 July 2021; (b) Saturday (weekend), 3 July 2021; and (c) Sunday (first workday of the week), 4 July 2021.

3.2 Wind Velocity

Overall, the wind velocity patterns highlight a strong relationship between urban configuration and wind circulation, see Fig. 3. The residential area consistently recorded the lowest wind speeds, ranging between 0.5–1.0 m/s, suggesting localized overheating. This phenomenon is likely related to the dense low-rise neighborhood configuration and its downwind position to the Alon Towers and surrounding high-rise development, which partially obstruct natural airflow. On Saturday higher wind velocities were observed at the Alon Towers, Kremenetzky, and City Center stations, likely due to their exposure to the prevailing Mediterranean breeze, while Yehudit Bridge remained relatively stagnant. Despite increased traffic activity on Sunday, no clear traffic-related influence on wind velocity was observed, indicating that urban morphology plays a stronger role in shaping airflow patterns than short-term human activity.

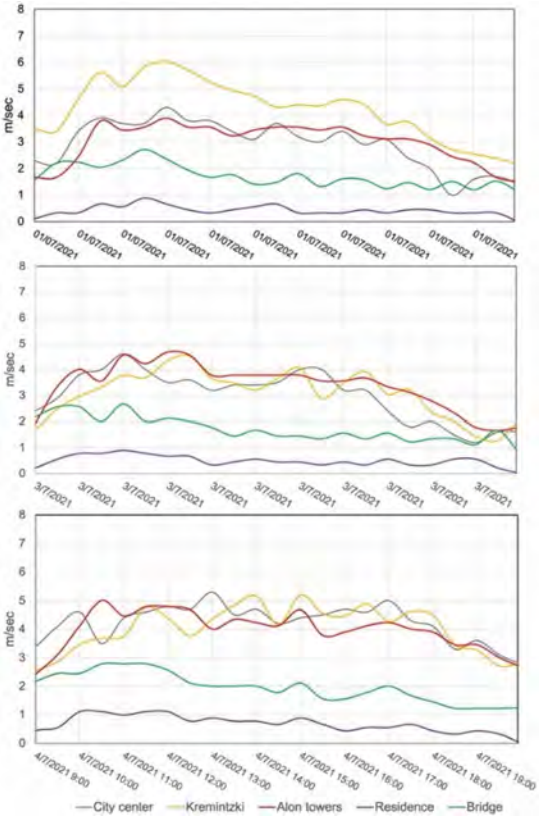

Fig. 3. Wind velocity (m/s) measured at the investigated sites between 08:00–20:00 during the monitoring campaign: (a) Thursday, 1 July 2021; (b) (weekend), 3 July 2021; and (c) Sunday (first workday of the week), 4 July 2021.

3.3 Air Pollution

In this section, air temperature and wind velocity are examined in relation to air pollution levels. Although all monitoring sites exhibited comparable temporal trends, the Alon Towers site demonstrated the clearest relationship between air temperature highs, wind velocity, and $PM_{2.5}$ concentrations, allowing the influence of meteorological conditions and urban morphology to be more clearly interpreted, see Fig. 4.

On Thursday, pollutant levels remained elevated during the morning hours before gradually declining as wind speeds increased. On Saturday (weekend), despite reduced traffic activity, $PM_{2.5}$ concentrations remained high throughout the day. Pollutant levels continued to rise even during periods of stronger winds (>6 m/s), suggesting that the high-rise canyon geometry may trap pollutants and limit effective dispersion. A similar pattern was observed at Yehudit Bridge, where $PM_{2.5}$ concentrations peaked at approximately 60–65 $\mu g/m^3$, likely influenced by regional haze, high temperatures, and limited atmospheric mixing during the heatwave. There is also the speculation that the absence

of train activity on Saturday passing beneath Yehudit Bridge and near Alon Towers could have reduced the piston dispersing effect that temporarily enhances pollutant dispersion during workdays when trains are running.

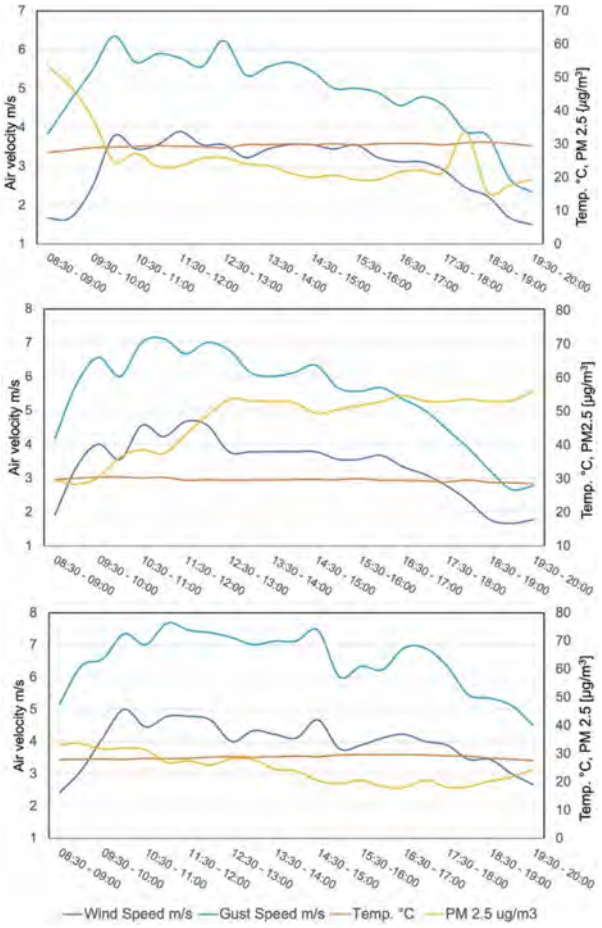

Fig. 4. Correlating PM2.5, Air Temperature (°C) and Air Speed (Wind and Gusts) in Alon Towers between 08:00–20:00 during the monitoring campaign: (a) Thursday, 1 July 2021; (b) Saturday, 3 July 2021; and (c) Sunday, 4 July 2021.

On Sunday (first workday of the week), concentrations decreased compared to Saturday at both sites, coinciding with slightly improved ventilation conditions and the resumption of urban activity. In contrast, the low wind speeds and limited air circulation throughout the three days at the residencial area, resulted in relatively stable but elevated $PM_{2.5}$ concentrations of around 30 µg/m^3. Overall, the results suggest that meteorological conditions, particularly during the heatwave, played a dominant role in pollutant accumulation**.**

4 Conclusions

This study examined the relationship between urban morphology, microclimatic conditions, and air pollution in Tel Aviv through in-situ monitoring at three representative urban typologies: Alon Towers, Yehudit Bridge, and low-rise residential area (Bitzaron). Results demonstrate a clear relationship between high $PM_{2.5}$ concentrations, elevated air temperatures, and low wind velocities, highlighting the role of urban form in local environmental conditions and pollution accumulation.

The residencial area exhibited the highest temperatures and lowest wind speeds, resulting in limited pollutant dispersion. In contrast, the high-rise cluster generated complex airflow patterns that enhanced ventilation but also created canyon effects capable of trapping pollutants. During the regional heatwave on Saturday, pollutant concentrations remained high despite reduced traffic activity.

These findings underline the importance of climate-sensitive urban planning, particularly in rapidly densifying Mediterranean cities. Ensuring adequate ventilation corridors, appropriate building spacing, and the integration of green spaces can improve urban airflow and reduce both heat accumulation and pollutant exposure as climate change intensifies heatwaves and urban air-quality challenges.
